Non-Leukemic Granulocytic Sarcoma Presenting with Multiple Lymphadenopathies

Çoklu Lenfadenopati ile Ortaya Çıkan Alösemik Granülositik Sarkom

To the Editor,

Granulocytic sarcoma (GS) is a rare tumor with poor prognosis that is composed of primitive myeloid cells, localized in extramedullary sites. The incidence is 2.5%-9.1% in acute myeloid leukemia (AML) patients and it may also occur in association with a myeloproliferative neoplasm or myelodysplastic disorders. The most common locations are the skin, lymph nodes, gastrointestinal tract, bones, and soft tissues [1].

A 68-year-old man presented with the complaint of bilateral inguinal swelling. On physical examination bilateral cervical, axillary, and inguinal multiple lymphadenopathies (LAP), approximately 2-3 cm in diameter, were noted. Initial workup revealed normal liver and renal functions; negative viral serology for epstein-barr virus, cytomegalovirus, HIV, and hepatitis B/C; and mild neutropenia (1020/µL). An excisional LAP biopsy revealed disruption of the normal lymph nodal architecture by a diffuse monomorphic infiltrate comprising medium-sized mononuclear cells with a high nuclear cytoplasmic ratio and fine chromatin pattern. In immunohistochemical study, these cells were positive for CD34, CD43, CD117, and myeloperoxidase and negative for Tdt, CD3, CD5, CD20, CD15, CD30, CD56, EMA, and Pax–5. The Ki–67 proliferation index was 45% and EBER was negative. Leukemic infiltration could not be detected in the bone marrow examination. Cytogenetic analysis was negative for t(9,22), t(15,17), t(8,21), and inv16 but positive for NPM1 and 11q23 rearrangement. The results confirmed the diagnosis of GS (Figures 1A-1C). A positron emission tomography/computed tomography (PET/CT) scan showed multiple hypermetabolic lymph nodes (SUVmax: 11.8) in bilateral cervical, axillary, paracardiac, and both common iliac areas (Figure 1D). Cytosine-arabinoside plus idarubicin (3+7 regimen) was started. PET/CT was repeated after chemotherapy and revealed partial response (Figure 1E). The persistent disease was confirmed by an excisional LAP biopsy and a fludarabine, cytarabine, G-CSF and idarubicin regimen was started. Since complete metabolic response was detected in the follow-up PET/CT, he underwent a matched related donor reduced-intensity conditioning hematopoietic stem cell transplantation (HSCT) (Figure 1F). He engrafted successfully and has had no recurrent GS for 8 months since the transplant.

Although it is well recognized that GS can cause localized lymphadenopathy, manifestation as bilateral multiple LAP is
rare [2]. Nandedkar et al. [3] reported a case of GS presenting with bilateral multiple LAP without evidence of leukemia, which is similar to our patient. In these two cases the interesting point is a myeloid malignancy presenting with only lymphatic spread. There is no consensus on the treatment of non-leukemic GS. Common practice suggests AML-like induction chemotherapies as first-line treatment and allogeneic HSCT for relapsed/refractory disease. Radiotherapy and surgery are also options in selected cases [4]. In a study by Chevallier et al. [5] that assessed the outcome of 30 patients with non-leukemic GS who underwent allogeneic HSCT, 5-year overall survival and leukemia-free survival were 48% and 36%, respectively. In another study, a significantly longer event-free survival rate was detected in patients treated with chemotherapy and allogeneic HSCT [6]. These data suggest that allogeneic HSCT is efficient as a consolidation regimen for GS. In our case, PET/CT was used for disease detection and in the monitoring of treatment response, which is an effective imaging tool for GS [7]. In conclusion, we present a case of GS with lymphatic spread like a lymphoma.

To the Editor,

Leukemia cutis (LC) is an extramedullary form of leukemia. The frequency and onset age of LC depends on the subtype of underlying leukemia. Clinical presentations of LC can be variable but it generally appears as nodules and plaques [1]. Herein, we report a case of LC with acute myeloid leukemia on azacitidine therapy.

A 70-year-old male presented with spontaneous ecchymoses and weakness in the Hematology Outpatient Clinic. Physical examination was normal. Laboratory tests were as follows: hemoglobin: 4.1 g/dL, leukocyte count: 17,600/mm³, platelet count: 57,000/mm³, and lactate dehydrogenase: 605 U/L. Peripheral blood smear revealed 60% myeloblasts. Eighty percent of blastic infiltration and positive staining with myeloperoxidase (MPO) were detected in the bone marrow biopsy. The patient was diagnosed with acute myelomonocytic leukemia (AML-M4) with the morphological and immunopathological findings. Flow cytometry of the bone marrow or peripheral blood was not done. In the conventional cytogenetic analysis done before the treatment, 20 metaphases were detected. Six of them had "add" (46,XY,add(8)(q24)[6]) and 10 were diploids and 4 were hypodiploids. In the fluorescence in situ hybridization (FISH) analysis [5q31, t(15;17)(q22-24;q21), trisomy 8, t(9;22) (q34;q11.2), inv(16)(p13q22), del(7q31), del/inv11q23, monosomy 7, t(8;21)(q21.3;q22), and del20q], there was no abnormality.

After four cycles of therapy with azacitidine (75 mg/m² daily for 7 days in a month), the need for red blood cells decreased but the need for platelets remained. Furthermore, some skin lesions appeared on the trunk. On dermatological examination, multiple discrete, violaceous-erythematous papules and nodules were observed on the trunk (Figures 1a and 1b). Histopathological examination of the skin lesions showed blastic cell infiltration with large pleomorphic nuclei and narrow cytoplasm in the dermis and also positive staining with CD34, CD117, and MPO (Figures 1c and 1d). The patient was diagnosed with LC with AML-M4 relapsed in the bone marrow synchronously and the...
