Fifteen years after the discovery of high temperature superconductivity in cuprates, the search for the “final” theory continues unabated. Nevertheless, certain important clues about the elements that such a theory must contain appear to be established. One of the most significant results of the past few years is that, in the superconducting state, cuprates seem to be well described by the familiar BCS-type formalism with Cooper pairs binding in the d-wave channel. This is a far from trivial observation in the materials known to exhibit strong correlations. Soon after the original discovery, Anderson identified one of the key features of the new superconductivity: the materials are basically two-dimensional. Subsequently, a large number of experiments have been performed in order to elucidate evidence for the BCS character of the fermionic excitations and the presence of nodal points on an otherwise gapped Fermi surface governs the low temperature properties of the high-Tc superconductors (HTS). Corroborating evidence for the BCS character of the fermionic excitations comes from diverse spectroscopic and transport experiments.

Especially informative probe of the quasiparticle dynamics is the thermal Hall conductivity, $\kappa_{xy}$, particularly since phonons, which usually contribute to the longitudinal thermal conductivity, $\kappa_{xx}$, do not contribute to $\kappa_{xy}$ by the virtue of their being electrically neutral. In addition, from the theoretical point of view, in the leading “nodal” approximation, $\kappa_{xy}$ vanishes and one must consider curvature terms. For these reasons a special opportunity emerges to scrutinize, both theoretically and experimentally, the extent to which the fermionic quasiparticles in HTS exhibit the BCS-type behavior.

Our starting point is a 2-dimensional Bogoliubov-de Gennes Hamiltonian in the vortex state

$$H_{BdG} = \sigma_3 \left( \frac{(p - \sigma_3 \hat{A})^2}{2m^*} - \sigma_3 \mu + \sigma_1 e^{-i\sigma_3 \phi/2} \Delta(p) e^{-i\sigma_3 \phi/2} \right)$$

(1)

where $A(x)$ is the vector potential associated with the uniform external magnetic field $B$, $p$ is a momentum operator, and $\sigma$’s are Pauli matrices operating in the Nambu space. The vortex phase fields satisfy $\nabla \times \nabla \phi(x) = 2\pi \sum_i \delta(x - x_i)$ with $x_i$ denoting the vortex positions and $\delta(x - x_i)$ being a 2D Dirac delta function.

For a $d_{x^2-y^2}$-wave superconductor $\Delta(p) = \frac{f_p}{p^2} (p_x^2 - p_y^2)$.

Following Franz and Tesanovic (see also [1, 3, 4]) we divide the vortices into two sets $A$ and $B$, positioned at $\{x^A_i\}$ and $\{x^B_i\}$ respectively (see Fig. 1) and define two phase fields $\phi^A(x)$ and $\phi^B(x)$ such that $\nabla \times \nabla \phi^\alpha(x) = 2\pi \sum_i \delta(x - x^\alpha_i)$, $\alpha = A, B$. The Hamiltonian (1) is then transformed into

$$H = U^\dagger H_{BdG} U = \sigma_3 \left( \frac{(p - \sigma_3 \mathbf{v} + \mathbf{a})^2}{2m^*} - \sigma_3 \mu + \sigma_1 \Delta(p + \mathbf{a}) \right)$$

(2)

using the unitary operator

$$U = e^{i\chi + i\sigma_3 \Phi}$$

(3)

where $\chi = \frac{1}{2}(\phi^A - \phi^B)$ and $\Phi = \frac{1}{2}(\phi^A + \phi^B) = \frac{1}{2}\phi$.

In Eq. (2), $\mathbf{v} = \frac{1}{\mu} \nabla \phi - \frac{\mu}{c} \mathbf{A}$ is the superfluid velocity and $\mathbf{a} = \frac{1}{\mu} (\nabla \phi^A - \nabla \phi^B)$ is the Berry gauge field which imposes the condition that a quasiparticle wavepacket encircling an $\frac{hc}{2e}$ vortex must pick up an overall minus sign.

In addition to keeping the wavefunctions single-valued, the advantage of this “bipartite” singular gauge transformation is that for a periodic arrangement of vortices (Abrikosov vortex lattice) the resulting Hamiltonian is itself periodic. This is not true of Hamiltonian (1) and the eigenstates of (2) can be expressed through the familiar Bloch waves $\psi_{nk}(x) = e^{ik_n x} u_{nk}(x)$ labeled by one discrete quantum number, the band index $n$, and two continuous quantum numbers, the vortex crystal momenta $k_x$, $k_y$ that range in the first Brillouin zone. Note that $u_{nk}(x)$ is not periodic with the periodicity of the vortex lattice, but with the periodicity of the vortex sublattice containing a unit of electronic flux $\frac{hc}{2e}$ (see Fig. 1).

By extracting the plane wave part of the Bloch states

Presented is the theory of thermal Hall conductivity $\kappa_{xy}$ in the vortex state of high temperature cuprate superconductors in the clean limit. We show that \( \lim_{T \to 0} \kappa_{xy} / T \) is a staircase function of \( 1/B \) with an envelope that scales as \( 1/B \). The relation to the experiments is discussed.

Thermal Hall Conductivity of High Temperature Superconductors: Quantization and Scaling

Oskar Vafek and Zlatko Tešanović

arXiv:cond-mat/0202287v1 [cond-mat.supr-con] 17 Feb 2002.
we can define a Hamiltonian
\[
\mathcal{H}(\mathbf{k}) = \frac{\sigma_3 (\mathbf{p} + \mathbf{k} - \sigma_5 \mathbf{v} + \mathbf{a})^2}{2m^*} - \sigma_3 \mu + \sigma_1 \Delta (\mathbf{p} + \mathbf{k} + \mathbf{a})
\]
where \(\mathcal{H}(\mathbf{k}) = e^{-i\mathbf{k} \cdot \mathbf{x}} \mathcal{H} e^{i\mathbf{k} \cdot \mathbf{x}}\). We now wish to point out an important feature of \(\mathcal{H}(\mathbf{k})\) in the case when the vortex lattice has an inversion symmetry. As shown in Ref. [14] an operator \(\mathcal{P} = i \sigma_3 \mathcal{C} \mathcal{T}\), where \(\mathcal{C}\) represents charge conjugation and \(\mathcal{T}\) takes \(x\) into \(-x\), with the following property
\[
\mathcal{P}^{-1} \mathcal{H}(\mathbf{k}) \mathcal{P} = -\mathcal{H}(\mathbf{k}); \quad \langle u_{n\mathbf{k}} | \mathcal{P} | u_{n\mathbf{k}} \rangle = 0.
\]
This means that for every energy band \(\epsilon_{n\mathbf{k}}\) there is another \(\epsilon_{n\mathbf{q}}\) such that \(\epsilon_{n\mathbf{q}} = -\epsilon_{n\mathbf{k}}\), i.e. the band spectrum has reflection symmetry about the Fermi level and if a band were to cross the Fermi level (\(\epsilon_{n\mathbf{q}} = 0\) for some \(\mathbf{q}\)) then there would have to be a twofold degeneracy at \(\mathbf{q}\). However, by the von Neumann-Wigner “non-crossing” theorem [13], the degeneracy unrelated to symmetry cannot happen for a time reversal breaking Hamiltonian which depends only on two continuous parameters. Thus, the quasiparticle spectrum of the \(d_{x^2-y^2}\) superconductor in the vortex state is gapped by a (direct) gap \(\Delta_m \ll \Delta_0\) unless a third parameter is fine tuned, e.g. the band crossing at the Fermi level can be achieved by fine-tuning the chemical potential \(\mu\).

If we rescale all coordinates by the magnetic length \(l = \sqrt{c/eB}\) (see Fig. 1), \(x \rightarrow lx\), then
\[
\mathcal{H}(\mathbf{k}, l, \mu, \Delta_0) \rightarrow \frac{1}{l^2} f(l^2 \mu, \frac{\Delta_0}{l^2})
\]
where \(f\) is a universal (operator) function. Consequently, the small band gap \(\Delta_m\) at the Fermi level, which is equal to the minimum of the lowest positive eigen-energy of \(\mathcal{H}(\mathbf{k}, l, \mu)\) with respect to \(\mathbf{k}\), is also a universal function that can be written as
\[
\Delta_m(B, \mu, \Delta_0) = B \times F\left(\frac{\mu}{B}, \frac{\Delta_0}{B^2}\right),
\]
Thus, in order to determine the dependence of \(\Delta_m\) on the magnetic field \(B\), all we need to know is the dependence of \(\Delta_m\) on \(\mu\) for some fixed \(B\) and \(\frac{\Delta_0}{B}\), and then use the scaling relation (4). This dependence is determined numerically by diagonalizing a tight-binding version \((\mathcal{H})\) of the Hamiltonian (4) close to the bottom of the tight-binding band where we expect to recover the continuum theory (4). The numerical calculations confirm the scaling (4) which gives us confidence in relating the continuum results to the tight-binding approximation. As shown in Fig. 2 for a fixed value of \(\frac{\Delta_0}{B} = 10\), the tight-binding hopping constant, \(\frac{1}{B} \Delta_m(B)\) is a saw-tooth function with a period of approximately \(4\pi\).

In Ref. [14] it was demonstrated that the gapped quasiparticle spectrum leads to the quantization of the spin Hall conductivity \(\sigma_{xy}^{\text{spin}}\) (see also Ref. [11]), which is in turn related to the thermal Hall conductivity, \(\kappa_{xy}\), via the Wiedemann-Franz law
\[
\lim_{T \rightarrow 0} \frac{\kappa_{xy}}{T} = \frac{4\pi^2}{3} \left(\frac{k_B}{h}\right)^2 \sigma_{xy}^{\text{spin}}(B).
\]

Because the quantization of \(\sigma_{xy}^{\text{spin}}\) is topological in origin [3], any continuous change in a parameter of the Hamiltonian results in the same quantized value of \(\sigma_{xy}^{\text{spin}}\) unless the quasiparticle gap collapses. Therefore, for a fixed Dirac anisotropy \(\alpha_D\), by virtue of Eq. (8), the dependence of \(\sigma_{xy}^{\text{spin}}\) on \(B\) and \(\mu\) can be expressed entirely as a dependence of \(\sigma_{xy}^{\text{spin}}\) on \(\frac{1}{B} \Delta_m(B, \mu)\), i.e.
\[
\sigma_{xy}^{\text{spin}}(B, \mu) = G\left(\frac{\mu}{B}\right),
\]
where \(G\) is a universal function of its argument that in addition depends on the geometry of the vortex lattice.
are resolution limited below 12.5K, seen that for the magnetic fields above 4T, spin
weak. In Fig. 3 we re-analyze the data of Ref. [8]. It is evident in Fig. 3, remains mysterious to us and we can only speculate that it is not of quasiparticle origin.

In summary, based on a general analysis of the full non-linearized Bogoliubov-de Gennes equations, we argued that magnetic field \( B \) will induce a small gap \( \Delta_m \) in the quasiparticle spectrum which is a non-monotonic function of the magnetic field. Rather, \( \Delta_m \) vanishes at some special values of \( \mu/B \) which depend on the details of the vortex lattice and the Dirac cone anisotropy (Fig. 3). The dependence of \( \kappa_{xy} \) on \( B \) is entirely due to this non-monotonic behavior of \( \Delta_m \), since \( \kappa_{xy}/T \) is a topological quantity and therefore can change only at the band crossings [4]. The topological quantization of \( \kappa_{xy} \) was also discussed in the Ref. [1]. However, we wish to point out a significant qualitative difference between the results presented here and those of Ref. [1]: as we argued before \( \kappa_{xy} \) is a quantized staircase function of \( 1/B \) with an envelope that itself scales as \( 1/B \), while Ref. [1] states that \( \kappa_{xy}/T \) can take on only one of the three allowed values 0, ±2 and is otherwise field-independent. Consequently, in a typical experimental situation, the explicit values for \( \kappa_{xy} \) obtained from these two works will differ significantly. Still, there is an agreement on the fact that since the quasiparticle spectrum is gapped \( \kappa_{xy} \) does not obey simple Simon-Lee scaling, at least when the temperature is comparable to the quasiparticle gap.

We thank Marcel Franz, Ashot Melikyan and Ady Stern for comments and discussions. This work was supported in part by NSF grant DMR00-94981.

\[ \lim_{T \to 0} \left( \frac{\kappa_{xy}}{T} \right) \propto \frac{1}{B} \]  

This expression is reminiscent of the electrical Hall conductivity in the 2D electron gas.

Recently, measurements of \( \kappa_{xy} \) were conducted by Ong’s group [8] on YBCO samples with a very long mean free path. These experiments were carried out over a wide range of magnetic fields (up to \( \sim 14T \)) and at temperatures from \( T \approx 12.5K \) to above the superconducting transition \( T_c \approx 90K \). Unfortunately, the experiments are resolution limited below 12.5K as signal becomes too weak. In Fig. 3, we re-analyze the data of Ref. [8]. It is seen that for the magnetic fields above 4T, \( \kappa_{xy} \) decreases with decreasing \( B \) and vanishes at \( B = 0 \) [8]. At low magnetic fields \( T \) divergence of \( \kappa_{xy} \) is cut-off by disorder

\begin{align*}
\kappa_{xy} &= \frac{\rho_{xx}}{\rho_{xy}^2 + \rho_{xx}^2} \\
\text{i.e. } \kappa_{xy} &= \frac{\rho_{xy}}{\rho_{xy} + \rho_{xx}} \text{ with non-vanishing longitudinal quasiparticle thermal resistivity } \rho_{xx}. \quad \text{Even in the presence of weak disorder, we still expect } \rho_{xy} \propto B \text{ and } \rho_{xx} \text{ to be approximately field independent. Therefore, the transverse thermal conductivity in the presence of disorder should vanish in the limit of vanishing } B. \text{ We must admit that the origin of the residual thermal conductivity at } \frac{T}{T_c} = 0,
\end{align*}

\[ \text{FIG. 3: Thermal Hall conductivity data of Zhang et. al. [8] for } B > 4T \text{ plotted vs. } B^{-1}. \]
