ABSTRACT
The most important task in personalized news recommendation is accurate matching between candidate news and user interest. Most of existing news recommendation methods model candidate news from its textual content and user interest from their clicked news in an independent way. However, a news article may cover multiple aspects and entities, and a user usually has different kinds of interest. Independent modeling of candidate news and user interest may lead to inferior matching between news and users. In this paper, we propose a knowledge-aware interactive matching method for news recommendation. Our method interactively models candidate news and user interest to facilitate their accurate matching. We design a knowledge-aware news co-encoder to interactively learn representations for both clicked news and candidate news by capturing their relatedness in both semantic and entities with the help of knowledge graphs. We also design a user-news co-encoder to learn candidate-news-aware user interest representation and user-aware candidate news representation for better interest matching. Experiments on two real-world datasets validate that our method can effectively improve the performance of news recommendation.

1 INTRODUCTION
Online news platforms such as Microsoft News, Apple News and News Break, have attracted a huge number of users to consume news information [21, 33]. However, since massive new published news articles are collected by these platforms every day, users often have difficulties in finding the news information they need [34, 47]. Personalized news recommendation techniques, which aim to help users find their interested news, usually play an essential role in online news platforms to alleviate the information overload of users [1, 32]. Thus, the study on personalized news recommendation has attracted much attention from both academia and industry [1, 2, 10, 13, 19, 42, 43, 46].

Figure 1: An example user with four clicked news, and two candidate news for recommendation.

Accurate matching between user interest and candidate news is critical for personalized news recommendation [31, 32]. Existing methods usually model candidate news from its textual information and infer user interest from user’s click history in an independent way [21, 37]. For example, Wu et al. [34] learned news representations via a word-level personalized attention network and learned user interest representations via a user-level personalized attention network, independently. They further performed interest matching via the inner product of user interest representation and candidate news representation. However, a candidate news article may contain multiple aspects and entities [18, 33], and a user may have multiple interests [32]. Thus, independent modeling of candidate news and user interest may be inferior for the interest matching [31].

In this paper, we explore to better model the relatedness between candidate news and user interests for accurate interest matching. Our paper is motivated by the following observations. First, a candidate news may cover different aspects and entities, and a user may have multiple interests. For example, the 2nd candidate news in Fig. 1 is related to a basketball star and a politician, and covers several entities, e.g., “Stephen Curry” and “Donald Trump”. Besides, the example user in Fig. 1 is interested in multiple areas such as autos, music and sports. The 2nd candidate news can only match a specific user interest, i.e., sports, and the user may be only interested in a single entity in the 2nd candidate news, i.e., “Stephen
Curry”. Thus, it is inferior for matching user interest with candidate news if they are independently modeled. Second, semantic matching of candidate news and clicked news can help perform interest matching more accurately. For instance, the 2nd clicked news also has semantic relatedness with the 1st candidate news since both of them are related to music. The 3rd clicked news has semantic relatedness with the 1st candidate news since they mention the same event. Based on these semantic relatedness, we can infer the user may be interested in the 1st candidate news. Third, with the help of knowledge graphs, the knowledge matching between entities in clicked news and candidate news is also informative for understanding user interest in candidate news. For example, the entity “Steve Kerr” in the 4th clicked news has inherent relatedness with the entity “Stephen Curry” in the 2nd candidate news since the former and the latter is the player and coach of the “Warriors” team of the “NBA” competition, respectively. According to the knowledge matching, we can infer the user may have interest in the 2nd candidate news. Thus, exploiting the relatedness between clicked news and candidate news in both semantic and knowledge levels is beneficial for interest matching.

In this paper, we propose a knowledge-aware interactive matching framework for personalized news recommendation (named KIM). Our method can interactively model candidate news and user interest to learn candidate news-aware user interest representation and user-aware candidate news representation to match user interest and candidate news more accurately. In the framework, we propose a knowledge co-encoder to model user interest in candidate news from the relatedness between entities in clicked news and candidate news with the help of knowledge graphs. More specifically, we first propose a graph co-attention network to learn representations of entities from the knowledge graph by selecting and aggregating their neighbors that are informative for interest matching. We further propose to use an entity co-attention network to interactively learn knowledge-based representations of both clicked news and candidate news by capturing relatedness between their entities. Moreover, we also propose a semantic co-encoder to interactively learn semantic-based representations for user’s clicked news and candidate news by modeling semantic relatedness between their texts. The unified representation of news is formulated as the aggregation of its knowledge- and semantic-based representation. In addition, we further propose a user-news co-encoder to build candidate news-aware user interest representation and user-aware candidate news representation from representations of clicked news and candidate news to better model user interest in candidate news. Finally, the candidate news is ranked based on the relevance between representations of candidate news and user interest. We conduct extensive experiments on two real-world datasets and show that our method can effectively improve the performance of news recommendation and outperform other baseline methods.

2 RELATED WORK

Personalized news recommendation is an important task for online news services [4, 17] and has been widely studied in recent years [14, 16, 24, 30, 35, 36, 41, 44]. Existing methods usually model candidate news from its content and model user interest from clicked news independently, and then match candidate news and user interests based on their relevance [5, 32, 33, 37, 38]. For example, Okura et al. [21] represented candidate news from its bodies via an auto-encoder and represented user interest from user’s click history via a GRU network, independently. They further matched user interest and candidate news based on the dot product between their representations. Wu et al. [37] adopted a multi-head self-attention network to model candidate news from its title and another multi-head self-attention network to model user interest from user’s click history. Liu et al. [18] proposed to learn knowledge-based candidate news representation from entities in news title and their neighbors on knowledge graphs and learn user interest representation from user’s clicked news via an attention network. Besides, these methods also performed interest matching via the inner product of user interest representation and candidate news representation. In general, a candidate news may cover multiple aspects and entities [18, 33], and a user may have multiple interests [32]. Only a part of candidate new aspects and user interests are useful for matching user interest with candidate news. However, these methods model candidate news and user interest independently, which may be inferior for the further interest matching. Different from these methods, in the KIM method we propose a knowledge-aware interactive matching framework to interactively model candidate news and user interest with the consideration of their relatedness, which can better match user interest with candidate news.

Some methods model user interest in a candidate-aware way [32, 47]. For example, Wang et al. [32] obtained news representations from aligned words and entities in news titles via a multi-channel CNN network. Besides, they applied a candidate-aware attention network to learn user interest representation by aggregating clicked news based on their relevance with candidate news. They further used a dense network to model the relevance of user interest and candidate news from their representations. Zhu et al. [47] proposed to learn news representations from words and entities in news titles via multiple CNN networks and learn user interest representations from historical clicks via a LSTM network and an candidate-aware attention network. They matched user interest and candidate news based on the cosine similarity of their representations. In fact, candidate news may contain multiple aspects and entities [18, 33] and only a part of them may match user interest. However, these methods model candidate news without the consideration of the target user, which maybe inferior for further matching user interest with candidate news. Different from these methods, our KIM method models candidate news with the consideration of target user. In addition, these methods model clicked news and candidate news without the consideration of their relatedness, which may also be suboptimal for further measuring relevance between candidate news and user interest inferred from clicked news. Different from these methods, KIM can interactively learn representations of both clicked news and candidate news for better interest matching.

3 METHODOLOGY

We first introduce the problem definition of personalized news recommendation. Next, we introduce our knowledge-aware interactive matching framework for personalized news recommendation (named KIM) in detail.
3.1 Problem Formulation

Given a user $u$ and a candidate news $n^c$, we need to compute the relevance score $z$ measuring the interest of user $u$ in the content of candidate news $n^c$. Then different candidate news are ranked and recommended to user $u$ based on their relevance scores. The user $u$ is associated with the set of his/her clicked news. Each news $n$ is associated with its texts $T$ and entities $E$ in its texts. Besides, there is a knowledge graph $G$ used to provide the relatedness between entities. It contains entities and relations between entities. Each entity $e$ in $G$ is associated with its embeddings $e$ pre-trained based on the knowledge graph. In our method, we only utilize the links between entities to represent their relatedness and do not utilize the specific relations (e.g., located_at).

3.2 Framework of KIM

In this section, we introduce the news recommendation framework of KIM, which can interactively model candidate news and user interest for better interest matching. As illustrated in Fig. 2, KIM contains two major modules. The first one is a knowledge-aware news co-encoder, which interactively learns the knowledge-aware representations of a user’s clicked news and the candidate news by capturing their relatedness at both semantic and knowledge levels. The second one is a user-news co-encoder, which interactively learns candidate news-aware user interest representation $u$ and user-aware candidate news representation $c$ from the representations of user’s clicked news and candidate news generated by the knowledge-aware news co-encoder. Finally, we match candidate news with user interest based on the relevance between the candidate news-aware user interest representation and user-aware candidate news representation. Next, we introduce each module in detail.

3.3 Knowledge-aware News Co-Encoder

In this section, we introduce the framework of the knowledge-aware news co-encoder, which interactively learns representations of a user’s clicked news $n^u$ and candidate news $n^c$ from their texts and entities in texts. As shown in Fig. 3, it contains three sub-modules. The first one is a knowledge co-encoder (denoted as $\Phi_k$), which interactively learns knowledge-based representations $k^u \in \mathbb{R}^{d_k}$ for clicked news $n^u$ and candidate news $n^c$ from the relatedness between their entities based on the knowledge graph:

$$[k^u, k^c] = \Phi_k(E^u, E^c),$$

where $d_k$ denotes knowledge-based news representation dimensions, $E^u$ and $E^c$ denote entities in news $n^u$ and $n^c$ respectively. The second one is a semantic co-encoder (denoted as $\Phi_t$), which interactively learns semantic-based representations $t^u \in \mathbb{R}^{d_t}$ and $t^c \in \mathbb{R}^{d_t}$ for news $n^u$ and $n^c$ to model user interests in candidate news from the semantic relatedness between their texts:

$$[t^u, t^c] = \Phi_t(T^u, T^c),$$

where $d_t$ denotes semantic-based news representation dimensions, $T^u$ and $T^c$ denote texts of news $n^u$ and $n^c$ respectively. Finally, we project the knowledge- and semantic-based representation of the same news to learn the unified news representation:

$$n^u = P_n[t^u; k^u], \quad n^c = P_n[t^c; k^c],$$

where $n^u \in \mathbb{R}^{d_n}$ denotes the knowledge-aware representation of user’s clicked news $n^u$, $n^c \in \mathbb{R}^{d_n}$ denotes the corresponding knowledge-aware representation of candidate news $n^c$, $d_n$ denotes news representation dimensions, $[\cdot; \cdot]$ denotes the concatenation operation, and $P_n \in \mathbb{R}^{d_n \times (d_t+d_k)}$ is the trainable projection matrix.

3.3.1 Knowledge Co-Encoder. We introduce the proposed knowledge co-encoder, which interactively learns the knowledge-based representations of user’s clicked news $n^u$ and candidate news $n^c$. It aims to better represent these news for interest matching from relatedness between entities $E^u$ and $E^c$ in user’s clicked news and candidate news with the help of the knowledge graph $G$. As shown in Fig. 4, it contains three components. First, to summarize the information for each entity in $E^u$ or $E^c$ from their neighbors within $K$ hops, we first utilize a graph attention (GAT) network [28] stacked $K$ layers to learn their representations, which are denoted as $M_u = \{m^u_i\}_{i=1}^K \in \mathbb{R}^{d_k \times D}$ and $M_c = \{m^c_i\}_{i=1}^K \in \mathbb{R}^{d_k \times D}$ respectively, where $D$ is the number of entities in news.

The second one is a stacked graph co-attention (GCAT) network proposed in this paper. In general, an entity usually has rich relatedness with multiple entities on the knowledge graph [6, 29].
“Movie Cats” has many neighbor entities on knowledge graphs, such as its representation by aggregating representations of its neighbors. For entities in news $n_1$, we propose a graph co-attention network (GCAT) to better select informative relatedness between entities for matching. Besides, relatedness among entities usually provides different informativeness to model the relatedness between clicked news and candidate news for interest matching. For example, given a clicked news “Style is the trending song today,” and a candidate news “Song Style is the most popular movie in the Netflix,” the entity “Taylor” is informative for modeling the relatedness between clicked news and candidate news since it is also the singer of the entity “Song Style” in clicked news. To model the conceptual relatedness between different neighbor entities guided by entities in news $n^c$, we first apply a multi-head self-attention network [27] to the representations of its neighbor entities generated by the $(l-1)$-th GCAT network to model the conceptual relatedness between different neighbor entities. Next, we propose a match-aware attention network to aggregate neighbor entities of entity $e$ based on their relevance with entities in news $n^c$ measured by a relevance matrix $I_u \in \mathbb{R}^{D \times B}$:

$$I_u = M_u^T W_c^T \hat{G}_l,$$  

(4)

where $\hat{G}_l = \{\hat{g}_1, \hat{g}_2, \ldots, \hat{g}_{B}\}$ is the representation of neighbor entities generated by the self-attention network, $B$ denotes the number of neighbors, and $W_c^T \in \mathbb{R}^{d_k \times d_k}$ is a trainable weights. Then the attention vector $\psi^u = q^T f(I_u)$, where $f$ denotes the softmax activation which normalizes each column vector of the input matrix. $q \in \mathbb{R}^D$ denotes the trainable attention query, $d_k$ denotes its dimensions, $W_c^T \in \mathbb{R}^{d_k \times d_k}$ and $W_c^T \in \mathbb{R}^{d_k \times d_k}$ are trainable weights. Then we aggregates neighbors of entity $e$ into a unified representation $g^u \in \mathbb{R}^{d_k}$:

$$g^u = \sum_{i=1}^{B} \lambda_i^u g_i^u, \quad \lambda_i^u = \frac{\exp(v_i^u)}{\sum_{j=1}^{B} \exp(v_j^u)},$$  

(6)

where $v_i^u$ is the $i$-th element of vector $v^u$ and $\lambda_i^u$ denotes the attention weight of the $i$-th neighbor entity. Finally, the representation $g^u \in \mathbb{R}^{d_k}$ of the entity $e$ generated by the $l$-th GCAT network is formulated as $g^u = P_e [g^1, g^2, \ldots, g^l]$, where $P_e \in \mathbb{R}^{d_k \times d_k}$ is the projection matrix. In this way, the GCAT network stacked $K$ layers can learn match-aware representations. $S_u = \{s^1, s^2, \ldots, s^K\}$ for entities in user’s clicked news by capturing the relatedness between their neighbors within $K$ hops and entities in candidate news, where $s^1$ is the representation of the $i$-th entity in clicked news $n^u$. In a symmetrical way, we can learn the match-aware representations.

---

1 The input of the 1-th GCAT network are the initialized embeddings of each entity.
where $S_c = \{s^D_c\}_{i=1}^D \in \mathbb{R}^{d_x \times D}$ of entities in candidate news from relatedness between their neighbors and entities in clicked news, where $s^D_c$ is the representation of the $i$-th entity in candidate news $n^c$.

The third one is an entity co-attention network. Entities in clicked news and candidate news usually have different informativeness for interest matching. For example, given a clicked news "Style is the trending song in iTunes this week." and a candidate news "The movie Cats is the most popular movie in the Netflix", the entity "Song Style" is more informative than the entity "iTunes" for matching user interest with candidate news since the entity "Song Style" has inherent relatedness with the entity "Movie Cats" in candidate news. Thus, we apply an entity co-attention network to interactively learn knowledge-based representations for news $n^u$ and $n^c$ by capturing relatedness between their entities. In detail, we first calculate an affinity matrix $C_c \in \mathbb{R}^{D \times D}$ to measure the relevance among entities in news $n^u$ and $n^c$:

$$C_c = S^T_c W^c_c S_c,$$

where $W^c_c \in \mathbb{R}^{d_x \times d_x}$ is the trainable weights. Then we calculate attention vectors $a^u, a^c \in \mathbb{R}^D$ of entities in news $n^u$ and $n^c$:

$$a^u = q^T_k \cdot \text{tanh}(W^k_c S_c + W^k_c S_c f(C_c)),$$

$$a^c = q^T_k \cdot \text{tanh}(W^k_c S_c + W^k_c S_c f(C_c)),$$

where $q_k \in \mathbb{R}^{d_k}$ is the trainable attention query, and $W^k_c \in \mathbb{R}^{d_k \times d_k}$ are trainable weights. Finally, we obtain knowledge-based representations $k^u \in \mathbb{R}^{d_k}$ and $k^c \in \mathbb{R}^{d_k}$ of clicked news and candidate news by aggregating their entities respectively:

$$k^u = \sum_{i=1}^D a^u_i s^u_i, \quad a^u_i = \frac{\exp(a^u_i)}{\sum_{j=1}^D \exp(a^u_j)},$$

$$k^c = \sum_{i=1}^D a^c_i s^c_i, \quad a^c_i = \frac{\exp(a^c_i)}{\sum_{j=1}^D \exp(a^c_j)},$$

where $a^u_i$ and $a^c_i$ denote the attention weight of the $i$-th entity in news $n^u$ and $n^c$ respectively.

### 3.3.2 Semantic Co-Encoder

As shown in Fig. 4, semantic co-encoder interactively learns the semantic-based representations for user’s clicked news $n^u$ and candidate news $n^c$. It aims to better model user interests in candidate news from semantic relatedness between their texts ($T^u$ and $T^c$). We first independently learn contextual representations for words in texts $T^u$ and $T^c$. More specifically, take texts $T^u$ as an example, we first convert it into an embedding vector sequence $T_u \in \mathbb{R}^{d_x \times M}$ via a word embedding layer, where $d_x$ denotes word embedding dimensions, and $M$ denotes the number of words in $T^u$. Next, since both local and global contexts are important for semantic modeling [33, 37], we apply a CNN network [11] and a transformer network [27] to $T_u$ to learn both local- and global-contextual word representations respectively, i.e., $L_u \in \mathbb{R}^{d_l \times M}$ and $L_e \in \mathbb{R}^{d_g \times M}$. Then, we add the local- and global-contextual representations of each word and obtain their unified representations $H_u = \{h^e_u\}_{i=1}^M \in \mathbb{R}^{d_g \times M}$, where $h^e_u \in \mathbb{R}^{d_g}$ is the representation of the $i$-th word in $T^u$. Besides, we can learn contextual word representations $H_c = \{h^e_c\}_{i=1}^M \in \mathbb{R}^{d_g \times M}$ for $T^c$ in the same way, where $h^e_c \in \mathbb{R}^{d_g}$ is the $i$-th word representation in $T^c$.

Finally, in general, different semantic aspects in clicked news and candidate usually have different importance for matching user interest with candidate news [39]. For example, given a clicked news “Apple’s plans to make over-ear headphones,” it contains two semantic aspects, i.e., “Apple’s product plan” and “headphones”. The former is important for matching user interest with candidate news “The best headphones of 2020,” since users who are interested in headphones may click both of them. While the latter is important for matching user interest with candidate news “iPhone 12 cases buyer’s guide,” since users who are interested in the products of Apple may read them. Thus, we apply a semantic co-attention network [25, 40] to interactively learn semantic-based representations of news $n^u$ and $n^c$ by capturing semantic relatedness between their texts for interest matching. Specifically, we first calculate the affinity matrix $C_t \in \mathbb{R}^{M \times M}$ measuring the semantic relevance between different words in texts $T^u$ and $T^c$:

$$C_t = H^T_u W^u_t H_u,$$

where $W^u_t \in \mathbb{R}^{d_t \times d_t}$ is the trainable weights. Then we compute the attention vector $b^u \in \mathbb{R}^{M}$ and $b^c \in \mathbb{R}^{M}$ for words in user’s clicked news and candidate news respectively based on $C_t$:

$$b^u = q^T_t \cdot \text{tanh}(W^u_t H_u + W^u_t H_u f(C_t)),$$

$$b^c = q^T_t \cdot \text{tanh}(W^c_t H_c + W^c_t H_c f(C^T_t)),$$

where $q_t \in \mathbb{R}^{d_t}$ is the trainable attention query, $W^u_t \in \mathbb{R}^{d_t \times d_t}$ and $W^c_t \in \mathbb{R}^{d_t \times d_t}$ are trainable parameters. Finally, we learn semantic-based representations $t^u \in \mathbb{R}^{d_t}$ and $t^c \in \mathbb{R}^{d_t}$ of news $n^u$ and $n^c$:

$$t^u = \sum_{i=1}^M \beta^u_i h^e_u, \quad \beta^u_i = \frac{\exp(b^u_i)}{\sum_{i=1}^M \exp(b^u_i)},$$

$$t^c = \sum_{i=1}^M \beta^c_i h^e_c, \quad \beta^c_i = \frac{\exp(b^c_i)}{\sum_{i=1}^M \exp(b^c_i)},$$

where $\beta^u_i$ and $\beta^c_i$ is weight of the $i$-th word in texts $T^u$ and $T^c$.

### 3.4 User-News Co-Encoder

We introduce our proposed user-news co-encoder, which learns candidate news-aware user interest representation and user-aware candidate news representation from representations of user’s clicked news and candidate news. Usually, interests of a user are diverse, and only part of them can be matched with a candidate news [20]. Thus, learning candidate news-aware user interest representation can better model user interest for matching candidate news. Similarly, a candidate news may cover multiple aspects, and a user may only be interested in part of them [33, 34]. Thus, learning user-aware candidate news representation is also beneficial for interest matching. Thus, we apply a news co-attention network to learn candidate news-aware user representation and user-aware candidate news representation. More specifically, we first calculate the affinity matrix $C_n \in \mathbb{R}^{N \times N}$ based on the representations of user’s clicked news $N_u = \{n^u_i\}_{i=1}^N \in \mathbb{R}^{d_u \times N}$ and candidate news $N_c = \{n^c_i\}_{i=1}^N \in \mathbb{R}^{d_u \times N}$ to measure their relevance:

$$C_n = N^T_u W^{n^u} u N_u,$$
We evaluate the performance of different methods on the public datasets. Where $\sigma$ denotes the sigmoid function, $z_i^p$ denotes the relevance score of the i-th positive sample, and $z_i^n$ denotes the relevance score of the j-th negative sample selected for the i-th positive sample.

Finally, we briefly discuss the computational complexity of KIM. Different from the methods that model user and candidate news independently, KIM calculates representations of clicked news and candidate news collaboratively, which requires more computation resources because these representations cannot be prepared in advance. Fortunately, in practice we can calculate contextual word embeddings $H$ and entity embeddings $M$ of different news offline and cache them to save the computational cost.

4 EXPERIMENT

4.1 Datasets and Experimental Settings

We evaluate the performance of different methods on the public MIND$^2$ dataset [45] as well as a private dataset (named Feeds) built from user logs of a commercial Feeds App in Microsoft.$^3$ MIND dataset was built from six-week sampled user logs in Microsoft News during Oct. 12 to Nov. 22, 2019, where the training and validation set were constructed by user logs in the fifth week, and the test set was constructed by user logs in the sixth week. In MIND dataset, entities in news titles were extracted and linked to WikiData automatically. Their embeddings were trained based on the knowledge tuples extracted from WikiData via the TransE method [3]. The Feeds dataset was built from thirteen-week user logs during Jan. 23 to Apr. 01, 2020, where the training and validation set were constructed by 100,000 and 10,000 impressions randomly sampled from the first ten weeks respectively, and the test set was constructed by 100,000 impressions randomly sampled from the last three weeks. Following Wu et al. [45], in Feeds dataset we also extracted entities in news titles and pre-trained their embeddings based on the WikiData. In these two datasets, we used news titles as news texts. Besides, we used WikiData as the knowledge graph in experiments. More detailed statistics is listed in Table 1.

Next, we introduce hyper-parameters of KIM$^4$ and experiment settings. For each news, we only used the first 30 words in news titles and first 5 entities in news. We randomly sampled 10 neighbors for each entity from the knowledge graph. Besides, we only used the recent 50 clicked news of each user. The word and entity embedding vectors were initialized by 300-dimensional glove embeddings [23] and 100-dimensional TransE embeddings [3], respectively. Due to limitation of GPU memory, we only fine-tuned word embeddings and did not fine-tune entity embeddings in experiments. In semantic co-encoder, the transformer contained 10 attention heads and output vectors of each head were 40-dimensional. Besides, the CNN network contained 400 filters. In knowledge co-encoder, all multi-head self-attention networks in the graph attention and co-attention networks contained 5 attention heads, and all of these heads output 20-dimensional vectors. Besides, all attention queries in KIM were set to 100-dimension. For effective model training we applied the dropout technique [26] with 0.2 dropout probability. We sampled 4 negative samples for each positive sample. We utilized Adam optimizer [12] to train KIM with 5 × 10⁻³ learning rate. All hyper-parameters of KIM and other baseline methods were selected based on the validation dataset. Following previous works [33], we used AUC, MRR, nDCG5, and nDCG10 for evaluation.

4.2 Performance Evaluation

We compare KIM with several state-of-the-art personalized news recommendation methods, which are listed as follow: (1) EBFRN [21]:

### Table 1: Detailed statistics of the MIND and Feeds datasets.

|          | MIND | Feeds |
|----------|------|-------|
| # Users  | 94,057 | 50,605 |
| # Impressions | 230,117 | 210,000 |
| # Clicks | 347,727 | 473,697 |
| # News   | 65,238 | 1,126,308 |
| Avg. # words in news title | 11.78 | 11.90 |
| Avg. # entities in news title | 1.43 | 0.99 |
| Avg. # neighbors in KG | 18.21 | 18.09 |

---

$^2$The small version of MIND is used in our experiments.

$^3$We used the same techniques as in MIND to protect user privacy in Feeds.

$^4$Codes are available at https://github.com/JulySinceAndrew/KIM-SIGIR-2021.
representing user interest from user’s click history via a GRU network. (2) **DKN** [32]: applying a multi-channel CNN network [15] to embeddings of aligned words and entities in news titles to learn news representations. (3) **DAN** [47]: learning news representations from words and entities of news titles via a CNN network, and learning user interest representations via an attentive LSTM network [8]. (4) **NAML** [33]: learning news representations from news titles, bodies, categories, and sub-categories via multiple attentive CNN networks. (5) **NPA** [34]: using attention networks with personalized attention queries to learn news and user representations. (6) **LSTUR** [1]: modeling short-term user interests from user’s recent clicked news via a GRU network and modeling long-term user interest via user ID embeddings. (7) **NRMS** [37]: modeling news content and user click behaviors via multi-head self-attention networks. (8) **KRED** [18]: learning representations for news from the entities in news and their neighbors in the knowledge graph via a graph attention network. (9) **FIM** [31]: matching user and news from texts of users’ clicked news and candidate news via CNN networks.

We repeat different experiments five times and list the average performance of different methods and corresponding standard deviations in Table 2. First, we can find **KIM** significantly outperforms other baseline methods which independently model candidate news and user interest without consideration of their relatedness, **LSTUR**, **NRMS** and **KRED**. This is because a user may be interested in multiple areas, and a candidate news may also contain multiple aspects and entities. Thus, it is difficult for these methods to accurately model user interest and candidate news since they are independently modeled in these methods. Different from these methods, our **KIM** can effectively incorporate relatedness between clicked news and candidate news at both semantic and knowledge levels for better interest matching. Second, **KIM** also outperforms baseline methods which model user interest with the consideration of candidate news, such as **DKN**, **DAN**. This is because candidate news may cover multiple aspects, and a user may only be interested in a part of them [33, 34]. However, these methods model candidate news without the consideration of the target user, which may be inferior for further matching candidate news with user interest.

**Table 2**: Results of different methods on the two datasets. We perform t-test on these results which shows **KIM** can significantly (at the level $p < 0.01$) outperform all baseline methods.

In this section, we conduct two ablation studies to evaluate the effectiveness of **KIM**. We first evaluate the effectiveness of different information, i.e., texts and knowledge, for news content modeling. Due to space limitation, we only show the experimental results on **MIND** in the following sections. The experimental results are shown in Fig. 6, from which we have several observations. First, removing semantic information (i.e., news texts) seriously hurts the performance of **KIM**. This is because texts usually contain rich information on news content and are vitally important for news content understanding [45]. Removing semantic information makes the news representations lose much important information and cannot model news content accurately. Second, removing knowledge (i.e., entities and their neighbors in the knowledge graph) in news content modeling also makes the performance of **KIM** decline significantly. This is because textual information is usually insufficient to understand news content [18, 32]. Fortunately, knowledge graph contains rich relatedness between different entities. Moreover, relatedness between entities in user’s clicked news and candidate news can provide rich information beyond semantic information for understanding user interest in candidate news. Thus, incorporating entity information into personalized news recommendation has the potential to improve the accuracy of recommendation.

Next, we evaluate the effectiveness of several important co-attention networks in **KIM** by replacing them with attention networks individually. Fig. 7 shows the experimental results, from which we have several findings. First, after removing the news co-attention network in user-news co-encoder, the performance of **KIM** gets worse. This is because user interest may be diverse, and only a
We evaluate the effectiveness of the knowledge co-encoder in KIM by comparing KIM with its variations which independently model clicked and candidate news from their entities. The first one is *Average*, which averages embeddings of entities in news and their neighbors within K hops as the knowledge-based news representations. The second one is *KCNN*, which learns knowledge-based news representations from entities and their neighbors via the KCNN network proposed in DKN [32]. The third one is *KGAT*, which uses a knowledge graph attention network proposed in KRED [18] to learn knowledge-based news representations from entities in news and their neighbors on the knowledge graph. Besides, all of these variations have the same text modeling method with KIM for fair comparisons. Fig. 8 shows the experimental results.

**4.4 Effectiveness of Knowledge Modeling**

We evaluate the effectiveness of the knowledge co-encoder in KIM by comparing KIM with its variations which independently model clicked and candidate news from their entities. The first one is *Average*, which averages embeddings of entities in news and their neighbors within K hops as the knowledge-based news representations. The second one is *KCNN*, which learns knowledge-based news representations from entities and their neighbors via the KCNN network proposed in DKN [32]. The third one is *KGAT*, which uses a knowledge graph attention network proposed in KRED [18] to learn knowledge-based news representations from entities in news and their neighbors on the knowledge graph. Besides, all of these variations have the same text modeling method with KIM for fair comparisons. Fig. 8 shows the experimental results.

**4.5 Influence of Hyper-parameters**

We evaluate the influence of an important hyper-parameter, i.e., the number of layers of the graph co-attention network, i.e., K, on the performance of KIM. Results are shown in Fig. 9, from which we have two observations. First, the performance of KIM first increases with the increase of K. This is because the relatedness between entities in clicked news and candidate news is informative for understanding user interest in candidate news. Besides, the GCAT network stacked for K layers can incorporate neighbors of entities in clicked news and candidate news within K hops for learning their representations. When K is too small, the relatedness between user’s clicked news and candidate news cannot be fully explored based on their entities, which is harmful to the recommendation accuracy. Second, when K is too large, the performance of KIM begins to decline. This is because when K becomes too large, too many multi-hop neighbors are considered when modeling the relatedness between user’s clicked news and candidate news. This may
Figure 9: Performance of KIM under different number of layers in the graph co-attention network, i.e., $K$.

bring much noise to the KIM model and hurt the recommendation accuracy. Thus, a moderate value of $K$, i.e., 1, is suitable for KIM.

4.6 Case Study

We conduct a case study to show the effectiveness of KIM by comparing it with LSTUR and KRED. We compare LSTUR since it achieves the best performance (Table 2) among baseline methods which model news content from plain news texts. Besides we compare KRED since it achieves the best performance (Table 2) among knowledge-aware baseline methods. We show the reading history of a randomly sampled user, and the news recommended by these methods in the same impression where the user only clicked one candidate news in Fig. 10, from which we have several observations. First, both KRED and KIM rank the candidate news clicked by the user higher than LSTUR. This is because it is difficult to understand the relevance of user interest and candidate news from the textual information of user’s clicked news and candidate news. However, since Miley Cyrus is a representative singer of country music, on the knowledge graph we can find that the entity “Country Music” in the first clicked news of the user has a link with the entity “Miley Cyrus” in the candidate news clicked by the user. Thus, based on the information provided by the knowledge graph, KRED and KIM can better understand the relevance of user interest and candidate news. Second, KIM ranks the candidate news clicked by the user higher than KRED. This is because both of these two entities have rich relatedness with many other neighbor entities on the knowledge graph. For example, besides “Miley Cyrus”, the entity “Country Music” also has relatedness with many other representative singers such as “Bob Dylan”, “Talyor Swift”, and so on. In addition, the entity “Miley Cyrus” also has relatedness with the entities of other areas which “Miley Cyrus” is skilled in, such as “rock music”, “dance-pop” and so on. However, it is difficult for KRED which independently model user’s clicked news and candidate news to accurately capture the useful relatedness between entities of clicked news and candidate news for interest matching. Different from KRED, KIM uses a knowledge co-encoder to interactively represent clicked news and candidate news from their relatedness at entity level, which can better capture user interest in candidate news than KRED.

Figure 10: News recommended to a randomly selected user by different methods. The news in blue is the news actually clicked by this user in this impression. The historical clicked news of this user are also shown in this figure.

5 CONCLUSION

In this paper, we propose a knowledge-aware interactive matching framework for personalized news recommendation (named KIM). The framework aims to interactively model candidate news and user interests for more accurate interest matching. More specifically, we first propose a graph co-attention network to model entities based on the knowledge graph by selecting and aggregating the information of their neighbors which are informative for interest matching. We also propose to use an entity co-attention network to interactively model clicked news and candidate news from relatedness between their entities. Besides, we propose to use a semantic co-attention network to interactively model clicked news and candidate news from semantic relatedness between their texts. Moreover, we propose a user-news co-encoder to learn candidate news-aware user representation and user-aware candidate news representation to better capture the relevance between user interest and candidate news. We conduct extensive experiments on two real-world datasets. The experimental results show that our KIM method can significantly outperform other baseline methods.
