Actin Filament Attachments for Sustained Motility In Vitro Are Maintained by Filament Bundling

Abstract

We reconstructed cellular motility in vitro from individual proteins to investigate how actin filaments are organized at the leading edge. Using total internal reflection fluorescence microscopy of actin filaments, we tested how profilin, Arp2/3, and capping protein (CP) function together to propel thin glass nanofibers or beads coated with N-WASP WCA domains. Thin nanofibers produced wide comet tails that showed more structural variation in actin filament organization than did bead substrates. During sustained motility, physiological concentrations of Mg2+ generated actin filament bundles that processively attached to the nanofiber. Reduction of total Mg2+ abolished particle motility and actin attachment to the particle surface without affecting actin polymerization, Arp2/3 nucleation, or filament capping. Analysis of similar motility of microspheres showed that loss of filament bundling did not affect actin shell formation or symmetry breaking but eliminated sustained attachments between the comet tail and the particle surface. Addition of Mg2+, Lys-Lys2+, or fascin restored both comet tail attachment and sustained particle motility in low Mg2+ buffers. TIRF microscopic analysis of filaments captured by WCA-coated beads in the absence of Arp2/3, profilin, and CP showed that filament bundling by polycation or fascin addition increased barbed end capture by WCA domains. We propose a model in which CP directs barbed ends toward the leading edge and polycation-induced filament bundling sustains processive barbed end attachment to the leading edge.

Introduction

Actin-based cell motility plays a crucial role throughout the lifetime of an organism. The front or leading edge of a typical crawling cell forms a broad, fan-like lamellipodial protrusion that contains a branching actin filament network generated by the Arp2/3 complex [1,2]. In the dendritic nucleation model of actin-based cell motility [3,4], binding of nucleation promoting factors (NPFs), such as Wiskott–Aldrich syndrome protein (WASP) or WASP-family verprolin-homologous protein (WAVE) to the leading edge membrane exposes their active C-terminal WASP homology 2, central, and acidic (WCA) domains. Exposed WCA domains bind to an actin monomer and to the Arp2/3 complex to form a complex that binds to the side of an existing filament to generate a new, rapidly-polymerizing filament with its barbed end directed towards the membrane. The combined force of many growing actin filament barbed ends push the cell membrane outwards until each filament’s growth is halted by barbed end capping protein (CP), which keeps actin filaments short and stiff. ATP-actin filaments are slowly hydrolyzed to ADP, providing a natural timing mechanism that delineates filament age and distance from the advancing membrane. Cofilin binds to and severs older ADP-actin filaments some distance away from the leading edge, and the severed oligomers rapidly depolymerize into ADP-actin monomers. Profilin replaces cofilin on actin monomers and promotes actin nucleotide exchange to provide a fresh pool of ATP-actin for filament polymerization. Profilin also suppresses de novo actin nucleation. In vitro these proteins are sufficient to reconstitute sustained, actin-based motility [5].

Much of the current understanding of dendritic nucleation dynamics comes from studies of in vitro reconstitution of actin-based motility. The pathogenic bacteria Listeria monocytogenes [6,7,8] and Shigella flexneri [9,10,11], which spread in the host body by subverting the host cell’s actin motility machinery [12]. Each bacterium species expresses a single surface NPF, ActA for Listeria [13,14] or IscA for Shigella [9,11], which activates the cellular Arp2/3 complex to form a shell of polymerizing actin. The actin shell eventually breaks symmetry [15,16,17,18] to form a branched, propulsive “comet tail” of polymerizing actin that is structurally similar to a lamellipodia [19].

Exogenous NPFs are sufficient to effect actin-based motility in cellular cytoplasmic extracts [11,20] or in a suite of purified proteins [5]. Thus, bacteria can be substituted with microspheres [18,21,22], micro-discs [23], lipid droplets [24], vesicles [25], or lipid-coated particles [26,27] that are coated with either bacterial or eukaryotic cellular NPFs such as WASP or WAVE family proteins [21,27,28] to study actin-based motility either in cell extracts or purified proteins.

The majority of barbed ends within a comet tail are directed toward the particle surface. How then does this filament network remain attached to the particle surface as it grows? Distortions of NPF coated lipid vesicles or droplets from round to teardrop shape...
show that some actin filaments must transiently attach to the particle to provide a pulling force that opposes the pushing force generated by growing barbed ends. The theoretic “tethered ratchet” model of Mogilner and Oster [29,30] and closely related “cooperative thermal breakage” models [31,32] predict that a subset of non-polymerizing actin barbed ends are transiently attached to the leading edge while other barbed ends push against the leading edge. The transient links are broken as the compressive force of polymerization against the barrier is translated through the crosslinked network to the attached ends. The WASP homology domain 2 (WH2, W, or V for Verprolin homology) of the cellular NPF, WASP can bind both to actin monomers [33] and the terminal subunit at the barbed end of an actin filament [34,35,36] and thus may provide this linkage. While some studies have shown that WH2 domains at the particle surface bind independently of the Arp2/3 complex [26], others have indirectly shown that WH2 domains maintain their attachment to filaments primarily through Arp2/3 [27] with direct WH2 to barbed end attachments playing a secondary role in a cycle of attachment, release, and elongation. While WASP likely plays roles in both maintaining comet tail attachment to the leading edge and in transiently maintaining barbed end orientation, both the mechanism and the role of Arp2/3 in this process remains unresolved.

In contrast to the tethered ratchet model, the “actoclampin” model of Dickinson and Purich [17,37,38] presumes that the particle surface remains processively bound to growing actin barbed ends. While processive barbed end binding has been shown for VASP [39] and formins [40], no evidence has been provided for processive attachment of WASP or WAVE proteins to barbed ends. A positively charged Arg at the N-terminus of WASP’s WH2 domain alpha helix sits at the longitudinal binding region between actin subdomains 1 and 3 [36], presumably blocking further barbed end addition. However, consecutive WH2 domains such as those in neuronal Wiskott–Aldrich syndrome protein (N-WASP) have been shown to bind longitudinal actin dimers [34]. Thus, individual WH2 domains might bind to the side of filaments without steric inhibition of barbed end addition. Though processive barbed-end binding proteins such as formin and VASP are respectively dimeric and trimeric, native WASP-family proteins require binding partners such as SH3 domain or PIP2 at the leading edge to form multimers [41]. New evidence that the Arp2/3 complex contains two WCA domains (GST-WCA) from N-WASP and observed formation of individual actin filaments with TIRF microscopy [48,49] and a modified in vitro motility assay to explore actin filament dynamics and the role of filament bundling in comet tail formation and maintenance. Thin glass nanofibers coated with WCA domains in motility buffers produced actin comet tails that propelled the particle yet were thin enough for observation of filament geometry in the comet tail. We found prominent filament bundles within the comet tail. The degree of bundle formation was controlled by CP concentration. These bundles grew faster than the surrounding dendritic actin network. Processive attachment of these fast-growing, bundled barbed ends to the particle surface often generated prominent bending and buckling of the bundle.

Results

Actin architecture in moving nanofibers

We coated thin glass nanofibers with GST-tagged WCA domains (GST-WCA) from N-WASP and observed formation of individual actin filaments with TIRF microscopy in the presence of profilin-actin, Arp2/3, and CP (Figure S1). We excluded cofilin, VASP, and actin bundling proteins from these experiments to understand how a minimal set of proteins direct filament organization in moving nanofibers. Although cofilin is an important player in dendritic nucleation, cofilin acts downstream of the dendritic nucleation pathway. For in vitro motility assays, cofilin increases propulsion rates in long-term studies by maintaining an actin monomer pool [5,50]. We therefore restricted our initial observations to the first 30 to 90 minutes of comet tail formation. Experiments with and without cofilin showed little difference in particle velocities in similar motility buffers for these short-term observations (Table 1).

In well-blocked flow-cells, nanofibers rarely adhered to the top surface but fell to the chamber bottom. We thus required a TIRF microscope with evanescent excitation at the chamber bottom to observe moving nanofibers. In contrast, previous prism-based TIRF microscopy observations of actin comet tails generated NPF-coated glass nanofibers [31] were restricted to nanofibers permanently affixed to the chamber top. Consequently, these experiments were limited to observations of actin architecture during branch initiation and not during sustained nanofiber motility.

Actin shells formed around nanofibers in motility buffer at actin concentrations of 8.5 µM and a CP to Arp2/3 ratio of 0.75 to 2,
often before the nanofiber drifted to the chamber bottom and into the TIRF microscopy excitation field. After initial shell formation, the nanofibers usually broke symmetry to form either one or two comet tails. Though 68% of observed nanofiber initially formed one comet tail of polymerizing actin, 32% initially formed two comet tails, one on either side of the nanofiber axis (Figure 1F, H). In the latter case, one tail usually attained dominance and the residual tail was left behind near the original shell as the nanofiber moved (Figure 1B). In rare cases, two tails persisted on either side of the nanofiber, and the nanofiber remained relatively stationary while the tails were pushed away from the nanofiber by new filament growth at the nanofiber surface (Figure 1G). For both single and double comet tails, the majority of new filament growth appeared at the nanofiber surface, while the network within the comet tail either remained stationary or was pushed rearward at a slow rate. Thus, the majority of barbed end growth was directed toward rather than away from the nanofiber surface, consistent with previous reports [21,46,50] and the dendritic nucleation model.

Nanofibers with single tails moved at 0.14 µm/min at an optimal CP to Arp2/3 ratio of 1.0 and slightly slower at a CP to Arp2/3 ratio of 2.0 (Table 1). These speeds were substantially slower than previous reports of 2.2 µm/min movement of spherical particles in similar buffers lacking cofilin [50]. Much of this difference could be attributed to our use of muscle actin, which produced 4-fold slower particle speeds than did cytoplasmic actin [50]. In support, we found that 4.5 µm diameter spherical particles moved at 0.48 µm/min in the same motility buffers used for nanofibers (Table 1). These rates were comparable to previous studies in which similarly sized beads moved at 0.5 µm/min in similar motility buffers containing muscle actin [52]. Thus, the 4-fold difference between nanofiber and bead speeds in our motility buffers was due to particle geometry, and likely attributable to the thin but wide comet tails generated by 200 nm thick nanofibers.

Capping Protein controls the transition between bundled or branched actin networks

Previous studies showed that actin filaments can form from dendritically nucleated networks in vitro and that CP can control the proportion of branched to bundled filaments [53,54]. However, filament barbed ends in these studies grew away from the particle surface and bundling did not result in particle motility. We found that comet tails with barbed ends directed toward WCA-coated nanofibers also contained two populations of actin filaments. Under TIRF microscopy, bundled filaments resembling microspikes primarily formed perpendicular to the direction of movement within a dendritic network of highly branched filaments. In contrast, these bundles were invisible under epifluorescence microscopy (Figure 1D). The variance in actin network architecture between bundled and branched filaments persisted as comet tails grew at the nanofiber interface. The dominance of these two structures in comet tails changed with different concentration of CP. Actin filament bundles were more prominent at lower CP concentration (100 nM) (Figure 1A) while branched filaments dominated at higher CP concentration (200 nM) (Figure 1B).

Actin branches and bundles were inter-convertible. Although comet tail formation was rare at lower actin concentrations of 2 µM, the origins of bundles and branches were more easily discerned in the few, sparse comet tails that formed. Here, individual filaments converged to form brighter bundles (Figures 1E left panel) and bundles could sometimes be seen to dissociate into individual daughter filaments emerging from the same mother filament (Figure 1E right panel).

Bundles terminate at the nanofiber surface

At low (≤75 nM) CP concentrations, actin bundle formation frequently projected beyond the nanofiber surface as they elongated (Figure 5S). In higher CP (≥100 nM), the majority of bundles continuously terminated at the nanofiber as they grew (Figure 1A C black arrowheads). In contrast to bundles, individual actin filaments within the comet tail often elongated across and beyond the nanofiber surface, even at higher CP concentrations (Figure 1A, G arrow).

Bundles elongated faster than the surrounding comet tail, consistent with previous studies in which filament bundling proteins increased motility speeds [5,28,47]. For example, four bundles from Figures 2A–B elongated at 0.22±0.05 µm/min, while the overall comet tails expanded at 0.09±0.01 µm/min. Faster bundle elongation often resulted in bending or buckling of the bundle between the fast growing barbed ends at the nanofiber surface and the pointed ends embedded within the dendritic network (Figure 2A, B arrowheads). Processive or semi-processive attachment between growing bundled barbed ends and the nanofiber surface was further illustrated by the reduction of CP concentration through an exchange of motility buffer on an existing comet tail (Figure 2C). Here, short bundles present before the buffer exchange (top panels) elongated substantially after CP concentration was reduced (bottom panels). Processive attachment of bundled barbed ends to the nanofiber surface coupled with their faster growth rates (2.4 µm/min) resulted in significant looping of these bundled filaments. We observed similar buckling and looping of bundles on moving nanofibers (Figure 5S, Table 2). Thus, bundled barbed ends were not physically trapped by strong attachments between the nanofiber and the chamber surface, but were likely attached through specific molecular interactions with GST-WCA at the nanofiber surface.

As bundled loops grew, they split into individual filaments of varied lengths. Measurement of individual filament growth rates from several bundles showed that filaments within a bundle grew in a salutatory fashion (Figure 2E–H), indicating that capping times varied between individual barbed ends within the bundle. During periods of elongation, bundled filaments grew 10-fold faster (2.4±1.1 µm/min, N = 7) after CP reduction than they did before CP reduction (0.20±0.002 µm/min, N = 2, Figure 2D).

While some filaments within a bundle elongated, others from the same bundle periodically halted. This lack of barbed end growth was likely due to capping either by CP or by WH2 domain attachment to the hydrophobic cleft of one of the barbed end

---

Table 1. Average particle velocities in 8.5 µM profilin-actin, 100 nM Arp2/3.

| Particle | [ATP] | [Cofilin] | [CP] | Tail Growth |
|----------|-------|-----------|------|-------------|
|          | mM    | µM        | nM   | µ.m/min     |
| Nanofibers | 0.38 | –         | 75   | 0.08±0.05 (14) |

subunits. In the latter case, WCA domain attachments could maintain the connection between the bundle and the nanofiber.

Cellular levels of magnesium generate actin bundles in vitro

Actin bundles or microspikes form at the leading edge of motile cells in vivo [53] and bead-based in vitro motility experiments have shown that actin bundles generate more propulsive force than individual branched filaments [5,28,47]. Our in vitro experiments indicated that actin filament bundles were prevalent even in the absence of specific actin crosslinking or bundling proteins in our motility buffers. We therefore sought to eliminate bundles to determine the relative contributions of dendritic and bundled filaments to particle motility.

Both the methylcellulose used in most in vitro TIRF microscopy assays of actin dynamics [56,57] and polyvalent cations such as Mg^{2+} [58] can bundle filaments. However, the mechanism of bundle formation by these two solutes differs substantially [59]. Methylcellulose contributes to bundle formation through entropic depletion forces that reduce effective solution volume. Polycations overcome the 14 e^-/subunit negative charge of filamentous actin to promote filament side-to-side association.
Figure 2. Filament bundles processively attach to the nanofiber. Conditions: 8.5 μM (8 to 20% labeled) Mg-ATP actin, 9 μM profilin, 100 nM Arp2/3, and indicated CP. Nanofiber coating and buffers as in Figure 1. (A–B) Bright filament spots grew against the nanofiber surface. Spots either remained attached to the same location on the moving nanofiber (A, black arrowhead) or oscillated back and forth along the moving nanofiber (B, black arrowhead). Bright spots grew faster than the surrounding comet tail network (T) and often buckled from compression between the nanofiber and tail network (arrow). White arrowhead in B indicates bundle starting position. (C) CP was lowered from 200 to 50 nM after the establishment of two comet tails (T) by motility buffer exchange. Short, bright bundles (top panels, black arrowheads) became rapidly polymerizing bundled loops (black arrowheads, bottom panels) that remained attached to the nanofiber at their growing ends (white arrowheads) and to the tail at their pointed ends (white arrows). Growing bundles splayed into filaments of different loop lengths. (D) Traces of bundles lengths over time before CP reduction. Zero seconds represents the point of buffer exchange, 163 min after the experiment start. (E–H) Traces of individual filament lengths over time after CP reduction showed that filament within each bundle grew at different rates. Plots represent filaments from the same bundle. Some filaments continuously elongated while others show pulsed growth. Scale bars are 1 μm for A–B and 5 μm for C. Times are shown in min:sec for A–B and hr:min:sec for C.

doi:10.1371/journal.pone.0031385.g002
One study of the concentration dependence of methylcellulose on bundling [60] found that filaments start to bundle in high viscosity methylcellulose (38 kDa, 4000 cPs at 2%) at a threshold concentration of 0.2%. Similar studies with polyethylene glycol showed that the filament bundling threshold also depends upon the chain length of the excluding solute [61,62]. Although we used 0.25% methylcellulose in our TIRF microscopic assays to stabilize actin filaments for imaging, we used a lower viscosity species (63 kDa, 1500 cPs at 2%). Thus, the contribution of methylcellulose to bundling was unclear but likely near the threshold concentration.

Actin paracrystals formation requires Mg$^{2+}$ concentrations of $\geq 10$ mM [58], but several studies have reported anecdotal evidence that bundles form at $1$ mM Mg$^{2+}$ concentrations used in typical TIRF microscopy and in vitro motility buffers once filament densities increase [49,53,63]. We therefore sought Mg$^{2+}$ concentrations that would eliminate filament bundling in the presence of minimal, 0.25% of 63 kDa methylcellulose.

In typical actin polymerization assays, the Ca$^{2+}$ bound to the high affinity Mg$^{2+}$ site on actin is first exchanged with Mg$^{2+}$ by addition of an excess of Mg-EGTA prior to addition of KCl. To generate low Mg$^{2+}$ conditions, we diluted Ca-ATP-actin monomers into buffer without added Ca$^{2+}$ and reduced Mg-EGTA concentrations 5-fold during the exchange step. We correspondingly reduced ATP concentrations from 0.38 mM used above to 0.2 mM, a concentration sufficient for both actin polymerization and Arp2/3 nucleation. Total Mg$^{2+}$ concentration in the assay was regulated by subsequent addition of MgCl$_2$. We calculated free Mg$^{2+}$ concentration from the pH and total buffer CaCl$_2$, MgCl$_2$, ATP, and KCl concentrations using existing methods [64,65]. At standard 1 mM total Mg$^{2+}$ concentration, filament bundles could be seen after 30 min of polymerization (Figure 3A). An increase in total Mg$^{2+}$ to either 5 or 10 mM increased both the speed of bundle formation and thickness of bundles. Reduction of total Mg$^{2+}$ to 0.5 mM (0.3 mM free) or below severely reduced bundle formation in the presence of minimal, 0.25% of 63 kDa methylcellulose. Quantification of bundle formation under a range of Mg$^{2+}$ concentrations (Figure 3B) showed that bundles, assessed as overlap of two or more filaments, rarely formed at or below 0.5 mM Mg$^{2+}$ but formed readily at concentrations of 1 mM and above. Correspondingly, bundle onset time (Figure 3C) was significantly shortened at high Mg$^{2+}$ concentrations. As the typical cellular Mg$^{2+}$ ranges from 0.3 to 1.5 mM [66,67,68], we expect that similar Mg-actin bundles form at the leading edge where filament density is high.

**Reduction of Mg$^{2+}$ below cellular levels abolishes motility**

Remarkably, lowering Mg$^{2+}$ 10-fold to 0.1 mM total (0.03 mM free) completely abolished nanofiber motility (not shown). Restoration of Mg$^{2+}$ to 1 mM total (0.7 mM free) with additional MgCl$_2$ restored nanofiber motility. While glass nanofibers provided a good model of a leading edge, they varied in length, diameter, and curvature. Thus, analysis of nanofiber motility speeds as a function of Mg$^{2+}$ concentration could be substantially influenced by variations in nanofiber geometry. As an alternative to nanofibers, we used 4.5 μm diameter polystyrene microspheres to quantify the dependence of particle motility on Mg$^{2+}$ concentration. We found that bead motility speeds also varied greatly with free Mg$^{2+}$ concentration (Figure 4A, C). Reduction of total Mg$^{2+}$ concentration to 0.5 mM (0.3 mM free) or below abolished comet tail growth from GST-WCA coated beads.

Restoration of total Mg$^{2+}$ to cellular concentration level of 1 mM total (0.7 mM free) restored comet tail growth rates to 0.16±0.07 μm/min (Figure 4E). Additional of Mg$^{2+}$ above 1 mM accelerated comet tail growth rates in a concentration-dependent manner. For example, 10 mM total (9.4 mM free) Mg$^{2+}$ accelerated comet tail growth rates to 0.59±0.17 μm/min, an approximately 4-fold increase over the rate in 1 mM Mg$^{2+}$. Comet tail growth showed a similar dependence on Mg$^{2+}$ in the absence of methylcellulose (Figure 4E). These results indicate that cellular levels of Mg$^{2+}$ are necessary for generating in vitro motility and that entropic depletion forces play little to no role in this requirement.

**Actin binding proteins show little Mg$^{2+}$ dependence**

Actin polymerization in KCl has been shown to be independent of excess magnesium [69]. We sought to test the possibility that Mg$^{2+}$ was necessary for some aspect of in vitro motility other than actin filament bundling. We thus measured actin polymerization, Arp2/3 nucleation, and CP binding using bulk pyrene actin assembly assays in the same range of Mg$^{2+}$ concentrations as our TIRF microscopy assays of bead motility (figure 5A). As expected, varying free Mg$^{2+}$ concentrations over a 300-fold range had no effect on KCl induced actin polymerization or Arp2/3 nucleation. Polymerization of profilin-actin from capped filament seeds showed a slight Mg$^{2+}$ dependent increase in apparent final filament concentration. However, the initial slope of polymerization, an indicator of concentration of free ends, decreased slightly with Mg$^{2+}$ concentration, and CP was the least active in low Mg$^{2+}$ concentrations that abolished bead motility. Thus, abolishment of motility in low Mg$^{2+}$ and restoration in high Mg$^{2+}$ was not due to the effect of Mg$^{2+}$ on individual components of the motility machinery.

**Cofilin does not rescue polyvcation-dependent motility**

At high Mg$^{2+}$ concentrations, comet tail elongation slowed over the course of each 140 min experiment (Figure 4C-D). This decrease was likely due to a decrease in available ATP-actin monomers over time from their incorporation into filaments. To test whether this decrease in monomers influenced Mg-dependent comet tail formation, we added cofilin to the motility buffer to establish a steady state of free actin monomers (Figure 5). Cofilin addition abolished the gradual decrease in comet tail elongation over time seen at high Mg$^{2+}$ concentrations but did not restore motility in low Mg$^{2+}$ buffers. As with motility in buffers lacking cofilin, addition of 0.7 mM or more free Mg$^{2+}$ restored motility in the presence of cofilin. Average comet tail growth rates were slightly higher in cofilin than without, but growth rates showed approximately the same dependence on free Mg$^{2+}$ with or without cofilin (Figure 5C). Coupled with the formation of both primary and secondary actin shells around beads in low Mg$^{2+}$ buffers (see below), the lack of comet tail formation in low Mg$^{2+}$ buffers without cofilin was not due to a lack of polymerization competent actin monomers.

**Di-lysine restores bead motility in sub-cellular concentration Mg$^{2+}$ buffers**

Based on the above observations, we reasoned that in vitro bead motility depends upon the actin bundling activity of Mg$^{2+}$. 

### Table 2. Frequency of bundle formation on nanofibers.

| [CP] | Percentage of Nanofibers | No. Nanofibers |
|------|-------------------------|----------------|
| mM   | with bundles | with loops | with buckles observed |
| ≤75  | 100% | 27% | 0% | 37 |
| 100  | 96% | 8%  | 25% | 24 |
| 200  | 95% | 21% | 51% | 57 |

Conditions as in Table 1.

Figure 4. Polycations or fascin are required for bead motility. Conditions: 8.5 μM (20% labeled) Mg-ATP actin, 9 μM profilin, 100 nM Arp2/3, 200 nM CP, 4.5 μm diameter bead coated with 8.5 μM GST-WCA, low Mg2+ buffer (50 mM KCl, 0.105 mM MgCl2, 1.05 mM EGTA, 10 mM imidazole pH 7.0, 100 mM DTT, 0.2 mM ATP, 15 mM glucose, 0.25% methylcellulose, 20 μg/ml catalase, 100 ug/ml glucose oxidase) supplemented with MgCl2, Lys-Lys-2HCl, KCl, or fascin as indicated. (A) TIRF and Epifluorescence microscopy images show representative actin comet tails (T) grown from GST-WCA coated beads (B, dashed circle). All images were recorded 40 minutes after the reaction start. In low Mg2+, beads formed a shell (S) that broke symmetry but rarely a comet tail. Tails that did form remained short and detached from the bead. Restoration of cellular, 1 mM Mg2+ restored comet tail growth. Additional Mg2+ accelerated comet tail growth. (B) TIRF microscopy images of actin comet tails grown in 0.1 mM total Mg2+ with added Lys-Lys2+ as indicated. All images were recorded 40 minutes after the reaction start. Lys-Lys2+ substituted for Mg2+ to restore motility. (C–D) Comet tail growth over time after the reactions start. The lengths of actin comet tails from A–B were recorded in each frame. Line segments represent growth of individual comet tails. Comet tail growth increased with the concentration of divalent cation, either in the form of (C) Mg2+ or (D) Lys-Lys2+. (E) Comet tail growth rates from C–D as a function of free cation. Both MgCl2 and Lys-Lys-2HCl restored motility in a concentration dependent manner. Removal of methylcellulose did not influence the trend of comet tail growth rates as a function of Mg2+. Addition of 5, 10, or 15 mM KCl did not restore motility in low Mg2+ buffers. (F–G) Comet tail growth over time in low Mg2+ with added fascin. Line segments represent individual comet tails. (F) In low, 0.03 mM free Mg2+, 80 nM fascin optimally restored motility while (G) 500 nM fascin optimally restored motility in 0.3 mM free Mg2+. Line breaks (arrows) in no fascin represent growth of an actin shell followed by shell detachment during an observation. (H) Comet tail growth rates from F–G as a function of fascin concentration. Errors bars in E and H show S.D. of tail growth rates. Scale bars in A–B are 5 μm.

stiffness and persistence between fascin and magnesium bundles, coupled with competition between fascin and Mg\(^{2+}\) for inter-filament binding could explain the difference in comet tail elongation seen between fascin and high Mg\(^{2+}\).

Filament bundling mediates sustained comet tail attachment

Beads in low Mg\(^{2+}\) grew thick actin shells that eventually broke symmetry (Figure 4A, bottom panel). However, the resulting nascent comet tails did not elongate but completely detached from the bead surface and floated away (Figure 6A). Comet tail detachment was not due to a lack of polymerization competent actin or Arp2/3, as a secondary actin shell often formed on the bead surface after the primary shell detached (Figure 6B–C). We interpreted this comet tail detachment as a failure to establish rapid rebinding of barbed ends to WCA domain in moving particles in the absence filament bundling.

To test the dependence of attachment on bundling, we quantified the fraction of GST-WCA coated beads with attached actin shells or comet tails over time (Figure 6D). Of the beads that initially formed actin shells in 0.03 mM Mg\(^{2+}\) buffers, these shells were eventually lost so that by 90 minutes only 15% of beads retained their primary shell and 55% of beads had formed secondary shells (Figure 6E). Addition of either 1 mM (J), 5 mM (K), or 10 mM (L) Lys-Lys\(^{2+}\) restored actin shell or tail attachment in 0.03 mM free Mg\(^{2+}\) buffer. Addition of 80 nM (M), 0.5 µM (N), or 1 µM (O) fascin restored actin shell or tail attachment in 0.03 mM free Mg\(^{2+}\) buffer. Means and S.D. were calculated from three independent experiments. At least 50 beads were counted in each experiment.

doi:10.1371/journal.pone.0031385.g006
WCA at the bead surface to sustain bead motility. Similarly, addition of lys-lys²⁺ (Figure 6I–L) or fascin (Figure 6M–O) also restored sustained attachment of comet tails to the bead surface in 0.03 mM free Mg²⁺ buffers in a concentration dependent manner. Restoration of attachment was most dramatic in 1 μM fascin, as 100% of beads retained their comet tails over 90 minutes of observation. Thus, filament bundling did not mediate actin shell formation but continued attachment between actin filaments and the bead surface once motility was established.

### Discussion

We used TIRF microscopy to observe the generation and maintenance of actin filament architecture in an in vitro motility system that utilized thin glass nanofibers as an analog for the leading-edge membrane of a motile cell. Our assay differed from previous TIRF observations of nanofiber-supported nucleation [51] in that our nanofibers moved within the TIRF excitation field rather than being immobilized. Thus, we were able to observe actin filament architecture during the later stages of sustained nanofiber motility after shell formation and symmetry breaking.

Our central finding was that filament bundling was essential for maintaining persistent attachments between growing barbed ends and N-WASP WCA domains on the moving particle. Multiple lines of evidence support this claim. (1) Bundles form within the dendritic network in the absence of bundling proteins. While entropic depletion forces contribute to bundling, bundling is primarily due to cellular concentrations of the polycationic cation, Mg²⁺. (2) CP antagonizes bundle length, but short bundles are still generated within the comet tail even at high CP concentrations. (3) Like branched filaments, bundled barbed ends face the particle surface and can bind to WCA domains independently of Arp2/3. In moving nanofibers, these barbed end attachments are semi-processive and provide enough force to cause significant buckling of short bundles or looping of longer bundles. (4) Although filament bundling does not affect actin shell formation or symmetry breaking, bundling is required to maintain continued attachments between the growing comet tail and the particle surface. (5) WCA-tethered bundles elongate faster than the surrounding dendritic network, suggesting that WCA binding to bundled barbed ends antagonizes CP binding.

It is not surprising that bundles form in the absence of bundling proteins. In published ultrastructure studies of dense actin branched actin in motile cells [2,73], the leading edge contains a wealth of short, parallel actin filaments consistent with polycation-mediated bundles. Although many of the longer bundles are generated by VASP, VASP remains at the elongating bundle tip and fascin recruitment to the bundle is delayed [74]. Polycation-mediated bundling could serve as the bridge between initial bundle formation and bundle stabilization by specific bundling proteins. We propose that filament densities at the leading edge are high enough that filaments likely form initial bundles when cellular Mg²⁺ concentrations exceed 0.5 mM. Other cellular polycations such as spermine may further promote short filament side-to-side association typically seen in nascent filopodia or microspikes. Thus, multivalent cation-induced filament bundling in the absence of specific bundling proteins may be more important to dendritic nucleation than previously thought.

How might actin bundling promote processive barbed end attachment to monomeric WH2 domains at the leading edge? Both formin dimers [40,75] and VASP tetramers [39,76] can remain processively attached to growing barbed ends. Although WASP family proteins are monomeric in solution, they are present at high concentrations at the leading edge membrane and multiple WCA domains from adjacent WASP family proteins could cooperate to attach to filament barbed ends (Figure 8A). Bundling of filaments by divalent cations aids WCA binding to barbed ends at the leading edge (Figure 8A). Bundling would switch barbed end WGA attachments from slow, “cooperative thermal breakup” attachments (Figure 8B) found in branched networks [31,32] to fast, processive attachments (Figure 8A) to WCA domains. Dimerization of WASP/WAVE has been shown to greatly enhance Arp2/3 activation activity [41,77]. Similarly, dimerization of WASP/WAVE family WGA domains at the leading edge could act synergistically with filament bundling to enhance processive binding to barbed ends. In support, we note that our study used GST-tagged WCA, which has been shown to form dimers in vitro [41].
Although the affinity of WCA domains for actin monomers is weak ($K_d$ of 0.6 mM [33]), bundled filament barbed ends could cooperate to maintain processive attachments to several nearby WCA domains at the nanofiber surface. As one barbed end binds to a WCA domain, sister barbed ends within the bundle would be free to elongate. Rapid transmission of compressive force from free barbed ends polymerizing against the barrier to WCA-attached barbed ends within the same bundle would accelerate their detachment. In this way, the filament bundle could processively elongate and remain attached although individual ends would be free to attach and detach from WCA domains during polymerization.

Like VASP, cooperative enhancement of the apparent WCA-barbed end affinity might also allow several nearby WCA domains to compete with the high affinity binding of CP to barbed ends ($K_d$ of $\sim$0.1 nM [78]), either by delaying CP association or accelerating CP dissociation at the nanofiber surface. Decreased CP activity near the NPF-coated surface would bias productive barbed end elongation towards the surface, while nonproductive elongation away from the surface would be impeded.

Figure 7. Bundling promotes barbed end attachment to WCA domains in the absence of Arp2/3 complex. Conditions: 8 μM (30% labeled) actin was polymerized in low Mg$^{2+}$ F buffer. Filaments were incubated with GST-WCA coated microspheres with 1 μM ATP-actin monomers and the indicated final concentration of Mg$^{2+}$, Lys-Lys$^{+}$, fascin, or K$^+$ for 10 minutes. Beads were centrifuged, resuspended in low Mg$^{2+}$ buffer in the absence of methylcellulose, and imaged on poly-lysine coated coverslips. (A) TIRF microscopy images of actin filaments and bundles attached to the bottom of coated microspheres in the indicated concentration of Mg$^{2+}$, Lys-Lys$^{+}$, fascin, or K$^+$. The number of actin filaments and bundles crossing the bead boundary (dashed circle) were counted for each bead. Scale bar is 2 μm. An example measurement is shown in Figure S6. (B) Count of average number of captured filaments per bead as a function of Mg$^{2+}$ (○), Lys-Lys$^{+}$ (●), fascin (□), or K$^+$ (○) concentration. Bundles were counted as two filaments. Error bars show S.D. from at least 60 beads for each condition from three independent experiments. Coincidental filament overlap with control, BSA coated microsphere (●) was negligible. (C) Stacked bar chart showing average number of filaments (light gray) or bundles (dark gray) captured by WCA-coated microspheres, with indicated Mg$^{2+}$, Lys-Lys$^{+}$, fascin concentrations. The proportion of captured bundles increased with increasing polycation or fascin.

doi:10.1371/journal.pone.0031385.g007
Arp2/3 nucleated barbed ends that were pointed away from the surface would be rapidly capped. Though we showed that motility 	extit{in vitro} requires polycations, the requirement of polyvalent cations such as magnesium for motility 	extit{in vivo} remains unclear. Magnesium has long been associated with integrin-mediated cell attachments that provide traction for moving cells [79]. The metal ion-dependent adhesion site (MIDAS) extracellular domains found in all β- and some α-integrins requires Mg$^{2+}$ to coordinate extracellular matrix binding [80,81,82,83]. For example, wound healing 	extit{in vivo} is blocked by chronic removal of Mg$^{2+}$ from the wound fluid [84]. However, cell spreading is also an actin polymerization-driven process very similar to directed motility [85,86,87,88]. Like Ca$^{2+}$, Mg$^{2+}$ levels can be acutely increased by release from mitochondrial, nuclear, and ER stores, and chronic exposure of cells to low extracellular Mg$^{2+}$ would deplete stores.

Could the requirement of extracellular Mg$^{2+}$ for integrin-mediated cell adhesion have masked its intracellular requirement for actin-based motility? Typical cellular free Mg$^{2+}$ concentrations range from 0.5 to 1.5 mM [66,67,68,89], precisely the range at which we find the greatest effect on processive motility 	extit{in vitro} (Figure 4). While it should be noted that cellular Mg$^{2+}$ measurements have varied for the same cell type [89], intracellular Mg$^{2+}$ levels have been shown to increase upon cell stimulation. For example, free cellular Mg$^{2+}$ levels in platelets increase from 0.6 to 1.27 mM upon insulin stimulation [90] and from 0.5 to 1.3 mM upon thrombin stimulation [91].

High cellular Mg$^{2+}$ levels have been linked to angiogenesis and endothelial cell migration. Though Mg$^{2+}$ increases cell proliferation [92], its main action during angiogenesis appears to be linked to motility [93]. Lapidos et al [94] found that Mg$^{2+}$ acted as potent chemoattractant for endothelial cells. Chemotaxis towards Mg$^{2+}$ was blocked by inhibition of G$_{i3}$ heterotrimeric G-proteins. Thus, Mg$^{2+}$ chemotaxis involved second messengers and was not due solely to a gradient of integrin-mediated adhesion. Studies of free

**Figure 8. Model of bundle and branch cooperativity.** (A) Bundles cooperate efficiently to maintain barbed end orientation. (1) WASP binding to membrane and Rho family GTPase frees active WCA domains that can either bind to a free profilin-actin or the barbed end of a nearby filament bundle. (2) One filament in a bundle is attached to WCA (red), while sister filaments are free to either polymerize by subunit addition (green), bind to a nearby free WCA, or (3) bind to a profilin-actin bound WCA. The force of polymerization is efficiently transmitted through the stiff bundle to tethered barbed ends and promotes tether dissociation. (4) Dissociation of bound WCA frees a sister barbed end for polymerization. (B) Branches cooperative inefficiently to maintain barbed end orientation. (1) While one barbed end is tethered to the membrane through WCA, a nearby barbed end polymerizes against the membrane (green). The force of polymerization is transmitted through branches and flexible filaments to tethered barbed ends to promote tether dissociation. (2) WCA dissociation frees a barbed end for polymerization while other filaments within the branched network become tethered.

doi:10.1371/journal.pone.0031385.g008
cytoplasmic Mg\(^{2+}\) with mag-fura-2 showed that cytoplasmic Mg\(^{2+}\) rapidly increased in endothelial cells from basal levels of 0.5 mM to 1.1–1.2 mM upon stimulation with the chemotactants VEGF [95] or bFGF [96] due to release from intracellular stores. While this study does not directly address cellular Mg\(^{2+}\) levels, our findings point to direct participation of Mg\(^{2+}\) in the motility process.

Materials and Methods

Protein expression, purification, and fluorescent labeling

Actin was purified from rabbit skeletal muscle actin powder through one round of polymerization, depolymerization, and gel filtration [97]. Actin was labeled with pyrenyl iodoacetamide (Invitrogen, Carlsbad, CA) [98] or with Oregon green 488 iodoacetamide (Invitrogen) as previously described [49]. Before use, labeled and unlabeled actins were diazylated overnight against fresh buffer G (2 mM Tris-Cl pH 8, 0.2 mM ATP, 1 mM NaN\(_3\), 0.1 mM CaCl\(_2\), 0.5 mM diithiothreitol, DTT) and centrifuged at 100,000 g for 2 hr at 4°C. Arp2/3 complex was purified from bovine thymus as described [99]. Recombinant mouse capping protein was expressed in E. Coli and purified as described [100]. Human N-WASP-WCA was expressed as a glutathione S-transferase (GST) fusion proteins in E. Coli and purified on a Glutathione Agarose affinity column (Thermo Scientific, Rockford, IL) followed by anion exchange chromatography on a Source Q (GE Healthcare, Piscataway, NJ) column [33]. Recombinant human profilin I was expressed in E. Coli and purified by poly-L-proline affinity chromatography as described [101]. Recombinant human fascin I was expressed in E. Coli and purified and cleaved as described [102]. Actin and labeled actins were stored for 1 month at 4°C. All other proteins were flash frozen in liquid nitrogen and stored at -80°C.

Nanofiber and bead preparation

Nanofibers (200 nm nominal diameter, Johns Mansville, Denver, CO) were separated in chloroform with a Dounce homogenizer, centrifuged at 3750 rpm for 15 min in a clinical centrifuge, and the chloroform was evaporated in a fume hood. Nanofibers were washed once with deionized water by centrifugation and sonicated for 30 min in deionized water, resuspended in 1 M HCl, sonicated for 1 hour, and incubated overnight in HCl. Cleaned nanofibers were subsequently pelleted by centrifugation and sonicated for 30 minutes each in deH\(_2\)O, 1 mM ethylene diamine tetraacetic acid (EDTA), 70% ethanol, and absolute ethanol to dry, with pelleting between each step. Cleaned nanofibers were stored in glass containers in absolute ethanol for up to three months.

Carboxylated polystyrene 4.5 µm diameter microsphere (Polysciences, Warrington, PA) or glass nanofiber were coated respectively with 8.5 nM or 10 nM GST tagged WCA by incubation for 1 h at room temperature. Particles were pelleted by low speed centrifugation and resuspended in storage buffer (10 mM HEPES pH 7.8, 0.1 M KCl, 1 mM MgCl\(_2\), 1 mM ATP, 0.1 mM CaCl\(_2\), 0.01% NaN\(_3\)) containing 1 mg/ml bovine serum albumin (BSA, Sigma-Aldrich, St. Louis, MO) to block subsequent nonspecific binding. Particles were stored at 4°C for up to 1 week.

Reconstitution of nanofiber and bead motility under TIRF microscopy

Glass slides and coverslips were cleaned, and flow cells constructed as previously described [49]. For buffer exchange, flow cells were coated with 300 nM n-ethylmaleimide inactivated myosin II for 2 minutes. For all experiments, flow cells were coated with 1% BSA for 5–7 min as described [49]. After blocking, 16 µl of reaction mixture was wicked through the chamber and the chamber was either sealed with warm VALAP (1:1:1 vaseline/lanolin/paraffin) or left unsealed for subsequent buffer exchange. For bead motility assays, glass slides and coverslips were blocked overnight in 1% BSA at 4°C and dried in air before use. We placed 16 µl of reaction mixture on a BSA coated slide, covered with a BSA coated coverslip, and sealed the chamber with VALAP.

Labeled and unlabeled Ca-ATP actin were diluted to the desired labeled fraction, mixed 9:1 with 10× magnesium exchange buffer (10× ME: 10 mM ethylene glycol tetraacetic acid, EGTA, 1 mM MgCl\(_2\) and incubated on ice for 2 minutes to form 4× final concentrations of Mg-ATP actin. We placed 8 µl of Mg-ATP actin at the bottom of a 1.5 ml Eppendorf tube and added 7 µl of motility protein mixtures and 1 µl of coated nanofibers or beads on the side of the tube. Arp2/3 and CP were diluted in nanoparticle storage buffer (10 mM HEPES pH 7.8, 0.1 M KCl, 1 mM MgCl\(_2\), 1 mM ATP, 0.1 mM CaCl\(_2\), 0.01% NaN\(_3\)). We washed both drops together with 16 µl 2× TIRF buffer (2× 100 mM KCl, 2 mM MgCl\(_2\), 2 mM EGTA, 20 mM imidazole, pH 7.0, 200 mM DTT, 0.4 mM ATP, 30 mM glucose, 0.5% 1500 cP methylcellulose, 40 µg/ml catalase, 200 µg/ml glucose oxidase) and placed the reaction mixture in either a flow cell or slide-coverslip as described above.

Image acquisition and processing

Actin fluorescence was observed with a 60×1.4 NA TIRF objective on an Olympus IX2 inverted microscope. Images were captured with a Retiga Exi cooled CCD camera (QImaging) using SlideBook image acquisition software (Intelligent Imaging Innovations, Inc). All subsequent image-processing steps were performed in ImageJ, available at http://rsweb.nih.gov/j. TIRF microscopy images were gamma corrected using a value of between 0.5 and 0.8. An unsharp-mask filter was applied with a radius of 1 to 1.3 pixels and a 60% mask weight. Epi-fluorescence microscopy images were unprocessed. For differential interference contrast (DIC) images, each image was divided by an averaged background image and contrast was adjusted to locate the nanofiber. Images were rotated and cropped for publication.

Bundle formation during nanofiber motility

To quantify the frequency of bundling, loop, and buckle formation (Table 2), we counted the number of nanofibers with obvious filament bundles and divided by the total number of nanofibers observed. For nanofibers with bundles, we classified those bundles as looped, buckled, or neither. Looped or buckled bundles exhibited significant curvature and had one end terminating at the nanofiber surface and the other end embedded in the comet tail. Looped bundles were longer and had one significant curve. Buckled bundles were shorter and had two or more curved sections.

Bead motility in low magnesium

For low Mg\(^{2+}\) motility buffers, we made the following changes: (1) For each experiment, we diluted fresh Ca-ATP actin into buffer G with no added Ca\(^{2+}\). (2) We mixed actin 9:1 with 10× low magnesium exchange buffer (10× low ME: 2 mM EGTA, 0.2 mM MgCl\(_2\)) for 2 minutes to form 4× final concentration of actin. (3) We diluted all proteins in buffer G with no added Ca\(^{2+}\), or Mg\(^{2+}\), or EGTA. (4) We reduced MgCl\(_2\) in 2× TIRF buffer from 2 mM to 0.2 mM to form 2× low-ME TIRF buffer. The final total concentration of Mg\(^{2+}\), Ca\(^{2+}\), EGTA, and ATP were 0.105 mM,
Filament bundling in low and high magnesium

Labeled and unlabeled Mg-ATP-actin were diluted in buffer G without added calcium as above, mixed with low Mg\(^{2+}\) motility buffer supplemented with MgCl\(_2\), added to chambers pre-blocked with 1% BSA, and filament growth was observed by TIRF microscopy. To quantify bundling, a 47 μm x 35 μm subfield at the center of each video was chosen and the total numbers of individual filaments and the number of filaments converging into bundles were scored. Bundles were scored as filaments overlapping for two or more frames. The fraction of bundled filaments was scored from three independent experiments for each condition.

Filaments binding to microspheres

Coverslips were coated with 1 mg/ml poly-L-lysine (30 to 70 kDa, Sigma-Aldrich) for 2 minutes, rinsed 3× with deionized water, and dried in air. We polymerized 8 μM (30% Oregon green labeled) Mg-ATP actin in buffer F (buffer G with 10 mM Imidazole pH 7, 50 mM KCl, 0.105 mM MgCl\(_2\), 1 mM EGTA) for 10 minutes at room temperature. Actin seeds were vortexed at maximum speed for 1 minute to break filaments. To prepared seeds, we added 4.5 μm diameter microspheres coated with 8.5 μM GST-WCA, 1 μM Oregon green labeled Mg-ATP actin monomers, and 1 mg/ml BSA. Mg\(^{2+}\), Lys-Lys\(^{2+}\), fascin or K\(^{+}\) were also added at this step. The reaction was incubated for 10 minutes at room temperature, beads and bound filaments and bundles were pelleted by centrifugation at 5000 rpm for 1 min, and the supernatant was removed. The pellet containing beads and bound filaments was gently diluted 16-fold in buffer F, mixed 1:1 with 2× TIRF buffer in the absence of methylcellulose, and 16 μl was added to a poly-L-lysine coated coverslip. Filaments/bundles and beads were observed, respectively, by TIRF or DIC microscopy.

Bulk pyrene-actin spectroscopy assays

For actin and profilin-actin experiments, we diluted labeled and unlabeled Ca-ATP actin to 30% labeled fraction with or without added profilin, mixed 9:1 with 10× low-Mg exchange buffer, and incubated on ice for 2 minutes to form 2× final concentrations of Mg-ATP actin in the lower row (preparatory wells) of a 96 well half area flat bottom plate (Corning). Various concentrations of MgCl\(_2\) were placed in the upper row (reaction wells) of the same plate along with 1.6 μl of 100× antifoam (100×: 0.0035% antifoam-204, Sigma-Aldrich), 2× initial concentration of low-Mg KMEI (10×: 500 mM KCl, 1 mM MgCl\(_2\), 10 mM EGTA, 100 mM Imidazole, pH 7), and buffer G without added Ca\(^{2+}\). We started the reaction by transferring 80 μl of actin mixture from the lower preparatory row to the upper reaction row containing 80 μl in each well for a 160 μl total reaction. The reaction was gently mixed with a 12-channel pipette, and pyrene-actin fluorescence was measured in a Spectra MAX Gemini XPS fluorescent plate reader (Molecular Devices, Sunnyvale, CA) with excitation and emission wavelengths of 364 nm and 407 nm, respectively. Arp2/3 nucleation experiments were similarly performed with Arp2/3 and GST-WCA added to the reaction well prior to the reaction start. For capping protein activity assays, we added CP to the reaction well followed by short (vortexed) unlabeled actin filament seeds prior to the reaction start as previously described [103].

Supporting Information

Figure S2 Lys-Lys\(^{2+}\) restores motility. Conditions as in Figure 4B. TIRF and epi-fluorescence microscopy images of actin shells (S) and comet tails (T) grown from GST-WCA coated beads in 0.1 mM total, 0.03 mM free Mg\(^{2+}\) buffer with added Lys-Lys\(^{2+}\) as indicated. Each image was recorded 40 minutes after initiation of the reaction. Lys-Lys\(^{2+}\) substituted for Mg\(^{2+}\) to restore motility. Scale bar is 5 μm. (TIF)

Figure S3 Fascin restores motility. Conditions as in Figure 4. A) TIRF and epi-fluorescence microscopy images of actin shells (S) and comet tails (T) grown from GST-WCA coated beads in 0.1 mM total, 0.03 mM free Mg\(^{2+}\) buffer with added fascin as indicated. Fascin added to 80 nM optimally restored comet tail elongation. Straight fascin bundles (black arrowheads) can be seen both within the comet tail and in the surrounding media. B) Actin shells (S) and comet tails (T) grown in 0.5 mM total, 0.3 mM free Mg\(^{2+}\) buffer with added fascin as indicated. Although 0.3 mM free Mg\(^{2+}\) did not support motility on its own, fascin addition restored motility to a greater extent than in 0.03 mM free Mg\(^{2+}\). Each image was recorded 40 minutes after initiation of the reaction. Scale bar is 5 μm. (TIF)

Figure S4 Minimal Mg\(^{2+}\) is sufficient for actin polymerization, Arp2/3 nucleation, and CP activity. Polymerization of pyrene actin in low Mg\(^{2+}\) buffer (50 mM KCl, 0.105 mM MgCl\(_2\), 0.105 mM EGTA, 10 mM imidazole pH 7, 0.2 mM ATP), MgCl\(_2\) was added to generate indicated free [Mg\(^{2+}\)]. A) Polymerization of 8.5 μM (30% pyrene labeled) Mg-ATP-actin induced by KCl was not affected by MgCl\(_2\) concentration. B) Addition of 8.5 μM human profilin to 8.5 μM actin did not affect Mg\(^{2+}\) independent actin polymerization. C) Nucleation of 2 μM (30% labeled) Mg-ATP-actin by 40 nM Arp2/3 and 500 nM bovine N-WASP/WCA. Mg\(^{2+}\) did not affect the time course or extent of Arp2/3 mediated nucleation. D) Nucleation conditions in C with addition of 2 μM profilin. Profilin did not significantly alter the Mg\(^{2+}\) independence of Arp2/3 nucleation. E) Polymerization from capped seeds. Short unlabeled actin seeds diluted to 1.2 μM filament were incubated with 0.2 nM CP or buffer alone (no CP). Capped seeds were added...
to 1 μM (30% pyrene labeled) actin, 3 μM profilin at the reaction start. (F) Normalized initial slope from the first 200 s of polymerization from capped seeds in E.

(TIF)

Figure S5  Looped bundles formed in low CP. Conditions: 8.5 μM (8% labeled) actin, 9 μM profilin, 100 nM Arp2/3, CP as indicated. (A–C) At low CP concentrations, bundled loops (black arrowheads) often formed on both stationary (A) and moving (B–C) nanofibers. Loops grew with one end embedded in the comet tail (T) and the other attached to the nanofiber surface (dashed outline). In additional to looped bundles, straight bundles (white arrow) often projected beyond the nanofiber surface at low CP concentrations. Scale bar, 5 μm. Time, min: sec.

(TIF)

Figure S6 Scoring of bundles captured by GST-WCA coated beads. (A) Sample TIRF microscopy image of actin filaments captured by a GST-WCA coated bead (dashed circle) in 0.03 mM free Mg2+ supplemented with 1 mM Lys-Lys2+. Scale bar, 5 μm. (B) Profile plot of fluorescent intensity along the line in A that intersects seven filaments. Numbered peaks correspond to marked filaments. Two dim background filaments are included for comparison. (C) Sample scoring method for experiments shown in Figure 7. Camera gain, acquisition time, and display range were kept constant between experiments to give roughly the same apparent magnitude (peak-to- trough intensity) of background filaments (6–7). Filaments were scored as captured (+) if they crossed or were contained within the bead boundary as measured with DIC microscopy. Captured filaments with apparent magnitudes similar to background filaments were scored as individual filaments (II). Captured filaments with apparent magnitudes of at least double the average magnitude of background filaments were scored as bundles (Bum).
