Abstract

In many real-world scenarios, decision makers seek to efficiently optimize multiple competing objectives in a sample-efficient fashion. Multi-objective Bayesian optimization (BO) is a common approach, but many existing acquisition functions do not have known analytic gradients and suffer from high computational overhead. We leverage recent advances in programming models and hardware acceleration for multi-objective BO using Expected Hypervolume Improvement (EHVI)—an algorithm notorious for its high computational complexity. We derive a novel formulation of \( q \)-Expected Hypervolume Improvement (\( q \)EHVI), an acquisition function that extends EHVI to the parallel, constrained evaluation setting. \( q \)EHVI is an exact computation of the joint EHVI of \( q \) new candidate points (up to Monte-Carlo (MC) integration error). Whereas previous EHVI formulations rely on gradient-free acquisition optimization or approximated gradients, we compute exact gradients of the MC estimator via auto-differentiation, thereby enabling efficient and effective optimization using first-order and quasi-second-order methods. Lastly, our empirical evaluation demonstrates that \( q \)EHVI is computationally tractable in many practical scenarios and outperforms state-of-the-art multi-objective BO algorithms at a fraction of their wall time.

1 Introduction

The problem of optimizing multiple competing objectives is ubiquitous in scientific and engineering applications. For example in automobile design, an automaker will want to maximize vehicle durability and occupant safety, while using lighter materials that afford increased fuel efficiency and lower manufacturing cost [42, 68]. Evaluating the crash safety of an automobile design experimentally is expensive due to both the manufacturing time and the destruction of a vehicle. In such a scenario, sample efficiency is paramount. For a different example, video streaming web services commonly use adaptive control policies to determine the bitrate as the stream progresses in real time [45]. A decision maker may wish to optimize the control policy to maximize the quality of the video stream, while minimizing the stall time. Policy evaluation typically requires using the suggested policy on segments of live traffic, which is subject to opportunity costs. If long evaluation times are the limiting factor, multiple designs may be evaluated in parallel to significantly decrease end-to-end optimization time. For example, an automaker could manufacture multiple vehicle designs in parallel or a web service could deploy several control policies to different segments of traffic at the same time.

Multi-objective Optimization

In this work, we address the problem of optimizing a vector-valued objective \( \mathbf{f}(\mathbf{x}) : \mathbb{R}^d \rightarrow \mathbb{R}^M \) with \( \mathbf{f}(\mathbf{x}) = (f^{(1)}(\mathbf{x}), \ldots, f^{(M)}(\mathbf{x})) \) over a bounded set \( \mathcal{X} \subset \mathbb{R}^d \). We consider the scenario in which the \( f^{(i)} \) are expensive-to-evaluate black-box functions with no known analytical expression, and no observed gradients. Such multi-objective (MO) optimization problems typically do not have a single best solution; rather, the goal is to identify the set of Pareto optimal solutions such that any improvement in one objective means deteriorating another.
Without loss of generality, we assume the goal is to maximize all objectives. We say a solution \( f(x) \) Pareto dominates another solution \( f(x') \) if \( f^{(m)}(x) \geq f^{(m)}(x') \forall m \in \{1, \ldots, M\} \) and there exists \( m' \in \{1, \ldots, M\} \) such that \( f^{(m')}(x) > f^{(m')}(x') \). We write \( f(x) \succ f(x') \). Let \( P^* = \{f(x) \ s.t. \ \exists x' \in X' ; \ f(x') > f(x)\} \) denote the set of Pareto optimal solutions, and \( X^* = \{x \in X \ s.t. \ f(x) \in P^*\} \) the corresponding set of Pareto optimal inputs. Provided with the Pareto set, decision-makers can select a solution with an objective trade-off according to their preferences.

A common approach for solving MO problems is to use evolutionary algorithms (e.g. NSGA-II), which are robust multi-objective optimizers, but require a large number of function evaluations [13].

Bayesian optimization (BO) offers a far more sample-efficient alternative [54]. Bayesian Optimization [37] is an established method for optimizing expensive-to-evaluate black-box functions. BO relies on a Bayesian surrogate model, typically a Gaussian Process (GP) [52], to provide a posterior distribution \( p(f|D) \) over the true function values \( f \) given the observed data \( D = \{(x_i, y_i)\}_{i=1}^n \). An acquisition function \( \alpha : X_{\text{cand}} \mapsto \mathbb{R} \) employs the surrogate model to assign a utility value to a set of candidates \( X_{\text{cand}} = \{x_i\}_{i=1}^q \) to be evaluated on the true function. While the true \( f \) may be expensive-to-evaluate, the surrogate-based acquisition function is not, and can thus be efficiently optimized to yield a set of candidates \( X_{\text{cand}} \) to be evaluated on \( f \). If gradients of \( \alpha(X_{\text{cand}}) \) are available, gradient-based methods can be utilized. If not, gradients are either approximated (e.g. with finite differences) or gradient-free methods (e.g. DIRECT [36] or CMA-ES [31]) are used.

Limitations of current approaches In the single-objective (SO) setting, a large body of work focuses on practical extensions to BO for supporting parallel evaluation and outcome constraints [47, 29, 62, 24, 41]. Less attention has been given to such extensions in the MO setting. Moreover, the existing constrained and parallel MO BO options have limitations: 1) many rely on scalarizations to transform the MO problem into a SO one [59]; 2) many acquisition functions computationally expensive to compute [49, 20, 6, 67]; 3) few have known analytical gradients or are differentiable [18, 58, 32]; 4) many rely on heuristics to extend sequential algorithms to the parallel setting [26, 58].

A natural acquisition function for MO BO is Expected Hypervolume Improvement (EHVI). Maximizing the hypervolume (HV) has been shown to produce Pareto fronts with excellent coverage [69, 11, 65]. However, there has been little work on EHVI in the parallel setting, and the work that has been done resorts to approximate methods [67, 27, 58]. Furthermore, a vast body of literature on has focused efficient EHVI computation [33, 19, 63], but the time complexity for computing EHVI is exponential in the number of objectives—in part due the hypervolume indicator itself incurring a time complexity that scales super-polynomially with the number of objectives [64]. Our core insight is that by exploiting advances in auto-differentiation and highly parallelized hardware [48], we can make EHVI computations fast and practical.

Contributions In this work, we derive a novel formulation of the parallel \( q \)-Expected Hypervolume Improvement acquisition function (\( q \)EHVI) that is exact up to Monte-Carlo (MC) integration error. We compute the exact gradient of the MC estimator of \( q \)EHVI using auto-differentiation, which allows us to employ efficient and effective gradient-based optimization methods. Despite its computational cost, our formulation of \( q \)EHVI is embarrassingly parallel, and would achieve constant time complexity given infinite processing cores. We demonstrate that, using modern GPU hardware and computing exact gradients, optimizing \( q \)EHVI is faster than existing state-of-the-art methods in many practical scenarios. Moreover, we extend \( q \)EHVI to support auxiliary outcome constraints, making it practical in many real-world scenarios. Lastly, we demonstrate how modern auto-differentiation can be used to compute exact gradients of analytic EHVI, which has never been done before for \( M > 2 \) objectives. Our empirical evaluation shows that \( q \)EHVI outperforms state-of-the-art multi-objective BO algorithms using a fraction of their wall time.

2 Related Work

Yang et al. [65] is the only previous work to consider exact gradients of EHVI, but the authors only derive an analytical gradient for the unconstrained \( M = 2, q = 1 \) setting. All other works either do not optimize EHVI (e.g. they use it for pre-screening candidates [17]), optimize it with gradient-free methods [64], or using approximate gradients [58]. In contrast, we use exact gradients and demonstrate that optimizing EHVI with gradients is far more efficient.
There are many alternatives to EHVI for MO BO. For example, ParEGO [39] randomly scalarizes the objectives and uses Expected Improvement [37], and SMS-EGO [50] uses HV in a UCB-based acquisition function and is more scalable than EHVI [51]. Both methods have only been considered for the $q = 1$, unconstrained setting. Predictive entropy search for MO BO (PESMO) [32] has been shown to be another competitive alternative and has been extended to handle constraints [24] and parallel evaluations [26]. MO max-value entropy search (MO-MES) has been shown to achieve superior optimization performance and faster wall times than PESMO, but is limited to $q = 1$.

Wilson et al. [61] empirically and theoretically show that sequential greedy selection of $q$ candidates achieves performance comparable to jointly optimizing $q$ candidates for many acquisition functions (including [59, 62]). The sequential greedy approach integrates over the posterior of the unobserved outcomes corresponding to the previously selected candidates in the $q$-batch. Sequential greedy optimization often yields better empirical results because the optimization problem has a lower dimension: $d$ in each step, rather than $q \cdot d$ in the joint problem. Most prior works in the MO setting use a sequential greedy approximation or heuristics [58] [27] [9], but impute the unobserved outcomes with the posterior mean rather than integrating over the posterior [29]. For many joint acquisition functions involving expectations, this shortcut sacrifices the theoretical error bound on the sequential greedy approximation because the exact joint acquisition function over $x_1, ..., x_i, \ 1 \leq i \leq q$ requires integration over the joint posterior $P(f(x_1), ..., f(x_q)|D)$ and is not computed for $i > 1$.

Garrido-Merchán and Hernández-Lobato [26] and Wada and Hino [58] jointly optimize the $q$EHVI acquisition function, but after finding it challenging to optimize $q$ candidates jointly (without exact gradients), the authors propose optimizing an alternative acquisition function instead of exact $q$EHVI. In contrast, our novel $q$EHVI formulation allows for gradient-based parallel and sequential greedy optimization, with proper integration over the posterior for the latter.

Feliot et al. [21] and Abdolshah et al. [11] proposed extensions of EHVI to the constrained $q = 1$ setting, but neither considers the batch setting and both rely on gradient-free optimization.

3 Differentiable $q$-Expected Hypervolume Improvement

In this section, we review HVI and EHVI computation by means of box decompositions, and explain our novel formulation for the parallel setting.

Definition 1. Given a reference point $r \in \mathbb{R}^M$, the hypervolume indicator (HV) of a finite approximate Pareto set $P$ is the $M$-dimensional Lebesgue measure $\lambda_M$ of the space dominated by $P$ and bounded from below by $r$: $HV(P, r) = \lambda_M(\bigcup_{i=1}^{\|P\|} [r, y_i])$.

Definition 2. Given a Pareto set $P$ and reference point $r$, the hypervolume improvement (HVI) of a set of points $Y$ is: $HVI(Y, P, r) = HV(P \cup Y, r) - HV(P, r)$.

EHVI is the expectation of HVI over the posterior $P(f, D)$: $\alpha_{EHVI}(\lambda_{cand}) = \mathbb{E}[HV(f(\lambda_{cand}))]$. In the sequential setting, and assuming the objectives are independent and modeled with independent GPs, EHVI can be expressed in closed form [63]. In other settings, EHVI can be approximated with MC integration. The reference point is typically specified by the decision maker [63] (see Appendix E.1.1 for more discussion).

3.1 A review of hypervolume improvement computation using box decompositions

Definition 3. For a set of objective vectors $\{f(x_i)\}_{i=1}^{\|Y\|}$, a reference point $r \in \mathbb{R}^M$, and a non-dominated set $P$, let $\Delta(\{f(x_i)\}_{i=1}^{\|Y\|}, P, r) \subset \mathbb{R}^M$ denote the set of points that $\{f(x_i)\}_{i=1}^{\|Y\|}$ dominates, but $P$ does not dominate.

Given $P, r$, the HVI of a new point $f(x)$ is the HV of the intersection of space dominated by $P \cup \{f(x)\}$ and the non-dominated space. Figure [1b] illustrates this for one new point $f(x)$ for $M = 2$. The yellow region is $\Delta(\{f(x)\}, P, r)$ and the hypervolume improvement is the area covered by $\Delta(\{f(x)\}, P, r)$. Since $\Delta(\{f(x)\}, P, r)$ is often a non-rectangular polytope, HVI is typically

\footnote{In this work, we omit the arguments $P$ and $r$ when referring to HVI for brevity.}
computed by partitioning the non-dominated space into disjoint axis-parallel rectangles (see Figure 1a) and use piece-wise integration [17].

Let \( \{ S_k \}_{k=1}^{K} \) be a partitioning of the non-dominated space into disjoint hyper-rectangles, where each \( S_k \) is defined by a pair of lower and upper vertices \( l_k \in \mathbb{R}^M \) and \( u_k \in \mathbb{R}^M \cup \{ \infty \} \). The high level idea to sum the HV of \( S_k \cap \Delta(\{ f(x) \}, \mathcal{P}, r) \) over all \( S_k \). For each hyper-rectangle \( S_k \), the intersection of \( S_k \) and \( \Delta(\{ f(x) \}, \mathcal{P}, r) \) is a hyper-rectangle where the lower bound vertex is \( l_k \) and the upper bound vertex is the component-wise minimum of \( u_k \) and the new point \( f(x) \): \( z_k := \min \{ u_k, f(x) \} \).

Figure 1: For \( M=2 \), (a) the dominated space (red) and non-dominated space partitioned into disjoint boxes (white), (b) the HVI of one new point \( f(x) \) and (c) the HVI of two new points \( f(x_1), f(x_2) \).

Hence, the HVI of a single outcome vector \( f(x) \) within \( S_k \) is given by \( \text{HVI}_k(f(x), l_k, u_k) = \lambda_M(S_k \cap \Delta(\{ f(x) \}, \mathcal{P}, r)) = \prod_{m=1}^{M} [z_k^{(m)} - l_k^{(m)}]_+ \), where \( u_k^{(m)}, l_k^{(m)}, f^{(m)}(x) \), and \( z_k^{(m)} \) denote the \( m \)th component of the corresponding vector and \([\cdot]_+\) denotes the \( \min(\cdot, 0) \) operation. Summing over rectangles yields

\[
\text{HVI}(f(x)) = \sum_{k=1}^{K} \text{HVI}_k(f(x), l_k, u_k) = \sum_{k=1}^{K} \prod_{m=1}^{M} [z_k^{(m)} - l_k^{(m)}]_+ \tag{1}
\]

### 3.2 Computing \( q \)-Hypervolume Improvement via the Inclusion-Exclusion Principle

Figure 1b illustrates the HVI in the \( q = 2 \) setting. Given \( q \) new points \( \{ f(x_i) \}_{i=1}^{q} \), let \( A_i := \Delta(\{ f(x_i) \}, \mathcal{P}, r) \) for \( i = 1, \ldots, q \) be the space dominated by \( f(x_i) \) but not dominated by \( \mathcal{P} \), independently of the other \( q-1 \) points. Note that \( |A_i| = \text{HVI}(f(x_i)) \). The union of the subsets \( A_i \) is the space dominated jointly by the \( q \) new points: \( \bigcup_{i=1}^{q} A_i = \bigcup_{i=1}^{q} \Delta(\{ f(x_i) \}, \mathcal{P}, r) \), and so \( \bigcup_{i=1}^{q} A_i \) is the joint HVI from the \( q \) new points. Using the inclusion-exclusion principle [12,56],

\[
\text{HVI}(\{ f(x_i) \}_{i=1}^{q}) = \left| \bigcup_{i=1}^{q} A_i \right| = \left| \bigcap_{j=1}^{q} (-1)^{j+1} \sum_{1 \leq i_1 \leq \ldots \leq i_j \leq q} |A_{i_1} \cap \cdots \cap A_{i_j}| \right| \tag{2}
\]

\( |A_{i_1} \cap \cdots \cap A_{i_j}| \) can be computed in a piecewise fashion across the \( K \) hyper-rectangles \( \{ S_k \}_{k=1}^{K} \) as the HV of the intersection of \( A_{i_1} \cap \cdots \cap A_{i_j} \) with each hyper-rectangle \( S_k \) since \( \{ S_k \}_{k=1}^{K} \) is a disjoint partition: \( |A_{i_1} \cap \cdots \cap A_{i_j}| = \prod_{k=1}^{K} |S_k \cap A_{i_1} \cap \cdots \cap A_{i_j}| \). The inclusion-exclusion principle has been proposed for computing HV (not HVI) [43], but it is rarely used because complexity scales exponentially with the number of elements. However, the inclusion-exclusion principle is practical for computing the joint HVI of \( q \) points since typically \( q \ll |\mathcal{P}| \).

This formulation has three advantages. First, while the new dominated space \( A_i \) can be a non-rectangular polytope, the intersection \( A_i \cap S_k \) is a rectangular polytope, which simplifies computation of overlapping hypervolume. Second, the vertices defining the hyper-rectangle \( S_k \cap A_{i_1} \cap \cdots \cap A_{i_j} \) are easily derived. The lower bound is simply the \( l_k \) lower bound of \( S_k \), and the upper bound is the component-wise minimum \( z_{k,i_1\ldots i_j} := \min \{ u_k, f(x_{i_1}), \ldots, f(x_{i_j}) \} \). Third, computation can be across all intersections of subsets \( A_{i_1} \cap \cdots \cap A_{i_j} \) for \( 1 \leq i_1 \leq \cdots \leq i_j \leq q \) and across all \( K \) hyper-rectangles can be performed in parallel. Explicitly, the HVI is computed as:

\[
\text{HVI}(\{ f(x_i) \}_{i=1}^{q}) = \sum_{k=1}^{K} \sum_{j=1}^{q} \sum_{X_j \in A_j} (-1)^{j+1} \prod_{m=1}^{M} [z_k^{(m)} - l_k^{(m)}]_+ \tag{3}
\]
where $X_j := \{ X_j \subset X_{\text{cand}} : |X_j| = j \}$ is the superset of all subsets of $X_{\text{cand}}$ of size $j$, and $z^{(m)}_{k,X_j} := z^{(m)}_{k,i_1,\ldots,i_j}$ for $X_j = \{ x_{i_1}, \ldots, x_{i_j} \}$. See Appendix \ref{app:derivation} for further details of the derivation.

### 3.3 Computing Expected $q$-Hypervolume Improvement

The above approach for computing HVI assumes that we know the true objective values $\{ f(x_i) \}_{i=1}^q$. In BO, we instead compute $q$EHVI as the expectation over the posterior:

$$\alpha_{q\text{EHVI}}(x) = \mathbb{E}_{\{ f(x_i) \}_{i=1}^q} [\text{HVI}(\{ f(x_i) \}_{i=1}^q)] = \int_{-\infty}^{\infty} \text{HVI}(\{ f(x_i) \}_{i=1}^q) df. \quad (4)$$

Since no known analytical form is known \cite{66} for $q > 1$ (or in the case of correlated outcomes), we estimate \cite{4} using MC integration with samples from the joint posterior $\{ f_i(x_i) \}_{i=1}^q \sim \mathbb{P}(f(x_1), \ldots, f(x_q)|D), t = 1, \ldots, N$. Let $z^{(m)}_{k,X_{j,t}} := \min \left[ u_k, \min_{x' \in X_j} f_i(x') \right]$. Then,

$$\hat{\alpha}^N_{q\text{EHVI}}(x) := \frac{1}{N} \sum_{t=1}^N \text{HVI}(\{ f_i(x_i) \}_{i=1}^q) = \frac{1}{N} \sum_{t=1}^N \sum_{k=1}^K \sum_{j=1}^q \sum_{X_j \in X_k} (-1)^{t+1} \prod_{m=1}^M \left[ z^{(m)}_{k,X_{j,t}} - j^{(m)}_k \right]. \quad (5)$$

Provided that $\{ S_k \}_{k=1}^K$ is an exact partitioning, \cite{5} is an exact computation of $q$EHVI up to the MC estimation error, which scales as $1/\sqrt{N}$ regardless of the dimension of the search space \cite{17}. In practice, we use randomized quasi MC methods \cite{8} to reduce the variance (see Figure \ref{fig:comp} in the Appendix for a comparison of analytic EHVI and MC-based $q$EHVI).

$q$EHVI requires computing the volume of $2^q - 1$ hyper-rectangles (the number of subsets of $q$) for each of $K$ hyper-rectangles and $N$ MC samples. Given posterior samples, the time complexity on a single-threaded machine is: $T_f = O(MNK(2^q - 1))$. In the two-objective case, $K = |P| + 1$, but $K$ is super-polynomial in $M$ \cite{64}. $q$EHVI is agnostic to the partitioning algorithm used, and the details of such algorithms are beyond the scope of this work. Despite the daunting workload, the critical work path—the time complexity of the smallest non-parallelizable unit—is constant: $T_\infty = O(1)$.$^3$

On highly-threaded many-core hardware (e.g. GPUs), our formulation achieves tractable wall times in many practical scenarios: as is shown in Figure \ref{fig:comp} in the Appendix, the computation time is nearly constant with increasing $q$ until an inflection point at which the workload saturates the available cores. For additional discussion of both time and memory complexity of $q$EHVI see Appendix \ref{app:complexity}.

### 3.4 Outcome Constraints

Our proposed $q$EHVI acquisition function is easily extended to constraints on auxiliary outcomes. We consider the scenario where we receive observations of $M$ objectives $f(x) \in \mathbb{R}^M$ and $V$ constraints $c^{(v)} \in \mathbb{R}^V$, all of which are assumed to be “black-box”. We assume w.l.o.g. that $c^{(v)}$ is feasible iff $c^{(v)} \geq 0$. In the constrained optimization setting, we aim to identify the feasible Pareto set: $\mathcal{P}_{\text{feas}} = \{ f(x) \ \text{s.t.} \ c(x) \geq 0, \ f(x') \forall x' : c(x') \geq 0, \ f(x') \succ f(x) \}$. The natural improvement measure in the constrained setting is feasible HVI, which we define for a single candidate point $x$ as $\text{HVI}_c(f(x), c(x)) := \text{HVI}[f(x)] \cdot 1[c(x) \geq 0]$. Taking expectations, the constrained expected HV can be seen to be the HV weighted by the probability of feasibility. In Appendix \ref{app:constraints} we detail how performing feasibility-weighting on the sample-level allows us to include such auxiliary outcome constraints into our MC formulation in a straightforward way.

### 4 Optimizing $q$-Expected Hypervolume Improvement

**Differentiability** While an analytic formula for the gradient of EHVI exists for the $M = 2$ objective case in the unconstrained, sequential (q = 1) setting, no such formula is known in 1) the case of $M > 2$ objectives, 2) the constrained setting, and 3) for $q > 1$. Leveraging the re-parameterization trick \cite{8,60} and auto-differentiation, we are able to automatically compute exact gradients of the MC-estimator $q$EHVI in all of the above settings, as well as the gradient of analytic EHVI for

$^2$The number of boxes required for a decomposition of the non-dominated space is unknown for $M \geq 4$ \cite{64}.

$^3$As evident from \cite{5}, the critical path consists of 3 multiplications and 5 summations.
Although sequential greedy approaches have been considered for many acquisition functions \cite{61}, no when selecting the next point \cite{61}. Using a submodularity argument similar to that in Wilson et al. (plus the initial quasi-random design). We report means and 2 standard errors across 20 trials.

Optimization via Sample Average Approximation We show in Appendix \cite{c} that if mean and covariance function of the GP are sufficiently regular, the gradient of the MC estimator \cite{5} is an unbiased estimate of the gradient of the exact acquisition function \cite{4}. To maximize \( qEHVI \), we could therefore directly apply stochastic optimization methods, as has previously been done for single-outcome acquisition functions \cite{60, 62}. Instead, we opt to use the sample average approximation (SAA) approach from Balandat et al. \cite{5}, which allows us to employ deterministic, higher-order optimizers to achieve faster convergence rates. Informally (see Appendix \cite{c} for the formal statement), if \( \hat{x}_N \in \arg\max_{x \in X} qEHVI(x) \), we can show under some regularity conditions that, as \( N \to \infty \), (i) \( \hat{\alpha}_{qEHVI}(\hat{x}_N) \to \max_{x \in X} \alpha_{qEHVI}(x) \) a.s., and (ii) \( \text{dist}(\hat{x}_N, \arg\max_{x \in X} \alpha_{qEHVI}(x)) \to 0 \) a.s.. Figure \ref{fig:2} demonstrates the importance of using exact gradients for efficiently and effectively optimizing \( EHVI \) and \( qEHVI \) by comparing the following optimization methods: L-BFGS-B with exact gradients, L-BFGS-B with gradients approximated via finite differences, and CMA-ES (without gradients). The cumulative time spent optimizing the acquisition function is an order of magnitude less when using exact gradients rather than approximate gradients or zeroth order methods.

Sequential Greedy and Joint Batch Optimization Jointly optimizing \( q \) candidates increases in difficulty with \( q \) because the problem dimension is \( dq \). An alternative is to sequentially and greedily select candidates and condition the acquisition function on the previously selected pending points when selecting the next point \cite{61}. Using a submodularity argument similar to that in Wilson et al. \cite{60}, the sequential greedy approximation of \( qEHVI \) enjoys regret of no more than \( \frac{1}{q} \alpha_{qEHVI}^* \), where \( \alpha_{qEHVI}^* \) is the optima of \( \alpha_{qEHVI} \) \cite{22} (see Appendix \cite{b}). Although sequential greedy approaches have been considered for many acquisition functions \cite{61}, no previous work has proposed a proper sequential greedy approach (with integration over the posterior) for parallel \( EHVI \) because it would require computing the Pareto front under each sample \( f_i \) from the joint posterior before computing the hypervolume improvement. These operations would be computationally expensive for even modest \( N \) and non-differentiable. \( qEHVI \) avoids determining the Pareto set for each sample by using inclusion-exclusion principle to compute the joint \( HVI \) over the pending points \( x_1, \ldots, x_{i-1} \) and new candidate \( x_i \) for each MC sample. Figure \ref{fig:2} empirically demonstrates the improved optimization performance from properly integrating over the unobserved outcomes rather than using the posterior mean or jointly optimizing the \( q \) candidates.

---

4 Technically, min and max are only sub-differentiable, but are known to be well-behaved \cite{60}. In our MC setting with GP posteriors, \( qEHVI \) is differentiable w.p. 1 if \( x \) contains no repeated points.

5 For the constrained case, we replace the indicator with a differentiable sigmoid approximation.
Figure 3: Optimization performance on (a) on the Branin-Currin problem ($q = 1$), (b) the C2-DTLZ2 problem with a proper sequential greedy approximation, (c) the vehicle crash safety problem ($q = 1$), and (d) the ABR control problem ($q = 1$). We report the means and 2 standard errors across 20 trials.

5 Experiments

We empirically evaluate $q$EHVI on synthetic and real world optimization problems. We compare $q$EHVI against existing state of the art methods including SMS-EGO, PESMO, and analytic EHVI with gradients. Additionally, we compare against a novel extension of ParEGO to support parallel evaluation and constraints, neither of which have been done before to our knowledge; we call this method $q$ParEGO. Additionally, we include a quasi-random baseline that selects candidates from a scrambled Sobol sequence. See Appendix E.1 for details on all baseline algorithms.

Synthetic Benchmarks: We evaluate optimization performance on four benchmark problems in terms of log hypervolume difference, which is defined as the difference between the hypervolume of the true Pareto front and the hypervolume of the approximate Pareto front based on the observed data; in the case that the true Pareto front is unknown (or not easily approximated), we evaluate the hypervolume indicator. All references points and search spaces are provided in Appendix E.2. For synthetic problems, we consider the Branin-Currin problem ($d = 2, M = 2$, convex Pareto front) and the C2-DTLZ2 ($d = 12, M = 2, V = 1$, concave Pareto front), which is a standard constrained benchmark from the MO literature (see Appendix F.1 for additional synthetic benchmarks).

Structural Optimization in Automobile Safety Design (VehicleSafety): Vehicle crash safety is an important consideration in the structural design of automobiles. A lightweight car is preferable because of its potentially lower manufacturing cost and better fuel economy, but lighter material can fair worse than sturdier alternatives in a collision, leading to increased vehicle damage and more severe injury to the vehicle occupants. We consider the problem designing the thickness of 5

Footnotes:

6. Acquisition functions implemented in BoTorch and will be made publicly available. For review purposes, see the code included with this submission.

7. We hope to compare to other, challenging-to-implement acquisition functions such as MES-MO and PPESTEMOC in a future draft of this work when the authors of these methods are prepared to share their code.

8. We leverage existing implementations from the Spearmint library. The code is available at https://github.com/HIPS/Spearmint/tree/PESM.
reinforced parts of the frontal frame of the vehicle that considerably affect crash safety. The goal is to minimize: 1) the mass of the vehicle; 2) the collision acceleration in a full frontal crash—a proxy for bio-mechanical trauma to the vehicle occupants from the acceleration; and 3) the toe-board intrusion—a measure of the most extreme mechanical damage to the vehicle in an off-frontal collision [42]. For this problem, we optimize the surrogate from Tanabe and Ishibuchi [57].

**Policy Optimization for Adaptive Bitrate Control** (ABR): Many web services adapt video playback quality on-the-fly based on the receiver’s network bandwidth to maintain steady, high quality stream with minimal stalls and buffer periods [45]. Previous works have proposed controllers with different scalarized objective functions [44], but in many cases, engineers may prefer to learn the set of optimal trade-offs between their metrics of interest, rather than specify a scalarized objective in advance. In this problem, we decompose the objective function proposed in Mao et al. [44] into its constituent metrics and optimize 4 parameters of an ABR control policy on the Park simulator to maximize video quality (bitrate) and minimize stall time. See E.2 for details.

Figure 3 shows qEHVI outperforming all baselines in terms of optimization performance on all evaluated problems. Table 1 shows that qEHVI achieves wall times that are an order of magnitude smaller than those of PESMO on a CPU in sequential optimization, and maintains competitive wall times even relative to qPAREGO (which has a significantly smaller workload) for large q on a GPU.

### 6 Discussion

We present a simple, practical, and efficient algorithm for parallel, constrained MO BO. Leveraging differentiable programming and modern parallel hardware, we are able to efficiently optimize qEHVI via quasi second-order methods, for which we provide convergence guarantees. We demonstrate that our method achieves performance superior to that of state-of-the-art MO BO approaches.

One limitation of our approach is that it currently assumes noiseless observations. Extending to noisy observations (e.g. by integrating over the uncertainty around the previous observations) would be nontrivial, particularly in the parallel case. Such an integration would be equivalent to noiseless qEHVI computation with a batch size $|\mathcal{P}| + q$, which would be prohibitively expensive since computation scales exponentially with the batch size. Additional wall-time performance improvements can be gained through the use of more efficient partitioning algorithms (e.g. [40] [16] [65]) that result in fewer disjoint hyper-rectangles. We hope this work encourages researchers to consider more improvements from applying modern computational paradigms and tooling to MO BO, and BO more generally.

Differentiable Expected Hypervolume Improvement for Parallel Multi-Objective Bayesian Optimization

A Derivation of $q$-Expected Hypervolume Improvement

A.1 Hypervolume Improvement via the Inclusion-Exclusion Principle

The hypervolume improvement of $f(x)$ within the hyper-rectangle $S_k$ is the volume of $S_k \cap \Delta(\{f(x)\}, P, r)$ and is given by:

$$
\text{HVI}_k(f(x), I_k, u_k) = \lambda_M(S_k \cap \Delta(\{f(x)\}, P, r)) = \prod_{m=1}^{M} \left[ z_k^{(m)} - l_k^{(m)} \right]_+,
$$

where $u_k^{(m)}$, $l_k^{(m)}$, $f(x)$, and $z_k^{(m)}$ denote the $m^{th}$ component of the corresponding vector and $[.]_+$ denotes the min$(\cdot, 0)$ operation. Summing over all $S_k$ gives the total hypervolume improvement:

$$
\text{HVI}(f(x)) = \sum_{k=1}^{K} \text{HVI}_k(f(x), I_k, u_k)
= \sum_{k=1}^{K} \lambda_M(S_k \cap \Delta(\{f(x)\}, P, r))
= \sum_{k=1}^{K} \prod_{m=1}^{M} \left[ z_k^{(m)} - l_k^{(m)} \right]_+.
$$

We can extend the HVI computation to the $q > 1$ case using the inclusion-exclusion principle.

**Lemma 1.** The inclusion-exclusion principle $[12, 56]$ Let $A$ be a $p$-system of some set $R$, i.e., a sequence of potentially empty or overlapping subsets $A_1, ..., A_p$ of $R$. Then

$$
\left| \bigcup_{i=1}^{p} A_i \right| = \sum_{i=1}^{p} |A_i| - \sum_{1 \leq i < j \leq p} |A_i \cap A_j| + \sum_{1 \leq i \leq j \leq k \leq p} |A_i \cap A_j \cap A_k| - \ldots + (-1)^{p-1} |A_1 \cap \ldots \cap A_p|
$$

Or equivalently,

$$
\left| \bigcup_{i=1}^{p} A_i \right| = \sum_{j=1}^{p} (-1)^{j+1} \sum_{1 \leq i_1 \leq \ldots \leq i_j \leq p} |A_{i_1} \cap \ldots \cap A_{i_j}|
$$

In the context of computing the joint HVI of $q$ new points $\{f(x_i)\}_{i=1}^{q}$, each subset $A_i$ for $i = 1, \ldots, q$ is the set of points contained in $\Delta(\{f(x_i)\}, P, r)$ — independently of the other $q-1$ points. $|A_i|$ is the hypervolume improvement from the new point $f(x_i)$: $|A_i| = \text{HVI}(f(x_i))$. The union of these subsets is the set of points in the new space dominated by the $q$ new points: $\bigcup_{i=1}^{q} A_i = \bigcup_{i=1}^{q} \Delta(\{f(x_i)\}, P, r)$. The hypervolume of $\bigcup_{i=1}^{q} \Delta(\{f(x_i)\}, P, r)$ is the hypervolume improvement from the $q$ new points:

$$
\text{HVI}(\{f(x_i)\}_{i=1}^{q}) = \left| \bigcup_{i=1}^{q} A_i \right|
= \sum_{j=1}^{q} (-1)^{j+1} \sum_{1 \leq i_1 \leq \ldots \leq i_j \leq q} |A_{i_1} \cap \ldots \cap A_{i_j}|
$$

To compute $|A_{i_1} \cap \ldots \cap A_{i_j}|$, we partition the space covered by $A_{i_1} \cap \cdots \cap A_{i_j}$ across the $K$ hyper-rectangles $\{S_k\}_{k=1}^{K}$ and compute the hypervolume of the overlapping space of $A_{i_1} \cap \cdots \cap A_{i_j}$ with each $S_k$ independently. Since $\{S_k\}_{k=1}^{K}$ is a disjoint partition, summing over $K$ gives the hypervolume of $A_{i_1} \cap \cdots \cap A_{i_j}$:

$$
|A_{i_1} \cap \cdots \cap A_{i_j}| = \sum_{k=1}^{K} |S_k \cap A_{i_1} \cap \cdots \cap A_{i_j}|
$$
This has two advantages. First, the new dominated space $A_i$ can be a non-rectangular polytope, but the intersection $A_i \cap S_k$ is a rectangular polytope, which simplifies computation of overlapping hypervolume. Second, the vertices defining the hyper-rectangle encapsulated by $S_k \cap A_{i_1} \cap \cdots \cap A_{i_j}$ are easily derived. The lower bound is simply the $l_k$ lower bound of $S_k$ and the upper bound is the component-wise minimum $z_{k,i_1,\ldots,i_j} = \min \{ u_k, f(x_{i_1}), \ldots, f(x_{i_j}) \}$.

Importantly, this is computationally tractable because this specific approach enables parallelizing computation across all intersections of subsets $A_{i_1} \cap \cdots \cap A_{i_j}$ for $1 \leq i_1 \leq \ldots \leq i_j \leq q$ and across all $K$ hyper-rectangles. Explicitly, the HVI is computed as:

$$
\text{HVI}(\{f(x_i)\}_{i=1}^q) = \left| \bigcup_{i=1}^p A_i \right|
= \sum_{j=1}^q \sum_{1 \leq i_1 \leq \ldots \leq i_j \leq q} \sum_{k=1}^{K_i} \prod_{m=1}^{M_j} \left( z_{k,i_1,\ldots,i_j} - l_k^{(m)} \right),
$$

where $X_j$ is the superset all subsets of $\mathcal{X}_{\text{cand}}$ of size $j$: $X_j = \{ X_j \subset \mathcal{X}_{\text{cand}} : |X_j| = j \}$ and $z_{k,i_1,\ldots,i_j}^{(m)} = z_{k,i_1,\ldots,i_j}$ for $X_j = \{ x_{i_1}, \ldots, x_{i_j} \}$.

### A.2 Computing Expected Hypervolume Improvement

The above approach for computing HVI assumes we know the true objective values $\{f(x_i)\}_{i=1}^q$. Since we do not know the true function values $\{f(x_i)\}_{i=1}^q$, we compute $qEHVI$ as the expectation over the GP posterior.

$$
\alpha_{qEHVI} = \mathbb{E} \left[ \text{HVI}(\{f(x_i)\}_{i=1}^q) \right] = \int_{\mathbb{R}^M} \text{HVI}(\{f(x_i)\}_{i=1}^q) df
$$

In the sequential setting and under the assumption of independent outcomes, $qEHVI$ is simply $EHVI$ and can be expressed in closed form [65]. However when $q > 1$, there is no known analytical formulation [66]. Instead, we estimate the expectation in (6) using MC integration with samples from the joint posterior $\mathbb{P}(f(x_1), \ldots, f(x_q)|D)$:

$$
\alpha_{qEHVI} \approx \frac{1}{N} \sum_{l=1}^N \text{HVI}(\{f_l(x_i)\}_{i=1}^q)
= \frac{1}{N} \sum_{l=1}^N \sum_{k=1}^{K_l} \sum_{m=1}^{M_l} \sum_{x_j \in X_j} (-1)^{j+1} \prod_{m=1}^{M_l} \left( z_{k,x_j}^{(m)} - l_k^{(m)} \right) +
$$

where $\{f_l(x_i)\}_{i=1}^q \sim \mathbb{P}(f(x_1), \ldots, f(x_q)|D)$ is the $l$th sample from the joint posterior over $\mathcal{X}_{\text{cand}}$ and $z_{k,x_j}^{(m)} = \min \{ u_k, \min_{x \in X_j} f_l(x) \}$.

### A.3 Supporting Outcome Constraints

Recall that we defined the constrained hypervolume improvement as

$$
\text{HVI}_c(f(x), c(x)) = \text{HVI}(f(x)) \cdot \mathbb{I}[c(x) \geq 0].
$$

For $q = 1$ and assuming independence of the objectives and the constraints, the expected $\text{HVI}_c$ is the product of the expected HVI and the probability of feasibility (the expectation of $\mathbb{I}[c(x) \geq 0]$) [21]. However, requiring
objectives and constraints to be independent is unnecessary when estimating the expectation with MC integration from samples from the joint posterior.

In the parallel setting, if all constraints are satisfied for all $q$ candidates $\mathcal{X}_{\text{cand}} = \{x_i\}_{i=1}^q$, $\text{HVI}_c$ is simply HVI. If a subset $\mathcal{V} \subset \mathcal{X}_{\text{cand}}, \mathcal{V} \neq \emptyset$ of the candidates violate at least one of the constraints, then the feasible HVI is the HVI of the set of feasible candidates: $\text{HVI}_c(\mathcal{X}_{\text{cand}}) = \text{HVI}(\mathcal{X}_{\text{cand}} \setminus \mathcal{V})$. That is, the hypervolume contribution (i.e., the marginal HVI) of an infeasible point is zero. In our formulation, HVI can be computed by multiplying (5) with an additional factor $\prod_{x' \in X_j} \prod_{v=1}^V 1[c(v)(x') \geq 0]$:

$$\text{HVI}_c(\{f(x_i), c(x_i)\}_{i=1}^q) = \frac{1}{N} \sum_{t=1}^N \text{HVI}_c(\{f_t(x_i), c_t(x_i)\}_{i=1}^q) \approx \frac{1}{N} \sum_{t=1}^N \sum_{k=1}^K \sum_{j=1}^q \sum_{x_j \in X_j} (-1)^{j+1} \left[ \prod_{m=1}^M \left[ f_k^{(m)}(x_j) - f_k^{(m)}(x_j) \right]_+ \right] \prod_{x' \in X_j} \prod_{v=1}^V 1[c(v)(x') \geq 0].$$

(10)

The additional factor $\prod_{x' \in X_j} \prod_{v=1}^V 1[c(v)(x') \geq 0]$ indicates whether all constraints are satisfied for all candidates in a given subset $X_j$. Thus $\text{HVI}_c$ can be computed in the same fashion as HVI, but with the additional step of setting the HVI of all subsets containing $x'$ to zero if $x'$ violates any constraint. We can now again perform MC integration as in (5) to compute the expected constrained hypervolume improvement.

In this formulation, the marginal hypervolume improvement from a candidate is weighted by the probability that the candidate is feasible. The marginal hypervolume improvements are highly dependent on the outcomes of the other candidates. Importantly, the MC-based approach enables us to properly estimate the marginal hypervolume improvements across candidates by sampling from the joint posterior.

Note that while the expected constrained hypervolume $\mathbb{E}[\text{HVI}_c(\{f(x_i), c(x_i)\}_{i=1}^q)]$ is differentiable, we may not differentiate inside the expectation (hence we cannot expect simply differentiating (10) on the sample-level to provide proper gradients). We therefore replace the indicator with a sigmoid function with temperature parameter $\epsilon$, which provides a differentiable relaxation

$$\mathbb{I}[c(v)(x') \geq 0] \approx s(c(v)(x'); \epsilon) := \frac{1}{1 + \exp(-c(v)(x')/\epsilon)}$$

that becomes exact in the limit $\epsilon \searrow 0$.

As in the unconstrained parallel scenario, there is no known analytical expression for the expected feasible hypervolume improvement. Therefore, we again use MC integration to approximate the expectation:

$$\alpha_{\text{E-HVI}}(x) = \mathbb{E}[\text{HVI}_c(\{f(x_i), c(x_i)\}_{i=1}^q)]$$

(12a)

$$\approx \frac{1}{N} \sum_{t=1}^N \text{HVI}_c(\{f_t(x_i), c_t(x_i)\}_{i=1}^q) \approx \frac{1}{N} \sum_{t=1}^N \sum_{k=1}^K \sum_{j=1}^q \sum_{x_j \in X_j} (-1)^{j+1} \left[ \prod_{m=1}^M \left[ f_k^{(m)}(x_j) - f_k^{(m)}(x_j) \right]_+ \right] \prod_{x' \in X_j} \prod_{v=1}^V s(c(v)(x'); \epsilon).$$

(12b)

A.3.1 Inclusion Exclusion principle for HVI

Equation (10) holds when the indicator function because $\text{HVI}_c$ is equivalent to HVI with the subset of feasible points. However, the sigmoid approximation can result in non-zero error. The error function $\varepsilon : 2^{\mathcal{X}_{\text{cand}}} \rightarrow \mathbb{R}$ can be expressed as

$$\varepsilon(X) = \prod_{x' \in X} \prod_{v=1}^V \mathbb{I}[c(v)(x') > 0] - \prod_{x' \in X} \prod_{v=1}^V s(c(v), x').$$

The error function gives a value to each to each element of $2^{\mathcal{X}_{\text{cand}}}$. Weight functions have been studied in conjunction with the inclusion-exclusion principle [33], but under the assumption of that the weight of a set is the sum of the weights of its elements: $w(\mathcal{A}) = \sum_{a \in \mathcal{A}} w(a)$. In our case, the weight function of a set $\mathcal{A}$ is the product the weights of its elements. There, it is not obvious whether the inclusion-exclusion principle will hold in this case.

**Theorem 1.** Given a feasible Pareto front $\mathcal{P}_{\text{feas}}$, a partitioning $\{\{I_k, \mathcal{U}_k\}\}_{k=1}^K$ of the objective space $\mathbb{R}^M$ that is not dominated by the $\mathcal{P}_{\text{feas}}$, then for a set of points $\mathcal{X}_{\text{cand}}$ with objective values $f(\mathcal{X}_{\text{cand}})$ and constraint values $c(\mathcal{X}_{\text{cand}})$,

$$\text{HVI}_c(f(\mathcal{X}_{\text{cand}}), c(\mathcal{X}_{\text{cand}}), \mathcal{P}, r) = \text{HVI}(f'(\mathcal{X}_{\text{cand}}), \mathcal{P}', r')$$

where $f'(\mathcal{X}_{\text{cand}})$ is the set of objective-constraint vectors for each candidate point $f'(x) \in \mathbb{R}^{M+V}$, $\mathcal{P}'$ is the set of vectors $[f^{(1)}(x), ..., f^{(M)}(x), 0_V] \in \mathbb{R}^{M+V}$, and $r' = [r^{(1)}, ..., r^{(M)}, 0_V] \in \mathbb{R}^{M+V}$. 

15
Thus, C are directly considered as components in the hypervolume computation, the inclusion-exclusion principle from all subsets containing x \in S. If change to Equation 14 is that

$$\text{HVI}_C(\{f(x_i), c(x_i)\})_{i=1}^q = \sum_{k=1}^K \sum_{j=1}^q \sum_{x_j \in X_j} (-1)^{j+1} \left[ \left( \prod_{m=1}^M \left[ z_{k,X_j}^{(m)} - l_{k}^{(m)} \right]_{-} \right) \prod_{v=1}^V \mathbb{I}[c^{(v)}(x') \geq 0] \right].$$

Note that the constraint product

$$\prod_{x' \in X_j} \prod_{v=1}^V \mathbb{I}[c^{(v)}(x') \geq 0] = \prod_{v=1}^V \min_{x' \in X_j} \mathbb{I}[c^{(v)}(x') \geq 0] \quad \text{(13)}$$

For v = 1, \ldots, V, k = 1, \ldots, K, let \( l_k^{(M+v)} = 0 \) and \( u_k^{(M+v)} = 1 \). Then, substituting into the following expression from Equation 13 gives

$$\min_{x' \in X_j} \left[ 1, \min \mathbb{I}[c^{(v)}(x') \geq 0] \right] = \min \left[ u_k^{(M+v)}, \min_{x' \in X_j} \mathbb{I}[c^{(v)}(x') \geq 0] \right]$$

Recall from Section 4, that \( z_k = \min \{ u_k, f(x) \} \). The high-level idea is that if we consider the indicator of the slack constraints \( \mathbb{I}[c^{(v)}(x') \geq 0] \) as objectives, then the above expression is consistent with the definition of \( z \) at the beginning of section 4. For v = 1, \ldots, V,

$$z_k^{(M+v)} = \min \left[ 1, \min_{x' \in X_j} \mathbb{I}[c^{(v)}(x') \geq 0] \right]$$

Thus,

$$\prod_{x' \in X_j} \prod_{v=1}^V \mathbb{I}[c^{(v)}(x') \geq 0] = \prod_{v=1}^V \min \left[ 1, \min_{x' \in X_j} \mathbb{I}[c^{(v)}(x') \geq 0] \right] - 0 \quad \text{(14)}$$

Returning to the HVI equation, we have

$$\text{HVI}_C(\{f(x_i), c(x_i)\})_{i=1}^q = \sum_{k=1}^K \sum_{j=1}^q \sum_{x_j \in X_j} (-1)^{j+1} \left[ \left( \prod_{m=1}^M \left[ z_{k,X_j}^{(m)} - l_{k}^{(m)} \right]_{-} \right) \prod_{v=1}^V \mathbb{I}[c^{(v)}(x') \geq 0] \right]$$

Now consider the case when a sigmoid approximation \( \mathbb{I}[c^{(v)}(x') \geq 0] \approx s(c^{(v)}(x') \geq 0) \) is used. The only change to Equation 14 is that

$$z_{k,X_j}^{(m)} \approx z_{k,X_j}^{(m)} = \min \left[ l_k^{(M+v)}, \min_{x' \in X_j} s(c^{(v)}, x') \right].$$

If \( S[c^{(v)}(x') \geq 0] \) for all v, x', then HVI is computed exactly without approximation error. If \( S[c^{(v)}(x') \geq 0] \approx \mathbb{I}[c^{(v)}(x') \geq 0] \) for any v, x', then there is approximation error: the hypervolume improvement from all subsets containing x' is proportional to \( \prod_{v=1}^V \min_{x' \in X} s(c(x'), x') \). Since the constraint outcomes are directly considered as components in the hypervolume computation, the inclusion-exclusion principle incorporates the approximate indicator properly.
### A.4 Complexity
Recall from Section 3.3 that, given posterior samples, the time complexity on a single-threaded machine is $T_1 = O(MNK(2^q - 1))$. The space complexity required for maximum parallelism is also $T_1$ (ignoring the space required by the models), which does limit scalability to larger $M$ and $q$, but difficulty scaling to large $M$ is a known limitation of EHVI [65]. To reduce memory load, rectangles could be materialized and processed in chunks at the cost of additional runtime. In addition, our implementation of qEHVI uses the box decomposition algorithm from Couckuyt et al. [10], but we emphasize qEHVI is agnostic to the choice of partitioning algorithm and using a more efficient partitioning algorithm (e.g. [65,16,40]) may significantly improve memory footprint on GPU and enable larger using $q$ in many scenarios.

### B Error Bound on Sequential Greedy Optimality
If the acquisition function $L(X_{\text{cand}})$ is a normalized, monotone, submodular set function (where submodular means that the increase in $L(X_{\text{cand}})$ is non-increasing as elements are added to $X_{\text{cand}}$ and normalized means that $L(\emptyset) = 0$), then the sequential greedy approximation of $L$ enjoys regret of no more than $\frac{1}{2}L^*$, where $L^*$ is the optimum of $L$ [22]. We have $\alpha_{qEHVI}(X_{\text{cand}}) = \frac{1}{2}s\left[HVI\left(f(X_{\text{cand}})\right)\right]$. Since HVI is a submodular set function [23] and the expectation of a stochastic submodular function is also submodular [2], $\alpha_{qEHVI}(X_{\text{cand}})$ is also submodular and therefore its sequential greedy approximation enjoys regret of no more than $\frac{1}{2}\alpha_{*EHVI}$. Using the result from Wilson et al. [61], the MC-based approximation $\alpha_{qEHVI}(X_{\text{cand}}) = \sum_{t=1}^{10} \text{HVI}[f_t(X_{\text{cand}})]$ also enjoys the same regret bound since HVI is a normalized submodular set function.

### C Convergence Results
For the purpose of stating our convergence results, we recall some concepts and notation from Balandat et al. [5]. First, consider a sample $\{f_t(x_1)\}_{t=1}^{N}$ from the multi-output posterior of the GP surrogate model. Let $x \in \mathbb{R}^q$ be the stacked set of candidates $X_{\text{cand}}$ and let $f(x) := [f_t(x_1)^T, \ldots, f_t(x_q)^T]^T$ be the stacked set of corresponding objective vectors. It is well known that, using the reparameterization trick, we can write

$$f_t(x) = \mu(x) + L(x)e_t,$$

where $\mu : \mathbb{R}^q \rightarrow \mathbb{R}^M$ is the mean function of the multi-output GP, $L(x) \in \mathbb{R}^{M \times q}$ is a root decomposition (typically the Cholesky decomposition) of the multi-output GP's posterior covariance $\Sigma(x) \in \mathbb{R}^{M \times q}$, and $e_t \in \mathbb{R}^q$ with $e_t \overset{\text{i.i.d.}}{\sim} \mathcal{N}(0, I_q)$. For $x \in X$, consider the MC-approximation $\hat{\alpha}_q^{\text{EHVI}}(x)$ from [5]. Denote by $\nabla_x \hat{\alpha}_q^{\text{EHVI}}(x)$ the gradient of $\hat{\alpha}_q^{\text{EHVI}}(x)$, obtained by averaging the gradients on the sample-level:

$$\nabla_x \hat{\alpha}_q^{\text{N,EHVI}}(x) := \frac{1}{N} \sum_{t=1}^{N} \nabla_x \text{HVI}\{f_t(x_1)\}_{t=1}^{N}$$

Let $\alpha_{*EHVI} := \max_{x \in X} \alpha_{qEHVI}(x)$ denote the maximum of the true acquisition function qEHVI, and let $X^* := \arg\max_{x \in X} \alpha_{qEHVI}(x)$ denote the set of associated maximizers.

**Theorem 2.** Suppose that $X$ is compact and that $f$ has a Multi-Output Gaussian Process prior with continuously differentiable mean and covariance functions. If the base samples $\{e_t\}_{t=1}^{N}$ are drawn i.i.d. from $\mathcal{N}(0, I_q)$, and if $\hat{x}_N \in \arg\max_{x \in X} \hat{\alpha}_q^{\text{EHVI}}(x)$, then

1. $\alpha_{qEHVI}(\hat{x}_N) \to \alpha_{*EHVI}$ a.s.
2. $\text{dist}(\hat{x}_N, X^*) \to 0$ a.s.

In addition to the almost sure convergence in Theorem 2 deriving a result on the convergence rate of the optimizer, similar to the one obtained in [5], should be possible. We leave this to future work. Moreover, the results in Theorem 2 can also be extended to the situation in which the base samples are generated using a particular class of randomized QMC methods (see similar results in [5]).

**Proof.** We consider the setting from Balandat et al. [5] Section D.5. Let $e \overset{\text{i.i.d.}}{\sim} \mathcal{N}(0, I_q)$, so that we can write the posterior over outcome $m$ at $x$ as the random variable $f^{(m)}(x, e) = S_{(t, m)}(\mu(x) + L(x)e)$, where $\mu(x)$

---

As noted in Wilson et al. [61], submodularity technically requires the search space $X$ to be finite, whereas in BO, it will typically be infinite. Wilson et al. [61] note that in similar scenarios, submodularity has been extended to infinite sets $X$ (e.g. Srinivas et al. [59]).
and $L(x)$ is the (vector-valued) posterior mean and the Cholesky factor of posterior covariance, respectively, and $S_{(i,j,m)}$ is an appropriate selection matrix (in particular, $\|S_{(i,j,m)}\|_{\infty} \leq 1$ for all $i$, $j$, and $m$). Let

$$A(x, \epsilon) = \sum_{k=1}^{K} \sum_{j=1}^{q} \sum_{X_j \in X_j} (-1)^{j+1} \prod_{m=1}^{M} \left[ z_{k,X_j}^{(m)}(\epsilon) - l_{k}^{(m)} \right]_+$$

where

$$z_{k,X_j}^{(m)}(\epsilon) = \min \left\{ u_k^{(m)}, f^{(m)}(x_{i1}, \epsilon), \ldots, f^{(m)}(x_{ij}, \epsilon) \right\}$$

and $X_j = \{ x_{i1}, \ldots, x_{ij} \}$. Following [5] Theorem 3, we need to show that there exists an integrable function $\ell : \mathbb{R}^{q \times M} \mapsto \mathbb{R}$ such that for almost every $\epsilon$ and all $x, y \in \mathcal{X}$, $x, y \in \mathbb{R}^{q \times d}$,

$$|A(x, \epsilon) - A(y, \epsilon)| \leq \ell(\epsilon)\|x - y\|.$$

(17)

Let us define

$$\tilde{a}_{kmjX_j}(x, \epsilon) := \min \left\{ u_k^{(m)}, f^{(m)}(x_{i1}, \epsilon), \ldots, f^{(m)}(x_{ij}, \epsilon) \right\} - l_{k}^{(m)} \right]_+.$$

Linearity implies that it suffices to show that this condition holds for

$$\tilde{A}(x, \epsilon) := \sum_{m=1}^{M} \tilde{a}_{kmjX_j}(x, \epsilon) = \sum_{m=1}^{M} \left[ \min \left\{ u_k^{(m)}, f^{(m)}(x_{i1}, \epsilon), \ldots, f^{(m)}(x_{ij}, \epsilon) \right\} - l_{k}^{(m)} \right]_+$$

(18)

for all $k$, $j$, and $X_j$. Observe that

$$\tilde{a}_{kmjX_j}(x, \epsilon) \leq \left| \min \left\{ u_k^{(m)}, f^{(m)}(x_{i1}, \epsilon), \ldots, f^{(m)}(x_{ij}, \epsilon) \right\} - l_{k}^{(m)} \right|$$

$$\leq |l_k^{(m)}| + \min \left\{ |u_k^{(m)}|, f^{(m)}(x_{i1}, \epsilon), \ldots, f^{(m)}(x_{ij}, \epsilon) \right\}.$$

Note that if $u_k^{(m)} = \infty$, then $\min \left\{ u_k^{(m)}, f^{(m)}(x_{i1}, \epsilon), \ldots, f^{(m)}(x_{ij}, \epsilon) \right\} = \min \left\{ f^{(m)}(x_{i1}, \epsilon), \ldots, f^{(m)}(x_{ij}, \epsilon) \right\}$. If $u_k^{(m)} < \infty$, then $\min \left\{ u_k^{(m)}, f^{(m)}(x_{i1}, \epsilon), \ldots, f^{(m)}(x_{ij}, \epsilon) \right\} < \min \left\{ f^{(m)}(x_{i1}, \epsilon), \ldots, f^{(m)}(x_{ij}, \epsilon) \right\} + |u_k^{(m)}|$. Let $w_k^{(m)} = u_k^{(m)}$ if $u_k^{(m)} < \infty$ and 0 otherwise. Then

$$\tilde{a}_{kmjX_j}(x, \epsilon) \leq |l_k^{(m)}| + |w_k^{(m)}| + \min \left\{ f^{(m)}(x_{i1}, \epsilon), \ldots, f^{(m)}(x_{ij}, \epsilon) \right\}$$

$$\leq |l_k^{(m)}| + |w_k^{(m)}| + \sum_{i_1, \ldots, i_j} |f^{(m)}(x_{i1}, \epsilon), \ldots, f^{(m)}(x_{ij}, \epsilon)|.$$

We therefore have that

$$|\tilde{a}_{kmjX_j}(x, \epsilon)| \leq |l_k^{(m)}| + |w_k^{(m)}| + |X_j| \left( \| \mu^{(m)}(x) \| + \| L^{(m)}(x) \| \| \epsilon \| \right)$$

for all $k$, $m$, $j$, $X_j$, where $|X_j|$ denotes the cardinality of the set $X_j$. Under our assumptions (compactness of $\mathcal{X}$, continuous differentiability of mean and covariance function, both $\mu(x)$ and $L(x)$, as well as their respective gradients w.r.t. $x$, are uniformly bounded). In particular there exist $C_1, C_2 < \infty$ such that

$$|\tilde{a}_{kmjX_j}(x, \epsilon)| \leq C_1 + C_2\| \epsilon \|$$

for all $k$, $m$, $j$, $X_j$.

Dropping indices $k$, $j$, $X_j$ for simplicity, observe that

$$|\tilde{A}(x, \epsilon) - \tilde{A}(y, \epsilon)| \leq |\tilde{a}_{1X_1}(x, \epsilon)\tilde{a}_{2X_2}(x, \epsilon) - \tilde{a}_{1X_1}(y, \epsilon)\tilde{a}_{2X_2}(y, \epsilon)|$$

(19a)

$$= |\tilde{a}_{1X_1}(x, \epsilon)(\tilde{a}_{2X_2}(x, \epsilon) - \tilde{a}_{2X_2}(y, \epsilon)) + \tilde{a}_{2X_2}(y, \epsilon)(\tilde{a}_{1X_1}(x, \epsilon) - \tilde{a}_{1X_1}(y, \epsilon))|$$

(19b)

$$\leq |\tilde{a}_{1X_1}(x, \epsilon)||\tilde{a}_{2X_2}(x, \epsilon) - \tilde{a}_{2X_2}(y, \epsilon)| + |\tilde{a}_{2X_2}(y, \epsilon)||\tilde{a}_{1X_1}(x, \epsilon) - \tilde{a}_{1X_1}(y, \epsilon)|$$

(19c)

Furthermore,

$$|\tilde{a}_{kmjX_j}(x, \epsilon) - \tilde{a}_{kmjX_j}(y, \epsilon)| \leq \sum_{i_1, \ldots, i_j} |S_{(i_1,m)}(\mu(x) + L(x)\epsilon) - S_{(i_1,m)}(\mu(y) + L(y)\epsilon)|$$

$$\leq |X_j| \left( \| \mu(x) - \mu(y) \| + \| L(x) - L(y) \| \| \epsilon \| \right).$$

Since $\mu$ and $L$ have uniformly bounded gradients, they are Lipschitz. Therefore, there exist $C_3, C_4 < \infty$ such that

$$|\tilde{a}_{kmjX_j}(x, \epsilon) - \tilde{a}_{kmjX_j}(y, \epsilon)| \leq (C_3 + C_4\| \epsilon \|)\| x - y \|$$

18
for all \( x, y, k, m, j, X_j \). Plugging this into (19) above, we find that
\[
|\hat{A}(x, \epsilon) - \hat{A}(y, \epsilon)| \leq 2 \left( C_1 C_3 + (C_1 C_4 + C_2 C_3)\|\epsilon\| + C_2 C_4 \|\epsilon\|^2 \right) \|x - y\|
\]
for all \( x, y \) and \( \epsilon \). For \( M > 2 \) we generalize the idea from (19), making sure to telescope the respective expressions. It is not hard to see that with this, there exist \( C < \infty \) such that
\[
|\hat{A}(x, \epsilon) - \hat{A}(y, \epsilon)| \leq C \sum_{m=1}^{M} \|\epsilon\|^m \|x - y\|
\]
Letting \( \ell(\epsilon) := C \sum_{m=1}^{M} \|\epsilon\|^m \), we observe that \( \ell(\epsilon) \) is integrable (since all absolute moments exist for the Normal distribution).

The result now follows from in Balandat et al. [5, Theorem 3]. \( \square \)

Besides the above convergence result, we can also show that the sample average gradient of the MC approximation of \( qEHVI \) is an unbiased estimator of the true gradient of \( qEHVI \):

**Proposition 1.** Suppose that the GP mean and covariance function are continuously differentiable. Suppose further that the candidate set \( \mathcal{X} \) has no duplicates, and that the sample-level gradients \( \nabla_x \text{HVI}(\{f_i(x_i)\})_{i=1}^{m} \) are obtained using the reparameterization trick as in [5]. Then
\[
E[\nabla_x \hat{a}_{\text{qEHVI}}(x)] = \nabla_x \alpha_{qEHVI}(x),
\]
that is, the averaged sample-level gradient is an unbiased estimate of the gradient of the true acquisition function.

**Proof.** This proof follows the arguments Wang et al. [59, Theorem 1], which leverages Glasserman [30, Theorem 1]. We verify the conditions of Glasserman [30, Theorem 1] below. Using the arguments from [5], we know that, under the assumption of differentiable mean and covariance functions, the samples \( f_i(x) \) are continuously differentiable w.r.t. \( x \) (since there are no duplicates, and thus the covariance \( \Sigma(x) \) is non-singular). Hence, Glasserman [30, A1] is satisfied. Furthermore, it is easy to see from (1) that \( \text{HVI}(\{f(x_i)\}_{i=1}^{m}) \) is a.s. continuous and is differentiable w.r.t. \( f_i(x) \) on \( \mathbb{R}^M \), except on the edges of the hyper-rectangle decomposition \( \{S_k\}_{k=1}^{K} \) of the non-dominated space, which satisfies [30, A3]. The set of points defined by the union of these edges clearly has measure zero under any non-degenerate (non-singular covariance) GP posterior on \( \mathbb{R}^M \), so Glasserman [30, A4] holds. Therefore Glasserman [30, Lemma 2] holds, so \( \text{HVI}(\{f(x_i)\}_{i=1}^{m}) \) is a.s. piece-wise differentiable w.r.t. \( x \).

Lastly, we need to show that the result in Glasserman [30, Lemma 3] holds:
\[
E\left[ \sup_{x \in \mathcal{X}} \left| \hat{a}'(x, \epsilon) \right| \right] < \infty.
\]
As in Wang et al. [59, Theorem 1], we fix \( x \) except for \( x_{ci} \), where \( x_{ci} \) is the \( c \)th component of the \( i \)th point. We need to show that \( E[\sup_{x_{ci} \in \mathcal{D}} |A'(x, \epsilon)|] < \infty \). By linearity, it suffices to show that \( E[\sup_{x_{ci} \in \mathcal{D}} |A'(x, \epsilon)|] < \infty \).

We have
\[
E\left[ \sup_{x_{ci} \in \mathcal{D}} |\hat{A}'(x, \epsilon)| \right] = E\left[ \sup_{x_{ci} \in \mathcal{D}} \left| \frac{\partial \hat{A}(x, \epsilon)}{\partial x_{ci}} \right| \right].
\]
Consider the \( M = 2 \) case. We have \( \hat{A}(x, \epsilon) = a_1(x, \epsilon) a_2(x, \epsilon) \), where
\[
a_m(x, \epsilon) = \min \left[ u^{(m)}_k , f^{(m)}(x_{i_1}, \epsilon), \ldots, f^{(m)}(x_{i_j}, \epsilon) \right] - l^{(m)}_k + .
\]
The partial derivative of \( \hat{A}(x, \epsilon) \) with respect to \( x_{ci} \) is
\[
\frac{\partial \hat{A}(x, \epsilon)}{\partial x_{ci}} = \frac{\partial a_1(x, \epsilon)}{\partial x_{ci}} a_2(x, \epsilon) + a_1(x, \epsilon) \frac{\partial a_2(x, \epsilon)}{\partial x_{ci}},
\]
and therefore
\[
\left| \frac{\partial \hat{A}(x, \epsilon)}{\partial x_{ci}} \right| \leq \left| \frac{\partial a_1(x, \epsilon)}{\partial x_{ci}} \right| \cdot |a_2(x, \epsilon)| + |a_1(x, \epsilon)| \cdot \left| \frac{\partial a_2(x, \epsilon)}{\partial x_{ci}} \right|
\]
Since we are only concerned with \( x_{ci} \notin \mathcal{D} \),
\[
a_m(x, \epsilon) = \min \left[ f^{(m)}(x_{i_1}, \epsilon), \ldots, f^{(m)}(x_{i_j}, \epsilon) \right] - l^{(1)}_k + .
\]
As in the proof of Theorem 2, we write the posterior over outcome \( m \)
Hence,

\[
a_m(\mathbf{x}, \epsilon) = \min \left\{ S_{(1,1)}(\mu(\mathbf{x}) + L(\mathbf{x})\epsilon), \ldots, S_{(j,j)}(\mu(\mathbf{x}) + L(\mathbf{x})\epsilon) \right\} - l_k^{(1)}.
\]

Since the interval \( \mathcal{X} \) is compact and the mean, covariance, and Cholesky factor of the covariance \( \mu(\mathbf{x}), C(\mathbf{x}), L(\mathbf{x}) \) are continuously differentiable, for all \( m \) we have

\[
\sup_{x_{ci}} \frac{\partial \mu^{(m)}(x_{ci})}{\partial x_{ci}} = \mu^{*,(m)} < \infty, \quad \sup_{x_{ci}} \left| \frac{\partial L^{(m)}(x_{ci})}{\partial x_{ci}} \right| = L^{*,(m)} < \infty.
\]

Let \( \mu^{(m)} = \max_a \mu^{a(m)}, L_{ab}^{(m)} = \max_{a,b} L_{ab}^{a,b}(m) \), where \( L_{ab}^{(m)} \) is the element at row \( a \), column \( b \) in \( L^{(m)} \), the Cholesky factor for outcome \( m \). Let \( \epsilon^{(m)} \in \mathbb{R}^q \) denote the vector of i.i.d. \( N(0, 1) \) samples corresponding to outcome \( m \). Then we have

\[
\left| \frac{\partial}{\partial x_{ci}} \left[ \min \left\{ S_{(1,1)}(\mu(\mathbf{x}) + L(\mathbf{x})\epsilon), \ldots, S_{(j,j)}(\mu(\mathbf{x}) + L(\mathbf{x})\epsilon) \right\} - l_k^{(1)} \right] \right| 
\leq \left| \left[ \mu^{*,(m)} + L^{*,(m)}||\epsilon^{(m)}||_1 - l_k^{(1)} \right] \right| 
\leq \left[ \mu^{*,(m)} + L^{*,(m)}||\epsilon^{(m)}||_1 \right] + |l_k^{(1)}|.
\]

Under our assumptions (compactness of \( \mathcal{X} \), continuous differentiability of mean and covariance function) both \( \mu(\mathbf{x}) \) and \( L(\mathbf{x}) \), as well as their respective gradients, are uniformly bounded. In particular there exist \( C_1^{(m)}, C_2^{(m)} < \infty \) such that

\[
\left| S_{(a,m)}(\mu(\mathbf{x}) + L(\mathbf{x})\epsilon) - l_k^{(m)} \right| \leq C_1^{(m)} + C_2^{(m)}||\epsilon^{(m)}||_1
\]
for all \( a = i_1, \ldots, i_j \).

Hence,

\[
\left| \frac{\partial A(\mathbf{x}, \epsilon)}{\partial x_{ci}} \right| \leq \left[ \mu^{(1)} + C_1^{(1)}||\epsilon^{(1)}||_1 \right] + |l_k^{(1)}| + \left[ C_1^{(2)} + C_2^{(2)}||\epsilon^{(2)}||_1 \right] + \left[ C_1^{(1)} + C_2^{(1)}||\epsilon^{(1)}||_1 \right] + |l_k^{(2)}|.
\]

Since \( \epsilon \) is absolutely integrable,

\[
\mathbb{E}\left( \left| \frac{\partial A(\mathbf{x}, \epsilon)}{\partial x_{ci}} \right| \right) < \infty.
\]

Hence, \( \mathbb{E}\left[ \sup_{x_{ci} \notin B} |A'(\mathbf{x}, \epsilon)| \right] < \infty \). This can be extended to \( M > 2 \) in the same manner using the product rule to obtain

\[
\mathbb{E}\left( \frac{\partial A(\mathbf{x}, \epsilon)}{\partial x_{ci}} \right) \leq \sum_{m=1}^{M} \left[ \mu^{(m)} + C_1^{(m)}\mathbb{E}[||\epsilon^{(m)}||_1] + |l_k^{(1)}| \right] \prod_{n=1, n \neq m}^{M} \left[ C_1^{(n)} + C_2^{(n)}\mathbb{E}[||\epsilon^{(n)}||_1] \right]
\leq \sum_{m=1}^{M} \left[ \mu^{(m)} + \frac{\pi}{2}qC_1^{(m)} \right] \prod_{n=1, n \neq m}^{M} \left[ C_1^{(n)} + \frac{\pi}{2}qC_2^{(n)} \right].
\]

Hence, \( \mathbb{E}\left[ \sup_{x_{ci} \notin B} |A'(\mathbf{x}, \epsilon)| \right] < \infty \) for \( M \geq 2 \) and Glasserman [30] Theorem 1 holds.
**D Monte-Carlo Approximation**

Figure 4b shows the gradient of analytic EHVI and the MC estimator $qEHVI$ on a slice of a 3-objective problem. Even using only $N = 32$ QMC samples, the average sample gradient has very low variance. Moreover, fixing the base samples also greatly reduces the variance without introducing bias.

(a) A comparison of the analytic EHVI acquisition function and the MC-based $qEHVI$ for $q = 1$.

(b) A comparison of the exact gradient of analytic EHVI and the exact sample average gradient of the MC-estimator $\hat{\nabla}qEHVI$ over a slice of the input space on a DTLZ2 problem ($q = 1, M = 3, d = 6$) [14]. $x^{(0)}$ is varied across $0 \leq \lambda \leq 1$, while $x^{(i)}$ for $i = 1, \ldots, D$ are held constant. In each of (a) and (b), the top row shows $qEHVI$ where the (quasi-)standard normal base samples are resampled for each value of $x^{(0)}$. The solid line is one sample average (across (q)MC samples) and the shaded area is the mean plus 2 standard errors across 50 repetitions. The bottom row uses the same base samples for evaluating each test point and the sample average for each of 50 repetitions is plotted.

**E Experiment Details**

**E.1 Algorithms**

For PESMO, we follow [26] and use a Pareto set of size 10 for each sampled GP, which is optimized over a discrete set of $1000d$ points sampled from a scrambled Sobol sequence. The current Pareto front is approximated by optimizing the posterior means over a grid as is done in Garrido-Merchán and Hernández-Lobato [25][26].
We also considered (but did not use in our experiments) a dynamic reference point strategy where at each BO q with a sigmoid to maintain differentiability as in constrained y where

Table 2: Reference points for all benchmark problems. Assuming minimization. In our benchmarks, equivalently maximize the negative objectives and multiply the reference points by -1.

| Problem                          | Reference Point             |
|----------------------------------|-----------------------------|
| BraninCurrin                     | (18.0, 6.0)                 |
| DTLZ2                            | (1.1, ..., 1.1) ∈ \mathbb{R}^M |
| ABR                              | (-150.0, 3500.0, 5.1)       |
| Vehicle Crash Safety             | (1864.72022, 11.81993945, 0.2903999384) |
| Constrained BraninCurrin         | (90.0, 10.0)                |
| C2-DTLZ2                         | (1.1, ..., 1.1) ∈ \mathbb{R}^M |

For SMS-EGO, we use the observed Pareto front. All acquisition functions are optimized with L-BFGS-B (with a maximum of 200 iterations); SMS-EGO [50] and PESMO [25] use gradients approximated by finite differences and all other methods use exact gradients. For all methods, each outcome is modeled with an independent Gaussian process with a Matern 5/2 ARD kernel. The methods implemented in Spearmint use a fully Bayesian treatment of the hyperparameters with 10 samples from posterior over the hyperparameters, and the methods implemented in BoTorch use maximum a posteriori estimates of the GP hyperparameters. All methods are initialized with 2(d + 1) points from a scrambled Sobol sequence. qPAREGO and qEHVI use N = 128 QMC samples.

E.1.1 Reference point specification

There is a large body of literature on the effects of reference point specification [4, 34, 35]. The hypervolume indicator is sensitive to specified the reference point: a reference point that is far away from the Pareto front will favor extreme points, where as reference point that is close to the Pareto front gives more weight to less extreme points [35]. Sensitivity to the reference point is affects both the evaluation of different MO methods and the utility function for methods that rely HV. In practice, a decision maker may be able to specify a reference point that satisfies their preference with domain knowledge. If a reference point is provided by the decision maker, previous work has suggested heuristics for choosing reference points for use in an algorithm’s utility function [34, 50]. If a reference point is known.

We also considered (but did not use in our experiments) a dynamic reference point strategy where at each BO iteration, the reference point is selected to be a point slightly worse than the nadir (component-wise minimum) point of the current observed Pareto front for computing the acquisition function: r = ynadir − 0.1 · |ynadir| where ynadir = \left( \min_{y \in D(1)} y(1), \ldots, \min_{y \in D(m)} y(m) \right). This reference point is used in SMS-EMOA in Ishibuchi et al. [34], and we find similar average performance (but higher variance) on problems to using a known reference point with continuous Pareto fronts. If the Pareto front is discontinuous, then it is possible not all sections of the Pareto front will be reached.

E.1.2 qPAREGO

Previous work has only considered unconstrained sequential optimization with ParEGO [39, 7] and ParEGO is often optimized with gradient-free methods [50]. To the best of our knowledge, qPAREGO is the first to support parallel and constrained optimization. Moreover, we compute exact gradients via auto-differentiation for acquisition optimization. ParEGO is typically implemented by applying the augmented Chebyshev scalarization and modeling the scalarized outcome [39]. However, recent work has shown that composite objectives offer improved optimization performance [3]. qPAREGO uses a MC-based Expected Improvement [17] acquisition function, where the objectives are modeled independently and the augmented Chebyshev scalarization [39] is applied to the posterior samples as a composite objective. This approach enables the use of sequential greedy optimization of q candidates with proper integration over the posterior at the pending points. Importantly, the sequential greedy approach allows for using different random scalarization weights for selecting each of the q candidates. qPAREGO is extended to the constrained setting by weighting the EI by the probability of feasibility [23]. We estimate the probability of feasibility using the posterior samples and approximate the indicator function with a sigmoid to maintain differentiability as in constrained qEHVI. qPAREGO is trivially extended to the noisy setting using Noisy Expected Improvement [41, 5], but we use Expected Improvement in our experiments as all of the problems are noiseless.

E.2 Benchmark Problems

The details for the benchmark problems below assume minimization of all objectives. Table 2 provides the reference points used for all benchmark problems.
Branin-Currin

\[
f^{(1)}(x_1', x_2') = (x_2 - \frac{5.1}{4\pi^2} x_1'^2 + \frac{5}{\pi} x_1' - r)^2 + 10(1 - \frac{1}{8\pi}) \cos(x_1') + 10
\]

\[
f^{(2)}(x_1, x_2) = \left[ 1 - \exp \left( -\frac{1}{(2x_2)} \right) \right] \frac{2300x_1'^2 + 1900x_1^2 + 2002x_1 + 60}{100x_1'^2 + 500x_1^2 + 4x_1 + 20}
\]

where \( x_1, x_2 \in [0, 1], x_1' = 15x_1 - 5, \) and \( x_2' = 15x_2. \)

The constrained Branin-Currin problem uses the following disk constraint from [28]:

\[
c(x_1', x_2') = 50 - (x_1' - 2.5)^2 - (x_2' - 7.5)^2 \geq 0
\]

DTLZ2 The objectives are given by [14]:

\[
f_1(x) = (1 + g(x_M)) \cos \left( \frac{\pi}{2} x_1 \right) \cdots \cos \left( \frac{\pi}{2} x_{M-2} \right) \cos \left( \frac{\pi}{2} x_{M-1} \right)
\]

\[
f_2(x) = (1 + g(x_M)) \cos \left( \frac{\pi}{2} x_1 \right) \cdots \cos \left( \frac{\pi}{2} x_{M-2} \right) \sin \left( \frac{\pi}{2} x_{M-1} \right)
\]

\[
f_3(x) = (1 + g(x_M)) \cos \left( \frac{\pi}{2} x_1 \right) \cdots \sin \left( \frac{\pi}{2} x_{M-2} \right)
\]

\[
\vdots
\]

\[
f_M(x) = (1 + g(x_M)) \sin \left( \frac{\pi}{2} x_1 \right)
\]

where \( g(x) = \sum_{i=x_M}^{d} (x_i - 0.5)^2, x \in [0, 1]^d, \) and \( x_M \) represents the last \( d - M + 1 \) elements of \( x. \)

The C2-DTLZ2 problem adds the following constraint [15]:

\[
c(x) = -\min \left[ \sum_{i=1}^{M} \left( f_i(x) - 1 \right)^2 + \sum_{j=1}^{M} \left( f_j^2 - r^2 \right) \right] \geq 0
\]

Vehicle Crash Safety The objectives are given by [57]:

\[
f_1(x) = 1640.2823 + 2.3573285 x_1 + 2.3220035 x_2 + 4.5688768 x_3 + 7.7213633 x_4 + 4.4559504 x_5
\]

\[
f_2(x) = 6.5856 + 1.15 x_1 - 1.0427 x_2 + 0.9738 x_3 + 0.8364 x_4 - 0.3695 x_1 x_4 + 0.0861 x_1 x_5
\]

\[
+ 0.3628 x_2 x_4 + 0.1106 x_3^2 - 0.3437 x_4^2 + 0.1764 x_5^2
\]

\[
f_3(x) = -0.0551 + 0.0181 x_1 + 0.1024 x_2 + 0.0421 x_3 - 0.0073 x_1 x_2 + 0.0242 x_2 x_3 - 0.0118 x_2 x_4
\]

\[
- 0.0204 x_3 x_4 - 0.0083 x_3^2 - 0.0241 x_2^2 + 0.0109 x_4^2
\]

where \( x \in [1, 3]^5. \)

Policy Optimization for Adaptive Bitrate Control The controller is given by: \( a_t = x_0 \hat{z}_{bd,t} + x_2 \hat{z}_{bd,t} + x_3, \)

where \( \hat{z}_{bd,t} = \frac{\sum_{i<t} \exp(-x_t x_i)}{\sum_{i} \exp(-x_t x_i)} \) is estimated bandwidth at time \( t \) using an exponential moving average, \( \hat{z}_{bd,t} \) is the buffer occupancy at time \( t, \) and \( x_0, \ldots, x_3 \) are the parameters we seek to optimize. We evaluate each policy on a set of 400 videos, where the number of time steps (chunks) in each video stream trajectory depends on the size of the video.
F Additional Results

F.1 Additional Synthetic Benchmarks

We include results for two additional synthetic benchmarks: a Constrained Branin-Currin problem and the DTLZ2 problem from the MO literature [14] \((d = 6, M = 2)\).

Figures 5a and 5b show that \(qEHVI\) outperforms all other baseline algorithms on both problems in terms of optimization performance, while achieving competitive wall times (see Table 3).

![Figure 5: Optimization performance on the Constrained Branin-Currin synthetic function \((d = 2, M = 2, V = 1)\) for various \(q\), and (b) sequential optimization performance on the DTLZ2 synthetic function \((d = 6, M = 2)\).](image_url)

F.1.1 Anytime Performance with Parallel Evaluation

Figure 6 shows that the anytime performance of \(qEHVI\) performance does not degrade with increasing \(q\), whereas performance does degrade for \(qPAREGO\) on the Constrained Branin-Currin problem.

![Figure 6: A comparison of anytime performance as \(q\) increases for \(qPAREGO\) and \(qEHVI\) on the Constrained Branin-Currin test problem \((d = 2, M = 2, V = 1)\).](image_url)
Table 3: Acquisition Optimization wall time in seconds on a CPU (2x Intel Xeon E5-2680 v4 @ 2.40GHz) and on a GPU (Tesla V100-SXM2-16GB). The mean and two standard errors are reported. NA indicates that the algorithm does not support constraints.

|             | CPU |     |     | GPU |     |     |
|-------------|-----|-----|-----|-----|-----|-----|
|             |     |     |     |     |     |     |

| EHVI \(q=1\) | NA | 84.15 (±6.9) |     |     |     |     |
| \(q\)EHVI \(q=1\) | 5.61 (±0.17) | 10.21 (±0.58) |     |     |     |     |
| \(q\)EHVI \(q=2\) | 19.06 (±5.88) | 17.75 (±0.97) |     |     |     |     |
| \(q\)EHVI \(q=4\) | 29.26 (±2.01) | 40.41 (±2.78) |     |     |     |     |
| \(q\)EHVI \(q=8\) | 91.56 (±5.51) | 106.51 (±7.69) |     |     |     |     |

F.2 Acquisition Computation Time

Figure 7 shows the acquisition computation time for different \(M\) and \(q\). The inflection points correspond to available processor cores becoming saturated. For large \(M\) an \(q\) on the GPU, memory becomes an issue, but we discuss ways of mitigating the issue in Appendix A.4.

Figure 7: Acquisition computation time for different batch sizes \(q\) and numbers of objectives \(M\) (this excludes the time required to compute the acquisition function given box decomposition of the non-dominated space). This uses \(N = 512\) MC samples, \(d = 6\), \(|\mathcal{P}| = 10\), and 20 training points. Measurements were taken on a Tesla V100-SXM2-16GB GPU using 64-bit floating point precision. The mean and 2 standard errors over 1000 trials are reported.
