Abstract

Background: I have designed a Q-shape biliary diversion pancreaticoduodenectomy (PD) to prevent delayed-hemorrhage in case of pancreaticojejunostomy (PJ) leakage. However, eliminating PJ leakage is the ultimate goal. A PJ anastomosis technique, irrespective of soft pancreatic texture or duct-size, has been found.

Methods: Nine PDs were included. An end-to-side anastomosed proximal jejunal loop (30 cm), divided by a GIA stapler at its top and reapproximated using serosal sutures, was used for a choledochojejunostomy and PJs (4 fistulation, 2 duct-to-mucosa, 1 conventional and 2 whole-thickness mattress end-to-side sutures) at each divided loop. Finally, a gastro/duodenojejunostomy was made 30 cm distal to this looped jejunoojejunostomy.

Results: There was no mortality. One minor PJ leakage healed spontaneously. One major PJ leakage had a delayed-hemorrhage crisis salvaged by continuous normal saline irrigation to neutralize the pH condition for bile and pancreatic juice interaction. The clinical courses were surprisingly uneventful and without fear of leakage in two PJs using whole-thickness mattress sutures. Secure ties without tearing were possible in the soft pancreatic texture.

Conclusion: Current evolutional strategies of biliary diversion reconstruction with whole-thickness-mattress PJ sutures plus normal saline irrigation can increase the safety of a pancreaticoduodenectomy by reducing PJ leakage and preventing the activation of pancreatic juice to eliminate a lethal delayed-hemorrhage.

Introduction

Pancreaticoduodenectomy (PD) is a complex operation with high morbidity and mortality. Because of continuous advances in technique and management, improved mortality data ranging from 0% to 8.2% have been reported in systematic [1,2] and evidence-based [3] reviews. Yet pancreaticojejunostomy (PJ) leakage rates ranging from 9% to 53% (>100 cases series) remain unacceptably high [1-8]. PJ Leakage after a PD always yields a lethal crisis because of a delayed intra-abdominal hemorrhage, which is often caused by arterial erosion around a PJ anastomotic leak after long-term exposure of the arteries to the intestinal mixture of bile and pancreatic juice. This is the major cause of death after a PD [5,6]. The author has designed a biliary diversion reconstruction procedure [9] to prevent the bile from activating the pancreatic juice and to minimize the lethal risk caused by PJ leakage. This procedure, however, does not solve the problem of PJ leakage.

A soft pancreatic texture [5-8] and a small pancreatic duct [8] often make the pancreas a high-risk gland; they are significant risk factors for PJ leakage. To solve this problem, the author has adapted for use with PJ anastomosis the whole-thickness mattress sutures he uses for liver resections [10]. I propose three simple ways to make PD a safer procedure for every surgeon.

Materials and Methods

Three innovative strategies were used to prevent PD leakage and leakage-induced delayed hemorrhage: (1) the reconstruction aimed to divert the bile juice from the pancreatic juice, (2) the whole-thickness mattress sutures for the PJ to reduce the chance of a tear in a soft pancreas after tying the suture or in a small pancreatic duct without an anastomosis, and (3) should a leak occur despite the first two procedures, to neutralize the pH of the bile and pancreatic juices to 7.0 using normal saline irrigation to inactivate their interaction.

Nine patients with periampullary lesions (Table 1) that underwent biliary diversion reconstruction (Figure 1A) after PD were included. For 7 of them, conventional end-to-side PJ anastomotic techniques were used, applied, but for the two latest patients, whole-thickness mattress sutures were used (Figure 2B).

After the diagnosis had been confirmed, a conventional PD was done to excise the lesion. A subtotal gastrectomy may or may not be done, depending upon each disease condition. Reconstruction was begun by looping the proximal jejunum into a Q shape and anastomosing its end to its distal portion, 30 cm away, in an end-to-side fashion (Figure 1A) and then bringing it to the hepatic hilar area through an incision in the right mesocolon. At the top of this loop, the jejunum was divided using a GIA stapler, but the mesentery was kept intact. Each divided stump was embedded into its respective jejunum using a purse-string suture. The two stumps were then re-approximated using intermittent serosal sutures (Figure 1A). For the first 7 cases, a PJ was done on the upper 1/3 of the medial side of the loop with one of the following three methods: the fistulation method (4 cases), the duct-to-mucosal anastomosis method (2 cases), or the conventional end-to-side method (1 case). For the latest two cases, end-to-side PJ with two layers whole-thickness mattress sutures (Figure 2B) were used. Subsequently, a choledochojejunostomy was done 3 cm lateral to the source are credited.

Table 1: Anastomotic methods, pancreatic parameters and postoperative complications of the patients.

Figure 1A: A reported biliary diversion reconstruction method for a pancreaticoduodenectomy, which diverts the bile flow using an independent, looped jejunal segment to prevent bile from activating pancreatic juice.

The reconstruction procedures (Figure 1A) were as follows: 1) an end-to-side anastomosed jejunal loop (30 cm); 2) a GIA stapler division at its top and re-approximated by serosal sutures; 3) a choledochojejunostomy at the lateral side of the loop; 4) an end-to-side PJ at the medial side of the loop (4 fistulas, 2 duct-to-mucosa, 1 conventional, and 2 whole-thickness mattress sutures; 5) finally, a gastro/duodenojejunostomy was made 30 cm distal to the looped jejunoejunojnostomy.

The one- or two-layer whole-thickness PJ pancreatic mattress suture
The clinical courses were surprisingly uneventful without fear of PJ leakage irrespective of soft pancreatic texture or small duct-size in the whole-thickness mattress suture group. Secure ties were possible without pancreatic tearing. There was no mortality. One minor pancreatic leakage (Table 1, #2) healed spontaneously. One major leakage (Table 1, #7) triggered by the interaction of bile and pancreatic juices after 2 weeks of constipation, had a delayed-hemorrhage crisis salvaged solely by continuous normal saline irrigation. Two pylorus-preserving patients (Table 1, #2 and #6) experienced a 3-week delay in gastric emptying. Two local intra-abdominal abscesses owing to poor drain placement healed after percutaneous drainage. Another patient required a reoperation for bleeding from a tiny superior mesenteric artery branch.

Discussion

The pancreatic properties of a soft parenchymal texture, small pancreatic duct, and powerful digestive capability are the Achilles heel of the PD. The inevitable problems of PJ leakage and fistulas [1-8] with subsequent delayed intra-abdominal bleeding remain unsolved and are still a nightmare and the major causes of postoperative morbidity and mortality. Efforts have been made to reduce PJ leakage via various types of PJ, pancreaticogastrostomy (PG) reconstructions, and a pharmacological approach (octreotide) that decreases pancreatic secretion [1-4,7]. Nevertheless, PJ leakage and the fistula rate still remain high [1-8] even in centralized high-volume medical centers [4]. This confirms that a perfect reconstruction method has not yet been established to solve these critical issues.

Solutions for a soft-textured pancreas and a small pancreatic duct: whole-thickness mattress sutures without duct anastomosis

A pancreas with a hard texture may have less PJ leakage if conventional suturing techniques are used, but for a pancreas with a soft texture, a special technique, viz., whole-thickness mattress sutures, is required to avoid tangential shearing forces. We make whole-thickness mattress sutures on liver resections using a long, straight needle [10,11], which satisfactorily simplifies the difficult transection procedure and minimizes ischemic and reperfusion injury by peripheral individual inflow control [11]. We recently adapted the same concept for pancreatic sutures and discovered its merit, especially for the soft-textured pancreas: it substantially reduces the risk, presented peripheral individual inflow control [11]. We recently adapted the same concept for pancreatic sutures and discovered its merit, especially for the soft-textured pancreas: it substantially reduces the risk, presented peripheral individual inflow control [11]. We recently adapted the same concept for pancreatic sutures and discovered its merit, especially for the soft-textured pancreas: it substantially reduces the risk, presented peripheral individual inflow control [11].
an external drainage tube, but the latter did not.

When the duct is small, the duct-to-mucosa anastomotic technique usually needs an expert hand, especially when using a microscope [14] to reduce the risk of leakage or a postoperative stricture. The easiest way to deal with the duct, no matter how large or small and no matter how good or bad one's technique, is not to suture the duct at all.

The difference between the current method and the Blumgart method [13] is to open whole layers of the jejunum to include (telescope or dunk) the pancreatic stump and duct by the dorsal and ventral walls of the incised jejunum. Instead of the one-layer of mattress sutures recommended in both the Blumgart method [13] and the Langrehr method [12], two or more rows of whole-thickness mattress sutures, including continuous marginal suturing of the pancreatic stump and incised jejunal walls, can be easily applied to offer a much more secure line of defense, if necessary, to prevent PJ anastomosis leakage. The accessory duct, if it exists, and which was not included in the Blumgart method, [13] will always be included in the PJ anastomosis method recommended by the present study. This method is so simple that it does not require expert technique, a medical center with high or low volume, a pancreas with a soft or hard texture, a specific ductal size, external P-du duct stent drainage, using a microscope [14] (PJ leakage rate 11% for high risk patients [n=148]), using prophylactic octreotide or fibrin glue, duct occlusion and ligation, omental or round ligament wrapping protection or shifting a PJ to a PG.

Factors causing delayed hemorrhage or pseudoaneurysm after PJ leakage: Trypsinogen, elastase or lipase

The pathogenesis for a delayed hemorrhage or pseudoaneurysm formation is unknown; however, the digestion by trypsin and elastase of an arterial vessel wall near a PJ leak is one commonly suggested mechanism [6,15,16]. Heidenhain [17] reported in 1875 that fresh pancreatic juice has no measurable active proteases.

In 1900, Schepowalnikov discovered that pancreatic juice is activated by enterokinase. In 1939, Kunitz showed that enterokinase is an enzyme which catalyses non-active trypsinogen to its active form: trypsin. A cascade reaction then occurs, because trypsin activates pro-phospholipase and all the other proteolytic zymogens in pancreatic juice. Therefore, without enterokinase, the zymogens remain inactivated. Immunofluorescent studies using antiserum to pure human enterokinase have demonstrated its presence in man on the brush-border and glycocalyx of the enterocytes of the duodenum and proximal 10-20 cm of the jejunum [18].

There was only minimal mucosal enterokinase activity in the remaining proximal jejunum in 5 patients given a proximal pancreaticoduodenectomy for a periampullary tumor in an endoscopic follow-up 6 months later [18]. This finding implies that trypsin and elastase (activated by enterokinase and trypsin) [19] might not be major factors causing the delayed hemorrhage after PJ leakage following a PD in which the high-enterokinase-secreting segment of the intestine had been removed.

Skin erosion around the cutaneous enterofistula containing a mixture of bile and pancreatic juice is frequently observed clinically, but neither bile nor pancreatic leakage alone can cause such erosion. Hence, the author assumes that a fatal delayed intra-abdominal hemorrhage caused by arterial erosion around a PJ leakage is attributable to the long-term exposure of these arteries to a mixture of bile and pancreatic juice. In pancreatic enzymes, lipase (active form), activated phospholipase A2 (via trypsin), colipase, and cholesterol esterase require the cooperation of bile salts for their lipolytic action [19].

Bile diversion reconstructions, such as double Roux limb reconstruction and triple Roux on a “P” loop to separate the bile and pancreatic juice flows, may not reduce the incidence of the PJ leakage, but it results in less delayed-hemorrhage mortality [9]. Our looped reconstruction design with a disconnection in the jejunum between the choledochojejunostomy and PJ not only has the same function as the double Roux limb reconstruction in a biliary diversion, but it also preserves the mesentery structure, which gives the area better blood circulation. Because this method has only one loop, it is much simpler than the double- and triple-loop methods. Furthermore, the procedure is as safe as a PG, but without the drawback of having the pancreatic duct exposed to gastric juice.

A previously reported method [9] (Figure 1A) includes an antiperistalsis function for the PJ loop and aims to reduce the amount of bile reflux from the loop jejunojejunostomy to the PJ anastomosis. However, there may remain a concern of increasing ascending cholangitis on the choledochojejunostomy side; however, in the present series, this was temporary and spontaneously solved months later (the incidence was held to 20%). Using current whole-thickness mattress sutures for PJ anastomosis eliminates the risk of PJ leakage, and the antiperistaltic loop can be adjusted to the bile diversion side (Figure 1B) to further minimize the risk of ascending cholangitis.

One minor PJ leakage, which healed spontaneously, and one major PJ leakage were encountered before applying the whole-thickness mattress sutures. In the latter case, the PJ leakage occurred on postoperative day (POD) 7, and only white pancreatic juice leakage from the drain was noticed. Biliary diversion reconstruction would have fulfilled its originally designed function of preventing the activation of pancreatic juice from the bile if the patient had not had an unexpected and undetected long-term bout of severe constipation for 14 days, which was thought to have initiated the bile reflux to the leaked PJ. Bile refluxed upward, reached the PJ, and was detected in the drain on POD 31. Oozing from the drain was first noticed on POD 39. Despite somatostatin and gabexate mesilate treatment, the bleeding was aggravated until impending shock on POD 54, when an emergency operation was arranged.

Literature on the strategy of preventing a reaction between bile and pancreatic juice is scarce. Most proteases and lipases have pH optima in the alkaline range [20]. While the patient was waiting for an available operating theater, we used a normal saline instillation from the fistula above the PJ to neutralize the patient's pH condition. Bleeding began to reduce gradually. Within 30 minutes, the patient's bleeding gradually slowed sufficiently to justify cancelling the scheduled reoperation. Two days later, the bleeding stopped. This patient's bleeding was massive enough to provide evidence of the efficacy of normal-saline irrigation.

Although a normal-saline irrigation after a PD has been advocated to prevent pancreatic fistulas and to reduce morbidity, [1,6,7] all three recommendations were made without mentioning theoretical or empirical supporting evidence. Using normal saline irrigation to stop a delayed massive hemorrhage after a PJ leak has never been reported.

Conclusion

In conclusion, the current concept of an end-to-side pancreateojunostomy with whole-thickness mattress sutures and without a ductal anastomosis is a simple and easy method to solve the major technical issues of a soft pancreatic texture and a small...

pancreatic duct that cause PJ leakage. The complementary biliary diversion reconstruction diverts the bile flow using an independent, looped jejunal segment to prevent bile from activating pancreatic juice when PJ leakage is encountered. Normal saline irrigation stopped a massive delayed hemorrhage after PJ leakage in the current series. The above-mentioned three procedures will ensure a safe PD and make this surgery safer for more surgeons.
