**Abstract**

In this paper, the physical simulation of filling process of vertical centrifugal casting (VCC) of complex titanium alloy casting was studied. Combined with the mature PTV particle tracking technology, the high-speed photography pictures of the filling process of VCC at different rotational speeds were obtained. The trajectory and velocity information of tracer particles in the rotating flow field were obtained by the corresponding analysis software. Then, through the analysis and modeling of quantitative experimental data, the flow behavior characteristics and movement law of titanium alloy melt in the mold cavity under different mold speeds were studied. The results show that: 1. When the mold is still, the front edge of the filling fluid forms a curved surface with the curvature center pointing to the outside of the mold; when the mold rotates, the front edge of the liquid flow forms a curved surface with the curvature center pointing to the inside of the mold; 2. With the increase of the mold rotation speed, the speed of the fluid filling the mold increases significantly; when the rotational speed is greater than 120 rpm, the fluid still has a certain driving force in the mold center far away from the gate; it is good for filling the inner corner of mold with fluid; and 3. When the rotational speed of centrifugal casting of titanium alloy reaches 45 rpm or above, typical turbulent vortices appear in the wake; with the increase of rotating speed to 180 rpm, the average curvature radius of turbulent vortices first increases and then decreases, and reaches the minimum value of 0.67 cm at 120 rpm.

**1 Introduction**

Vertical centrifugal casting (VCC) is one of the important technologies for titanium alloy precision casting [1, 2]. Centrifugal motion can make the filling melt fill along the radial direction and form the free surface of the casting [3]. However, in centrifugal casting of titanium alloy, if the process is not properly controlled, the fluid will couple the effects of multiple force fields, resulting in severe disorder of gas–liquid mixed flow, and then defects will form; the centrifugal speed of mold is the key process parameter to control the filling effect and casting quality [4–7]. Physical simulation experiment is an important means to study the filling process of titanium alloy. Many researchers have carried out a series of physical simulation experiments on the fluid filling process of centrifugal casting. Prasad et al. carried out cold simulation experiments with transparent water and 140 ep oil with different viscosities, and studied the application of different rotational speeds on cylinder castings. It was found that the optimal speed required to form a uniform cylinder increased with the increase of cylinder thickness [5]. Shiping deduced the physical similarity model of titanium alloy VCC process to simulate the filling flow behavior of titanium alloy fluid under different gating systems and rotating speeds. It was found that the cross-sectional area of fluid in the runner decreased with the increase of filling length [9, 10]. Through the same water simulation experiment, Changyun et al. found that with the increase of the fluid filling speed, the fluid filling capacity first increases and then decreases with the increase of the rotation speed [11]. Ren et al. studied the microscale liquid metal filling flow mode in centrifugal casting process through physical simulation experiments. The results show that with the increase of
rotating speed, the time required for fluid to reach the peak filling rate decreases sharply [12].

At present, there is little research on quantitative characterization of fluid motion state in the physical simulation experiment of vertical centrifugal casting process. The main reason is that the high-speed rotating factor of vertical centrifugation greatly increases the difficulty of on-line measurement of fluid physical data. In this paper, the fluid measurement method of particle tracking velocimetry (PTV) is used to obtain the quantitative data of fluid filling. PTV is to evenly put tracer particles into the experimental fluid to characterize the fluid movement, and then use image acquisition equipment to record continuous multi frame images with short exposure time [14, 15]. By analyzing the position of tracer particles in these sequential particle images, the motion characteristic values such as displacement and velocity of fluid motion are calculated [8]. Hagemeier et al. studied the trajectories and rotation characteristics of solid particles in 2D fluidized bed by color PTV method, and characterized the solid particles with different sizes and densities with different color tracer particles. The results show that PTV method can well describe the movement of gas–solid two-phase flow [17, 19]. Estrada-Perez et al. studied the turbulent flow of HFE-301 in a rectangular channel by time-resolved particle tracking velocimetry, and obtained the characteristic values of its two-dimensional velocity field and turbulence intensity [16]. Murai et al. [18] measured the rotating flow field with PTV method, and reconstructed the 3D visualization flow field of local cylindrical wake and Taylor column. Therefore, PTV method is an effective means to obtain flow data.

Based on the above analysis, this study will take the physical simulation of vertical centrifugal casting of complex titanium alloy castings as the research object, combined with the mature PTV particle tracer technology, to obtain the flow behavior characteristics and movement law of the fluid in the mold cavity under different rotational speeds of VCC.

2 Experimental methods

The experimental flow chart is shown in Fig. 1. The CMC concentration should be 6.8 g/L for the similar fluid with viscosity of 83 cp measured by viscometer. The CMC solution was dissolved in hot water according to the concentration in the mixer. After stirring for 2 h and standing for 10 h, the experimental similar fluid can be obtained, and then the experimental fluid is dyed blue, which is conducive to observe the filling morphology of the fluid. The experimental fluid was placed in a fluid storage container, and then the experimental tracer particles were put into the pipe with a funnel (holes were drilled on the pipe to release the particles). The centrifugal experimental platform was adjusted to the experimental speed, and the flow rate was set to 1.5 L (mold volume) through the fluid control system. Turn on the high-power LED light and high-speed camera and set it to continuous shooting mode, adjust the lens shooting range and exposure rate. After shooting, open the solenoid valve to start filling, and take photos of fluid filling. Finally, the trajectory and velocity of particles in continuous images are tracked by image processing software. The main experimental parameters are shown in Table 1.
Table 1 Experimental parameters

| Parameters       | Symbol | Value | Unit |
|------------------|--------|-------|------|
| Fluid density    | ρfluid | 0.998 | g/cm³|
| Flow             | Q      | 1.5   | L    |
| Pouring time     | Time   | 8     | s    |
| Ambient temperature | Temperature | 25 | °C   |
| Fluid viscosity  | η      | 83    | cp   |
| Particle diameter | d      | 0.4   | cm   |
| Particle density | ρparticle | 0.84 | g/cm³|

2.1 Experimental platform

The experimental platform is shown in Fig. 2, including titanium alloy VCC physical simulation experimental platform and PTV shooting device. The titanium alloy VCC physical simulation experimental platform includes pouring system, centrifugal turntable and its control platform, mold, and flow control system; PTV camera includes high-speed CCD camera, 200-W high-power LED lamp, and terminal upper computer. The fluid storage device is 2.2 m high. The centrifugal turntable rotates clockwise with the speed between 0 and 500 rpm. A speed sensor is installed on the side of the centrifugal turntable to measure and feedback the rotating speed of the rotary table to the control platform of the centrifugal turntable in real time. The flow control system is composed of solenoid valve, flowmeter, and control cabinet. The flowmeter feeds back to the control cabinet through the flow rate, and the control cabinet controls the solenoid valve switch through electrical signal, so as to control the pouring time and pouring flow. The detachable transparent plexiglass mold is fixed on the centrifugal turntable. The size of the die is Φ 50 cm * 7 cm, and Φ 0.4 cm is drilled evenly in the four modules as the riser. Figure 3 shows the experimental mold. This experiment only analyzes the flow pattern of single runner module.

The internal flow field of titanium alloy melt filling was studied by physical simulation experiment method, and the required similarity fluid was deduced according to the similarity principle. The key technologies of two-dimensional particle image include tracer particle selection, image acquisition, image processing, and error analysis.

2.2 Fluid selection

The actual filling process of high-temperature titanium alloy melt in centrifugal force field can be regarded as three-dimensional unsteady flow of viscous incompressible fluid with free surface. In the filling process of centrifugal casting, the liquid metal moves under the combined action of centrifugal force \( F_{ce} \), Coriolis force \( F_{co} \), and gravity \( G \) at a certain speed.

![Fig. 2 Schematic diagram of experimental platform (1. Fluid pump, 2. Storage tank, 3. Angle valve, 4. Flowmeter, 5. Solenoid valve, 6. High-speed camera, 7. Centrifugal turntable and mold, 8. Control cabinet, 9. Computer)](image-url)
of filling fluid (as shown in Fig. 4). Based on the momentum transfer N-S equation, considering the geometric similarity, kinematic similarity, and dynamic similarity, as well as the structural complexity and process complexity of actual castings, the similarity criteria (Froude number, Euler number, Reynolds number, etc.) [13] in the process of fluid movement are derived by using the principle of similarity transformation.

Where centrifugal force $F_{ce} = m\omega^2 r$; Coriolis force $F_{co} = 2m(\omega V_c)(V_c$: velocity of fluid relative to turntable); and gravity $G = mg$. Considering that gravity and Coriolis force have less effect than centrifugal force in vertical centrifugal casting, viscous force and inertial force play a decisive role at this time. Therefore, Reynolds number is selected as the standard number to obtain the following formula:

$$\frac{\rho_1 \omega_1 l_1}{\eta_1 \mu_1} = \frac{\rho_2 \omega_2 l_2}{\eta_2 \mu_2}$$  \hspace{1cm} (1)

Considering the similarity of dynamics, the above equation is simplified as:

$$\frac{\rho_1}{\eta_1} = \frac{\rho_2}{\eta_2}$$  \hspace{1cm} (2)

In this experiment, carboxymethyl cellulose aqueous solution was used as the experimental fluid, its density was 0.998 g/cm$^3$, while the density of titanium alloy melt was 4.11 g/cm$^3$, and the viscosity was 0.32663 Pas. Substituting into formula 2, the viscosity of carboxymethyl solution meeting the similarity criterion should be 0.083 Pas.

### 2.3 Measuring method

Particle tracking velocimetry (PTV) is to distribute a certain number of tracer particles in the flow field, and the pulsed laser sheet light source is incident into the measured flow field area. Through continuous exposure for many times, the images of particle position in the flow field at different times are obtained. The tracer particles and the fluid have a fixed following property. The fluid flow field is obtained by analyzing the motion of the tracer particles in the image. The concentration of tracer particles in PTV is low, and there is no interaction between particles, so it can track the movement of a single particle. In order to obtain more accurate fluid flow field, repeated experiments are needed to obtain a large number of data. In this paper, a tracking particle with a density of 0.84 and a diameter of 0.4 cm is used. The particle is bright yellow and its gray value is large in transparent liquid, so that it can be recognized by computer. The camera used in this paper is IDT high-speed camera, and the frame rate is 1800 Hz. The high-speed camera is installed vertically above the mold, and the focus corresponds to the mold center. Before shooting, the mold was calibrated in advance.
2.4 Data processing method

The tracer particle is bright yellow, which is different from the fluid particle in gray scale and particle size. Based on the characteristics of particle swarm motion and particle size matching, the position of particles in each image is recognized and obtained. The position coordinates of particles in each image are output, and the velocity and acceleration are calculated based on the time difference between each image. The output data takes the lower left corner of the image as the default origin and adopts the right-hand coordinate system. According to the mold rotation speed, the coordinates and velocities of particles in the rotation coordinate system are output by matrix coordinate transformation. The rotation coordinate system takes the center of the mold as the origin and the center of the runner as the R axis. The position relationship of particles in the rotating coordinate system and the natural coordinate system is shown in the formula 3. The natural coordinate system takes the lower left corner of the image as the origin, and the right is the X axis; the rotation coordinate system takes the mold rotation axis as the rotation center, and the central axis of the mold runner is the X axis. The schematic diagram is shown in Fig. 5.

Among them, \((x_0, y_0)\) represents the default coordinate system of image analysis software; \(K_{x1} \) and \(Y_{y1}\) represent the coordinates of any point \(K\) in the translation coordinate system with the same origin as the rotation coordinate system; and \(K_{x2}\) and \(K_{y2}\) represent the coordinates of any point \(K\) in the rotation coordinate system corresponding to the rotating mold. \(\theta_0\) represents the clockwise angle between the x-axis in the natural coordinate system and the x-axis at the initial moment of the filling. Fig. 6 Front of filling fluid at \(t = 4\) s at different rotating speeds.

\]

(4)

3 Experimental results and analysis

In order to better analyze the model, the following basic assumptions are made in this paper:

1. The continue medium model assumes that the fluid is composed of fluid microclusters, which continuously fill the space occupied by the fluid, ignoring the internal molecular spacing and molecular motion.
2. The fluid is incompressible.
3. The viscosity coefficient remains unchanged.

3.1 Morphology of fluid front at different mold speeds

Figure 6 shows the fluid morphology at \( t = 4 \) s at speeds of 0, 60, 120, and 180 rpm. When the mold is still, the front edge of the filling fluid forms a curved surface with the curvature center pointing to the outside of the mold; when the mold is rotating, the front edge of the liquid flow forms a curved surface with the curvature center pointing to the inside of the mold. At the same time, when the rotating speed is high, the fluid filling area also increases.

As shown in Fig. 7, the overall stress diagram of fluid during mold rotation in force analysis zone of Fig. 6 is shown. Among them, \( P_1 \) is the mold pressure, \( P_2 \) is the cavity pressure, \( \tau \) is the shear stress caused by fluid viscosity, and \( F_{ce} \) and \( F_{co} \) are the centripetal force and Coriolis force of the fluid under the rotating condition respectively. Centrifugal force and Coriolis force can only change the direction of fluid movement, but they cannot change its size. When the mold is still, due to the wall resistance on both sides of the fluid, the central velocity of the fluid is large, and the front edge of the fluid forms a paraboloid with the curvature center pointing to the opposite direction of the motion direction; when the mold is rotating, under the action of centrifugal force, the front edge of the fluid forms a paraboloid with the curvature center pointing to the direction of the rotation center. And with the increase of mold speed, the centrifugal force increases and the curvature of the curve decreases.

**Table 2** Experiment number

| No | 1 | 2 | 3 | 4 | 5 | 6 |
|----|---|---|---|---|---|---|
| Rotation rate (rpm) | 0 | 30 | 45 | 60 | 120 | 180 |

Fig. 7 Force diagram of fluid micromass. **a** Fluid force when mold is still. **b** Fluid force during mold rotation

Fig. 8 Fluid velocity at different speeds in natural coordinate system
Fig. 9  Fluid velocity at different speeds.  a Speed is 0. b Speed is 30 rpm. c Speed is 45 rpm. d Speed is 60 rpm. e Speed is 120 rpm. f Speed is 180 rpm.
mold speed reaches 60 rpm, the filling speed peak reaches 100 cm/s; when the mold speed reaches 180 rpm, the fluid filling speed peak reaches 300 cm/s. At the later filling stage, the fluid still has a certain filling speed. Such a large filling speed is conducive to filling the mold with fluid and reducing the occurrence of central shrinkage and porosity.

According to the force characteristics, the mold is divided into ten areas, as shown in Fig. 10. The average velocity of tracer particles in each area of the mold under each rotating speed condition is counted, that is, the average spatial velocity, as shown in Fig. 8. Calculate and count the average velocity of particles in each area under each rotating speed, and the results are shown in Fig. 11. It can be seen that the rotational speed of fluid in the mold follows the rule of first increasing and then decreasing. In area 3, the particle velocity reaches the maximum. This is because before the particles reach the corner of the mold, the speed of the particles gradually increases under the action of centrifugal force; when the particles reach area 4, they are subjected to the pressure of the mold opposite to the motion direction, and the kinetic energy is lost and the movement direction changes, and the velocity decreases rapidly. At the end of filling (area 7–area 9), the filling velocity of fluid tends to 0. In order to get better quality castings, the fluid should be evenly filled. At the speed of 120 rpm and 180 rpm, the fluid still has a certain speed in the later stage, which is the optimal filling state. It is found that with the increase of the rotational speed, the velocity of the fluid passing through the bend zone (area 4–5) increases significantly.

Figure 12 shows the average velocity of all particles at different positions of the mold at different speeds. It can be seen from the figure that when the mold is still, the fluid is easily cast without filling the mold. Therefore, centrifugal casting can improve this situation.

According to the momentum theorem, the fluid impact force on the mold is $F_{\text{impact}} = \rho s (v - v_0)^2$, where $(v - v_0) = at$. Figure 13 shows the variation of the acceleration of the tracer particle with time at different rotating speeds. The red curve represents the average acceleration at different times. It can be seen that the fluid acceleration varies from $-1500$ to $1500 \, \text{cm/s}^2$ under non-rotating condition, and the fluid acceleration is larger in $0$–$11 \, \text{s}$, and tends to $0$ after $11 \, \text{s}$. When the rotating speed is $30 \, \text{rpm}$, the fluid acceleration varies from $-5000$ to $5000 \, \text{cm/s}^2$, and the acceleration is larger between $0$ and $11 \, \text{s}$. From $11 \, \text{s}$ to the end of filling, the fluid maintains a small acceleration. When the rotating speed is $45 \, \text{rpm}$, the fluid acceleration varies from $-10,000$ cm/s$^2$.
Fig. 11 Average velocity of fluid at different positions of the mold at different rotation speeds. a 0 rpm. b 30 rpm. c 45 rpm. d 60 rpm. e 120 rpm. f 180 rpm
to 8000 cm/s², and the acceleration is large between 0 and 11 s. The fluid maintains a small acceleration from 11 s to the end of filling. When the rotating speed is 60 rpm, the fluid acceleration changes from −10,000 to 10,000 cm/s²; at 120 rpm, the fluid acceleration changes from −100,000 to 100,000 cm/s²; and at 180 rpm, the fluid acceleration changes from −150,000 to 150,000 cm/s². The results show that with the increase of mold speed, the pressure of mold under fluid particles increases in a multiple law.

Figure 14 shows the average acceleration statistics of tracer particles in different mold areas at different rotational speeds. It can be seen that under the non-rotating condition, the fluid acceleration varies from −60 to 80 cm/s², and the maximum acceleration is about 50 cm/s² in the first section of the mold. The acceleration of fluid changes from −20 to 20 cm/s². When the rotating speed is 30 rpm, the fluid acceleration varies from −80 to 100 cm/s², and the maximum acceleration is about 80 cm/s² in the second to fourth range of the mold. The acceleration of fluid varies from −30 to 10 cm/s². When the rotating speed is 45 rpm, the fluid acceleration varies from −200 to 200 cm/s². The acceleration reaches the maximum in the third to fourth range of the mold, and its absolute value can reach 200 cm/s². The acceleration of fluid varies from −50 to 10 cm/s². When the rotating speed is 60 pm, the acceleration of fluid varies from −400 to 500 cm/s², and the acceleration reaches the maximum in the third to fourth range of the mold, and its absolute value can reach 500 cm/s². The acceleration of fluid varies from −20 to 20 cm/s². When the rotating speed is 120 rpm, the fluid acceleration varies from −1000 to 2500 cm/s², and the maximum acceleration is obtained in the third to fourth area of the mold, and the absolute value can reach 2500 cm/s². The acceleration of fluid varies from −100 to 100 cm/s². When the rotating speed is 180 rpm, the fluid acceleration varies from 1500 to 3000 cm/s², and the maximum acceleration is obtained in the third to fourth area of the mold, and its absolute value can reach 2800 cm/s². The acceleration of fluid varies from −80 to 120 cm/s².

From the above analysis, it can be seen that with the increase of rotation speed, the average peak stress in fluid region increases in multiple form. On the other hand, with the increase of rotation speed, the maximum impact force of fluid on the mold gradually increases, and the location of the maximum impact force moves backward; at the same time, with the increase of rotation speed, the driving force of fluid in the late filling stage also increases. As can be seen from Fig. 10, the fluid acceleration increases first, then decreases, and finally increases to zero. This is due to the increasing centrifugal pressure when the fluid enters the mold. The calculation formula of centrifugal pressure is as follows, in which the rotation radius r reaches the maximum when the fluid enters the outermost part of the mold. When the fluid moves to the outermost part of the mold (area 4−5), the fluid is subjected to the pressure opposite to the direction of motion on the mold wall, and the fluid acceleration decreases rapidly. When the fluid flows through the mold bend and enters into the inside of the mold, the gravity, centrifugal force, and Coriolis force tend to be balanced, and the fluid acceleration tends to zero, and a stable free surface is formed as shown in Fig. 14c−d.

\[
P_c = \gamma \left[ 0.056 \left( \frac{n}{100} \right)^2 r^2 + h \right]
\]

where \(P_c\) is the centrifugal pressure strength produced by the fluid to each layer, N/cm²; \(\gamma\) is the fluid gravity, N/cm³; \(r\) is the rotation radius of the fluid particle, cm; \(n\) is the casting speed, r/min; and \(h\) is the static head height.

### 3.3 Fluid trajectory at different mold rotation speeds

The trajectories of tracer particles at different rotational speeds are shown in Fig. 15. It can be seen that typical turbulent vortices appear in the wake of the fluid under rotating conditions, and with the increase of rotation speed, the average diameter of the turbulent vortices decreases significantly, and the fluid tends to move along the edge of the mold. The appearance of turbulent vortex is due to the viscous effect of turbulent fluid. The vortices can deform, split, and diffuse under the viscous action, and these motions are random. The
Fig. 13 Fluid acceleration at different mold rotation speeds. a 0 rpm, b 30 rpm, c 45 rpm, d 60 rpm, e 120 rpm, f 180 rpm.
Fig. 14 Acceleration of fluid movement at different areas of the mold at different rotation speeds. 

- **a** 0 rpm
- **b** 30 rpm
- **c** 45 rpm
- **d** 60 rpm
- **e** 120 rpm
- **f** 180 rpm
Fig. 15 Fluid trajectory at different mold speeds. a 0 rpm, b 30 rpm, c 45 rpm, d 60 rpm, e 120 rpm, f 180 rpm
The vorticity equation is used to describe the vortex quantitatively, as shown in formula 7.

\[
\frac{D\Omega^*}{Dt^*} = \frac{1}{Re} \nabla^2 \Omega^2
\]

(7)

where \(\frac{1}{Re}\) is equivalent to the diffusion coefficient of vortices.

The average radius of curvature of turbulent vortex at different speeds is calculated and counted. The results are shown in Fig. 16. With the increase of mold rotation speed from 45 to 180 rpm, the average curvature radius of turbulent vortex first increases and then decreases, and reaches the minimum value of 0.67 cm when the mold speed is 120 rpm. The more uniform and fine turbulent vortices are, the more stable the filling fluid is, and the castings with dense microstructure and good mechanical properties are easily formed.

Equation (8) calculates the Reynolds number of fluid at different speeds.

\[
Re = \frac{\rho vd}{\mu}
\]

(8)

where the characteristic length \(d = \frac{4A}{D}\).

The fluid density \(\rho\) is 0.998 g/cm³, and the dynamic viscosity coefficient \(\mu\) is 83 Pas. \(A\) is the cross section of the pipe and \(D\) is the wetted perimeter. The characteristic length \(d1 = 4.5\) cm in the runner area, \(d2 = 4.7\) cm in the mold bend, and \(d3 = 7\) cm in the flow field around the bend. \(\mu\) is the characteristic velocity of the fluid.

Therefore, the Reynolds number of the fluid in the region after passing the bend would be \(Re = 42.08\), where \(V\) is the velocity of the fluid in the natural coordinate system. When \(Re\) is less than 2300, that is, the fluid velocity is less than 55.66 cm/s, the fluid is laminar flow. The velocity of fluid changes with time and area in natural coordinate system. It can be seen from the figure that when the rotating speed reaches 45 rpm, the fluid is turbulent, which also corresponds to the turbulent vortex in Fig. 7 at that time.

4 Conclusion

Based on the similarity criterion, a physical simulation experiment was carried out on the filling process in vertical centrifugal casting. The particle tracking method was used to obtain the morphological characteristics of fluid filling and the quantitative data such as the trajectory and velocity of fluid microclusters in the filling process. Through statistics and analysis, the following conclusions are obtained:

1. When the mold is still, the whole fluid fills forward along the mold direction; when the mold rotates, the fluid first fills into the mold along the bottom of the mold and the side wall opposite to the rotation direction. At the same time, when the mold is still, the front edge of the filling fluid forms a curved surface with the curvature center pointing to the outside of the mold; when the mold is rotating, the front edge of the liquid flow forms a curved surface with the curvature center pointing to the inside of the mold.

2. In vertical centrifugal casting, with the increase of mold speed, the peak pressure of fluid particles on the mold increases by multiple times, and the position of the peak pressure moves to the inside of the mold. When the mold speed reaches 120 rpm, the fluid still has a certain driving force in the mold center far away from the gate, which is conducive to the filling of the inner corner of the mold.

3. Under the experimental conditions, when the mold speed reaches 45 rpm, typical turbulent vortices appear in the wake. With the increase of mold speed from 45 to 180 rpm, the average curvature radius of turbulent vortex first increases and then decreases, and reaches the minimum value of 0.67 cm at 120 rpm. On the other hand, when the mold speed reaches 120 rpm, the fluid passes through the mold bend at a significantly faster speed and reaches the inside of the mold.
