Abstract | Rabies is a fatal zoonotic infection caused by negative-strand RNA-virus classified in the genus Lyssavirus, family Rhabdoviridae of the order Mononegavirales. Despite the importance of the RABV for human and animal health, little is known about the spread of the virus in different animal populations in Egypt. Therefore, the current study aimed to identify and analyze the nucleotide sequences of nucleoprotein (N), phosphoprotein (P) and Glycoprotein (G) genes of the rabies virus from 10 suspected rabid cases of cattle and foxes from Elwadi- Elgedid province, which collected in 2017-2019. Specimens from the brains of suspected animals with rabies were collected and identified using direct FAT and RT-PCR. Three positive samples were further subjected to sequencing the partially amplified N, P, and G genes. The phylogenetic analysis was performed concerning the Egyptian rabies virus isolates, vaccinal strains and other sequences from the neighbouring countries available on the GenBank. It was found that the nucleotide identity in comparison to our new Egyptian isolates of Elwadi- Elgedid decreases by time at the level of three genes of previously isolated strains. Our results revealed that these new RABV isolates were more homologous to each other and were genetically related to Egyptian dog rabies, which previously identified two decades ago. The studied vaccinal strains were of low nucleotide identity with the new isolates. They also share some similarities with the RABV isolates in the neighbouring endemic regions in the Middle East. Furthermore, these data extend our knowledge of the relatedness and genetic variation of RABVs circulating in Egypt.

Keywords | Molecular analysis, nucleoprotein (N), genes, Rabies, Elwadi- Elgedid.

INTRODUCTION

Rabies is a world-wide distributing zoonotic disease with highly acute fatal encephalomyelitis in humans. The etiological agent is the rabies virus (RABV) which belongs to the genus Lyssavirus in the family Rhabdoviridae. It has a linear non-segmented single-stranded RNA of a negative sense of 12 kb length (MacLachlan et al., 2016). The genome has 58-nt of 3′ leader and 70-nt 5′ trailer. The genome is composed of five genes Nucleoprotein (N) gene (nt 59 to 1483), phosphoprotein (P) gene (nt 1486 to 2475), matrix protein (M) gene (nt 2481 to 3283), gly-
The viral glycoprotein (G) is contributed to RABV pathogenicity. It has a significant role in viral neuroinvasiveness. Most of the molecular studies of the rabies virus were based on the glycoprotein (G) gene as a lower rate of nucleotide substitution gets occurred (Faber et al., 2004; Troupin et al., 2016). Also, the N gene sequence is the highly conserved sequence among the other viral genes so, these sequences used in genetic typing and evolutionary studies. Moreover, their a relative lower variation among reservoir-associated variants and geographic lineages (Bourhy et al., 1993; Kissi et al., 1995). In addition to; the multifunction of phosphoprotein (P), it antagonizes the type I interferon (IFN)-mediated antiviral responses helping in evasion of host innate immunity and plays an essential role in viral RNA synthesis (Wunner and Conzelmann, 2013; Blondel et al., 2002).

Several previous molecular and phylogenetic analyses were applied on individual genes, but no studies on multiple viral genes were done in Egypt decades ago. Therefore, the purpose of the present study was to provide insight into the genetic variability, and phylogenetic relatedness of the rabies virus isolates derived from rabid cattle and foxes in Egypt compared with the other strains of RABV vaccinal strains available on GenBank.

MATERIALS AND METHODS

COLLECTION AND PROCESSING OF SAMPLES
Ten brain samples were collected from suspected rabid animals (cattle and foxes) in Elwadi- Elgedid province (Figure 1). Each brain sample was processed as soon as it was received for laboratory diagnosis of the rabies virus. Impression smears were made from the hippocampus for direct fluorescent antibody techniques (FAT). The supernatants of brain samples homogenate were used to inoculate BHK-21 cells (Chhabra et al., 2007).

Figure 1: Geographical localities of rabies virus samples in Egypt including Elwadi-Elgedid.

DIRECT FLUORESCENT ANTIBODY TECHNIQUE (dFAT)
It was carried out as described previously by (Dean et al., 1996). The Brain impression smears, and inoculated BHK-21 cells were air-dried and fixed in chilled acetone, then stained with FITC- conjugated anti-RABV monoclonal antibodies (Catalog # MA1-90618, Invitrogen). The slides were kept in a humidified chamber for 45 minutes at 37 °C. and washed thoroughly with PBS for 15 min three times, then mounted with buffered glycerin and covered with a coverslip for examination by fluorescent microscope (Olympus, Japan).

NUCLEIC ACID EXTRACTION AND RT-PCR ASSAY
Ten grams of positively infected brain samples were used for RNA extraction using the QIAamp viral RNA mini kit (Cat. No: 52904, Qiagen, Germany). RT-PCR assay was performed on the extracted RNA using Qiagen one-step RT-PCR kit with three pairs of specific primer sets were used as in Table (1). These oligonucleotides primers were supplied by (Metabion, Germany). The PCR products were analyzed by electrophoresis on 1.5% agarose gel. Sequencing of the amplified products and analysis of sequencing data.

Gel purified PCR products for N, P and G genes were sequenced using the ABI PRISM BigDye terminator cycle V3.1 sequencing kit (Life Technologies, USA). The obtained sequence data were analyzed in MEGA X using ClustalW (Kumar et al., 2018).

GENE BANK ACCESSION NUMBERS
The obtained sequences for EgyWN17, EgyWN18 and EgyWN19 RABV isolates were assigned accession numbers MT036064, MT036065, MT036066, respectively for the N gene. While the P gene sequences were given ac-
cession numbers MT036067, MT036068, MT036069 and
The G gene sequences were allocated accession numbers
MT036061, MT036062, MT036063, respectively.

| Target gene | Primer sequence (5’-3’) | Target gene | Size of amplicons (bp) | Reference |
|-------------|-------------------------|-------------|------------------------|-----------|

**RESULTS**

**IDENfICATION OF THE RABIES VIRUS**
The rabies antigen in the infected brain tissue was detected by performing dFAT on both infected brain tissue and inoculated baby hamster kidney (BHK-21) cells. The obtained results approved the presence of RABV in the infected cells and brain specimens from the diseased cows and foxes, while the normal brain and uninfected cells showed a negative reaction (Figure 2).

**Molecular identification of viral samples by reverse transcriptase RT-PCR**
The PCR products obtained from the amplification process of the extracted RNA were as follow for nucleoprotein (N) gene with expected correct size (684 bp), Phosphoprotein (P) gene with (882 bp) and Glycoprotein (G) gene with (590 bp) when compared with each positive control samples (Figure 3).

**Nucleotide sequencing and phylogenetic analysis of sequencing data**
Our sequence data were compared with 30 different Egyptian rabies virus isolates, Egyptian vaccinal strains, and other nearby geographic location isolates for their N, P and G gene sequences. The phylogenetic analysis demonstrated that EgyWN17 (MT036064) and EgyWN18 (MT036065) were completely identical to each other with
99.7% of homology with EgyWN19 (MT036066) at the N gene sequence level. Moreover, these sequences were very close to rabies isolates in 2013 from the same locality (Elwadi-Elgedid). And with more than 98% of identity with horse RABVs with accession no. (KP119663 & KP119662) those were isolated from Cairo. While as; multiple nucleotide sequence alignment with the neighbouring countries rabies isolates revealed 92% of identity with RABVs of Israel and Turkey (accession no. DQ837455, DQ837393, DQ837480 & DQ837475), 90% of identity with Sudan RABVs and <90% with Saudi Arabia, Algeria and Italy viruses (Figure 4).

At the level of the P gene, EgyWN17 (MT036067), EgyWN18 (MT036068) and EgyWN19 (MT036069) were approximately identical to each other as 98.9% to 99.6% of similarity. They were significantly closer by 96.5% of homology with the old Egyptian isolates, and recent Egyptian isolates from Behera, Dakahlia and Alexandria. While, the nucleotide identity with Egy79 (KK148101) was 95%. By comparing our P gene sequence data with previously non-Egyptian isolates, it was found that the Israeli strain (KF154998) was the highest (>95%) than the other Asian, African and European Isolates (<90%) (Figure 5).

The obtained G gene sequences (MT036061, MT036062 and MT036063) were completely identical to each other. They had a higher degree of identity range from 97–97.7% with non-Egyptian isolates.
to the following Egyptian isolates (accession no. MG458315, MG458316, MG458317, MK760770, and MK760769). While MK760769 and KX148101 have shared 94.9% and 96% nucleotide identity, respectively (Figure 6). On comparing with some previously non-Egyptian isolates of nearby geographic locations, it was found that the divergence percentage was 6-9% based on pairwise distance analysis.

On studying the pattern of pairwise distances for ERA vaccinal strain, Flurry LEP strain, and Flurry HEP strain at the level N, P, and G genes to our new Egyptian isolates from Elwadi- Elgedid, it was ranged from 8.7-9.5% for N gene and from 12.4 – 12.8% for P gene, while it had a narrow range from 4.2-5.3% for G gene (Table 2).

Table 2: Pairwise distance percentages of the nucleotide sequences of N, P and G genes of the three new Egyptian isolates in relation to themselves and other Egyptian and vaccinal strains retrieved from the GenBank database. The highest related genes have a deep red color that converts to light red, light blue and deep blue with increasing distance.

| RABV strain | EgyWN17 | EgyWN18 | EgyWN19 |
|-------------|---------|---------|---------|
| N           | 0.00%   | 0.00%   | 0.00%   |
| P           | 0.00%   | 0.00%   | 0.00%   |
| G           | 0.00%   | 0.00%   | 0.00%   |

**DISCUSSION**

In Egypt, rabies is an enzootic viral disease-causing public severe health concerns. The persistence of RABV in various animals might be attributed to the significant population of roaming stray dogs. Moreover, a lack of effective control measures. Rabies viral infection needs immediate investigation for proper decisions as slaughter or immunization. dFAT and RT- RCR were used in the following study as they are rapid and efficient methods. They were used for laboratory investigation of ten brain samples of suspected cattle and foxes collected from Elwadi- Elgedid province in Egypt (El-Tholoth et al., 2015; Zhang et al., 2011). There is no need for virus propagation on cell culture as RT-PCR and dFAT can detect RABV in fresh brain tissue of infected animals. This might influence inappropriate measures for control (Singh et al., 2017).

The phylogenetic analysis of the new viral isolates (EgyWN17, EgyWN18 and EgyWN19) revealed a high degree of identity with the former Egyptian isolates that originated from different species. This was reasonable as the previous finding indicated that RABV isolates from different species clustered according to their geography and not their species (David et al., 2007; Nagarajan et al., 2006; Reddy et al., 2011). The partial nucleotide sequences of our new isolates for nucleoprotein (N) (684bp), phosphoprotein (P) (882bp) and glycoprotein (G) (590bp) genes; demonstrated an extremely close relation with previously isolated RABV from the same geographical region. This might be attributed to their originating from a common predecessor spread among different provinces that were agreeable with (Bourhy et al., 1993; Kissi et al., 1995).

Otherwise, our viral isolate sequences revealed distinctive identity with RABV from neighbouring countries as Israel, Turkey, and Sudan. This indicates the possibility of RABV transmission from and to our neighbouring countries (Body et al., 2014; Nagarajan et al., 2009). Regarding the Egyptian RABV vaccinal strains, they were far from our new isolates based on the similarity ratio in N, P, and G gene nucleotide sequence. Despite this, the P and N genes considered the most conserved among the other virus genes, and relatively lower variation among reservoir-associated variants and geographic lineages (Bourhy et al., 1993; Kissi et al., 1995).

From this study, we could conclude that the brain specimens of cattle and foxes revealed the presence of new RABV isolates that are relatively similar to RABVs from some neighbouring Middle East countries as the unrestricted movement of foxes and stray dogs possibly help in the transmission of rabies virus from and to nearby geographic regions.

**ACKNOWLEDGEMENTS**

The authors would like to thank the Virology laboratory unit in the Animal Health Research Institute (AHRI) for providing the facilities for conducting the study. The authors did not receive any funds for this study.

**CONFLICTS OF INTEREST**

The authors declare no conflict of interest.
