(Dated: December 11, 2013)

The cosmological power spectrum of the coherent matter flow is measured exploiting an improved prescription for the apparent anisotropic clustering pattern in redshift space. New statistical analysis is presented to provide an optimal observational platform to link the improved redshift distortion theoretical model to future real datasets. The statistical power as well as robustness of our method are tested against 60 realizations of $8\,h^{-1}\text{Gpc}^3$ dark matter simulation maps mocking the precision level of upcoming wide–deep surveys. We showed that we can accurately extract the velocity power spectrum up to quasi linear scales of $k \sim 0.1\,h\,\text{Mpc}^{-1}$ at $z = 0.35$ and up to $k \sim 0.15\,h\,\text{Mpc}^{-1}$ at higher redshifts within a couple of percentage precision level. Our understanding of redshift space distortion is proved to be appropriate for precision cosmology, and our statistical method will guide us to righteous path to meet the real world.

PACS numbers: draft

I. INTRODUCTION

The emergence of a standard model for the Universe dominated by an unknown substance of dark materials has revolutionized our understanding of the Universe. Since the first firm evidence of dark energy in 1998 \cite{1,2}, there has been substantial observational and theoretical research aiming at understanding the true nature of this phenomenon. In recent years, many authors have started exploring the possibility that dark energy, and the observed acceleration of the expansion of the Universe, could be the consequence of an incomplete theory of gravity on cosmological scales and may require modifications to Einstein’s theory of General Relativity. The information of underlying science about the Universe is given by looking at structure formation on large scales.

Several authors have shown that by combining various probes of the large–scale structure in the Universe, it is possible to test the relationship between these quantities which, in the linear regime, can generally be described by two functions of time and scale \cite{3,4}. Those can be constrained through a combination of weak lensing and an independent probe of matter–energy fluctuations. This is motivated by the fact that the weak lensing experiments probe the geometrical potential of combination between curvature perturbation and Newtonian force, which determines the trajectories of photons through the Universe, while matter fluctuation measurements probe the Newtonian force alone determining local inhomogeneities of matter–energy.

The coherent motion of the galaxies opens a unique opportunity to access the fluctuations of the underlying matter density field \cite{3,24}. This technique relies on the redshift space distortions seen in galaxy surveys. Even though we expect the clustering of galaxies in real space to have no preferred direction, galaxy maps produced by estimating distances from redshifts obtained in spectroscopic surveys reveal an anisotropic galaxy distribution. The anisotropies arise because galaxy recession velocities, from which distances are inferred, include components from both the Hubble flow and peculiar velocities driven by the clustering of matter \cite{24,27}. Measurements of the anisotropies allow constraints to be placed on the rate of growth of clustering.

Measurements of coherent motion field from redshift distortion maps have been plagued by systematic uncertainties which have made their cosmological constraints uncompetitive compared to other probes of the Universe. The cosmological density and velocity field couple together and evolve nonlinearly. In addition, the mapping formula between the real and redshift space is intrinsically nonlinear. These nonlinearities prevent us from inferring the linear coherent motion from the redshift space clustering straightforwardly. Recently, an accurate theoretical model for the redshift distortion was proposed in \cite{28}. They take into account the fact that the linear squeezing and non–linear smearing effects on distorted maps are not separable to each other and develop a more elaborate description than simple factorized formulation. The derived correction terms at leading higher orders assist us to achieve better fit to simulated data. They also include non–linear corrections formulated using the closure approximation to predict the non–linear growth in density–density, density–velocity and velocity–velocity spectra. In this work, we assume a perfect cross–correlation between density and velocity fields at linear level to decompose the coherent motion spectra. Thus

sity power spectrum and its velocity counterpart.

Despite all theoretical efforts, the exact form of FoG effect is unknown. We adopt most common functional form of FoG effect, such as Gaussian or Lorentzian, and parameterize FoG effect using one-dimensional velocity dispersion representing the randomness of the motion which erases the correlation structure on small scales. The parameter space is extended to include this uncertainty of FoG effect in addition to the linear spectra of density and velocity fields, which were originally proposed by [29, 30]. We run MCMC routine to find best set of spectra and FoG parameter, and we find that coherent motion spectra are measurable at linear regime with good precision. Coherent motion spectra are measured at a couple of percentage accuracy with appropriate k cut-off.

The paper is organized as follows. In Sec. III we begin by introducing suggested theoretical models of redshift distortions. We then describe the statistical method to extract the coherent motion spectra. Using this method, Sec. III presents our main results on the measurements of power spectra is discussed. Finally, we conclude in Sec. IV.

II. METHODOLOGY

We first highlight analytical models for the redshift-space power spectrum. We then show our methodology of reconstructing the linear density and velocity power spectra from the two-dimensional power spectrum observed in redshift space.

A. Analytical models for the power spectrum in redshift space

At large scale, we expect that the density field as well as the velocity field are small perturbations to the homogeneous universe. When the higher-order contributions are negligibly small, the two-dimensional power spectrum in redshift space, $\tilde{P}(k, \mu)$, can be expressed as

$$\tilde{P}(k, \mu) = P^{\text{lin}}(k) + 2\mu^2 P^{\text{lin}}_{\delta\Theta}(k) + \mu^4 P^{\text{lin}}_{\Theta\Theta}(k),$$

where we denote by $\delta$ and $\Theta$ the density contrast and the velocity divergence, with the latter defined by $\Theta \equiv -(1 + z)\nabla v/H$. The auto- and cross-power spectra of the two fields in linear theory are expressed as $P^{\text{lin}}_{ij}(k)$, with $i$ and $j$ being either $\delta$ or $\Theta$. This formula describes the effect of coherent velocity flow towards overdensity at large scale (Kaiser effect). Because of this effect, the clustering pattern in redshift space is enhanced along the line-of-sight direction. If the gravitational law follows the general relativity, the three spectra are not independent, but related as

$$P^{\text{lin}}_{\delta\delta}(k) = f(z)P^{\text{lin}}_{\delta\delta}(k),$$

$$P^{\text{lin}}_{\delta\Theta}(k) = f^2(z)P^{\text{lin}}_{\delta\delta}(k),$$

where $f(z) = d \ln D_L(z)/d \ln a$ is the growth rate parameter, $D_L(z)$ being the linear growth rate. In this case, all the velocity information is contained in the parameter, $f(z)$, which is constant over wavenumber $k$.

However, the planned/ongoing galaxy redshift surveys as well as the existing large surveys mainly target weakly nonlinear scale, where the feature of BAOs is prominent. Moreover, by appropriately modeling this regime, we can in principle enlarge the range of wavenumber to be taken into account in the analysis, and improve the constraints on the gravitational law. Thus, we have to somehow incorporate nonlinearity to make maximum use of these surveys.

First of all, the cross- and auto-power spectra of the density and the velocity fields are naturally expected to receive nonlinear corrections. Another important effect arises from the random motion of galaxies. By combining these two effects, Scoccimarro [27] proposes the following formula

$$\tilde{P}(k, \mu) = \{P^{\text{lin}}_{\delta\delta}(k) + 2\mu^2 P^{\text{lin}}_{\delta\Theta}(k) + \mu^4 P^{\text{lin}}_{\Theta\Theta}(k)\} G^X(k\mu),$$

where the effect of random motion is captured by the factor $G^X(k\mu)$. Note that we have replaced the three linear spectra in Eq. (1), $P^{\text{lin}}_{ij}(k)$, with their nonlinear counterparts, $P_{ij}(k)$. In the original paper by Scoccimarro [27], the factor $G^X(k)$ is designed so that it accounts for the random motion of the galaxies at large scale, and he considers the Gaussian shape for this factor:

$$G^X(k\mu) = G^{\text{GAU}}(k\mu) = \exp\left\{-k\mu \sigma_v^2\right\},$$

where $\sigma_v$ denotes the dispersion of the one-point PDF of the velocity in one-dimension. At smaller scale, inside the cluster of galaxies, the virial motion of galaxies also give a suppression of the power spectrum in redshift space. This effect is called Finger-of-God (FoG), and can also be approximately described by multiplication of the factor $G^X(k\mu)$. A Lorentzian form of this factor has been frequently adopted based on the results of N-body simulations:

$$G^X(k\mu) = G^{\text{LOR}}(k\mu) = \frac{1}{1 + k\mu \sigma_v^2},$$

For convenience, we do not distinguish between these damping effects, and simply call them as FoG in this paper, although, strictly speaking, the former one at large scale has a different origin.

Recently, Taruya, Nishimichi & Saito [28] proposed a more accurate model for the redshift-space distortion. Motivated by the fact that the Kaiser and the FoG effects can not be separated, and should not be described as a factorisable form as in Eq. (1), they derived correction
terms which have long been overlooked. Their formula reads
\[ \tilde{P}(k, \mu) = \{ P_\delta(k) + 2\mu^2 P_\theta(k) + \mu^4 P_{\theta\theta}(k) \]
\[ + A(k, \mu) + B(k, \mu) \} G^X(k\mu), \]
where the full expressions for the terms \( A(k, \mu) \) and \( B(k, \mu) \) based on perturbation theory can be found in the Appendix \( A \) of that paper. Let us note some important features in the new terms. First, they include higher-order polynomials in \( \mu \) and \( f \): the \( A \)-term has a term which scales as \( f^3 \mu^5 \), while we have a \( f^4 \mu^5 \) contribution in the \( B \)-term. Thus, they become relatively important at \( \mu \simeq 1 \). Another point is that as these terms arise as a non-linear coupling between the density and the velocity fields, they are of the order \( \mathcal{O}(\{ P_{ij}^\lambda(k) \})^2 \).

We thus may able to omit them on linear scales.

B. Decomposition strategy

We now describe how we decompose the power spectrum in redshift space into spectra of density and velocity. Before that, let us introduce two useful quantities controlling the amplitude of the linear power spectra. We define

\[ P_{ij}^{\text{lin}}(k, z) = g^2_i(k, z) P_{ij}^{\text{lin}}(k, z_{\text{lss}}), \]
\[ P^{\text{lin}}_{\delta \theta}(k, z) = g^2_{\delta \theta}(k, z) P^{\text{lin}}_{\delta \theta}(k, z_{\text{lss}}), \]
where \( z_{\text{lss}} \) stands for the redshift at the time of the last scattering. The parameters, \( g_\delta \) and \( g_{\delta \theta} \), describe the growth rate of the density and the velocity fields from that epoch. Since the spectrum \( P^{\text{lin}}_{\delta \delta}(k, z_{\text{lss}}) \) is well constrained by observations of the CMB temperature anisotropy, the parameters solely capture the properties of the gravitational law, and are expected to be free from the assumptions in the initial condition.

In reconstructing the spectra, we first bin the power spectrum measured from simulations into bins of \( k \) and \( \mu \). Then, for the \( i \)-th bin of wavenumber \( k \), which we denote \( k_i \), we estimate \( P^{\text{lin}}_{\delta \delta}(k_i) \), \( P^{\text{lin}}_{\delta \theta}(k_i) \) and \( P^{\text{lin}}_{\delta \theta \theta}(k_i) \) based on the \( \mu \) dependence. We assume that linear \( \delta \) and linear \( \Theta \) are perfectly correlated, \( P^{\text{lin}}_{\delta \theta} = \sqrt{P^{\text{lin}}_{\delta \delta} P^{\text{lin}}_{\theta \theta}} \), and treat two parameters, \( g_\delta(k_i) \) and \( g_{\delta \theta}(k_i) \), as free parameters for the \( k_i \)-bin. In fitting \( P(k_i, \mu) \), we scale the spectra according to the parameters \( g_\delta \) and \( g_{\delta \theta} \):

\[ P^{\text{lin}}_{ij}(k_i) = \frac{g_i(k_i) g_j(k_i)}{g'^{\text{fid}}_i(k_i) g'^{\text{fid}}_j(k_i)} P^{\text{fid}, \text{lin}}_{ij}(k_i). \]

where quantities with subscript “fid” are computed for the fiducial cosmological model.

When we restrict the analysis to linear regime, the above procedure is expected to work properly. We further elaborate the procedure to correctly handle the nonlinearity. We adopt the closure approximation (Taruya & Hiramatsu [51]) to predict the nonlinear growth in the three spectra, \( P_{ij}(k) \). In doing so, we simply assume the fiducial GR cosmology used in running the simulations. We pre-compute the nonlinear corrections to the three spectra up to the second-order in the Born approximation:

\[ \delta P^{\text{fid}, \text{lin}}_{ij}(k) = P^{\text{fid}, \text{lin}}_{ij}(k) - P^{\text{fid}, \text{lin}}_{ij}(k), \]

while we allow to vary the linear part according to Eq. \( 10 \). By adding up linear and nonlinear parts, we have

\[ P_{ij}(k) = \frac{g_i(k) g_j(k)}{g'^{\text{fid}}_i(k) g'^{\text{fid}}_j(k)} P^{\text{fid}, \text{lin}}_{ij}(k) + \delta P^{\text{fid}}_{ij}(k). \]

Strictly speaking, the second term depends on the cosmological model as well as the gravitational law. As a first trial, however, we simply let this term unchanged from its fiducial value. In Sec. [5] we will relax the assumption to execute a more general analysis: we adopt a wrong cosmological model as the fiducial model, and see how well we can recover the true spectra.

We also scale the correction terms, \( A(k, \mu) \) and \( B(k, \mu) \) as follows. In every step of the fitting, given set of \( g_\delta(k) \) and \( g_{\delta \theta}(k) \), we compute their simple arithmetic means:

\[ g_\delta = \frac{1}{N_{\text{bin}}} \sum_i g_\delta(k_i), \quad g_{\delta \theta} = \frac{1}{N_{\text{bin}}} \sum_i g_{\delta \theta}(k_i), \]

where the subscript \( i \) runs over \( k \)-bins up to a maximum wavenumber, \( k_{\text{max}} \), and we denote the number of the bins by \( N_{\text{bin}} \). Again, we pre-compute the correction terms for the fiducial cosmology using the standard perturbation theory, which we denote \( A^{\text{fid}} \) and \( B^{\text{fid}} \), and scale them according to the average values of \( g_\delta \) and \( g_{\delta \theta} \):

\[ A(k, \mu) = A^{\text{fid}} \left( k, \mu; \frac{g_\delta}{g'^{\text{fid}}_\delta}, \frac{g_{\delta \theta}}{g'^{\text{fid}}_{\delta \theta}} \right), \]
\[ B(k, \mu) = B^{\text{fid}} \left( k, \mu; \frac{g_\delta}{g'^{\text{fid}}_\delta}, \frac{g_{\delta \theta}}{g'^{\text{fid}}_{\delta \theta}} \right). \]

In the above, the terms originated from \( \delta (\Theta) \) are multiplied by \( g_\delta / g'^{\text{fid}}_\delta \left( g_{\delta \theta} / g'^{\text{fid}}_{\delta \theta} \right) \).

We finally explain our strategy for the FoG factor. We try both Gaussian and Lorentzian functions, and we let \( \sigma_v \) as a free parameter. This parameter is determined by fitting globally the broadband shape of \( \tilde{P}(k, \mu) \).

In summary, our reconstruction strategy is as follows. We model the redshift-space power spectrum, \( \tilde{P}(k, \mu) \), as

\[ \tilde{P}(k, \mu) = \left\{ \left( \frac{g_\delta(k)}{g'^{\text{fid}}_\delta(k)} \right)^2 P^{\text{fid}, \text{lin}}_{\delta \delta} + \delta P^{\text{fid}}_{\delta \delta} \right\}
\[ + \mu^2 \left( \frac{g_{\delta \theta}(k)}{g'^{\text{fid}}_{\delta \theta}(k)} \right)^2 P^{\text{fid}, \text{lin}}_{\delta \theta \delta} + \delta P^{\text{fid}}_{\delta \theta \delta} \right\}
\[ + \mu^4 \left( \frac{g_{\delta \theta}(k)}{g'^{\text{fid}}_{\delta \theta}(k)} \right)^2 P^{\text{fid}, \text{lin}}_{\delta \theta \theta} + \delta P^{\text{fid}}_{\delta \theta \theta} \right\}
\[ + A^{\text{fid}} \left( k, \mu; \frac{g_\delta}{g'^{\text{fid}}_\delta}, \frac{g_{\delta \theta}}{g'^{\text{fid}}_{\delta \theta}} \right) + B^{\text{fid}} \left( k, \mu; \frac{g_\delta}{g'^{\text{fid}}_\delta}, \frac{g_{\delta \theta}}{g'^{\text{fid}}_{\delta \theta}} \right) \}
\times G^X(k\mu; \sigma_v), \]
where factors with the subscript “fid” are pre-computed for the fiducial cosmology, and $g_0(k_i)$ and $g_{θθ}(k_i)$ as well as $σ_v$ are free parameters. We show results for various cases in what follows. We include/exclude $A(k, μ)$ and $B(k, μ)$, we adopt Gaussian and Lorentzian for the FoG damping factor, and we vary the maximum wavenumber included in the analysis, $k_{\text{max}}$.

III. MEASUREMENTS OF LINEAR SPECTRA

A. The observed spectra $\tilde{P}(k, μ)$ from mock catalogues

For subsequent analysis, we use the dark matter distributions created by the simulations in Ref. [32]. The volume size of the $N$-body simulations is $(2048h^{-1}\text{Mpc})^3$, and we have 60 independent snapshots at each of the four output redshifts, $z = 0.35, 1, 2$ and $3$. The fiducial cosmological parameters of the simulation are given by $(Ω_m = 0.279, Ω_b = 0.165, Ω_m, Ω_k = 0, h = 0.701, σ_8 = 0.816, n_s = 0.96)$. The distribution of dark matter particles is modified according to their peculiar velocity to incorporate the redshift distortion effect. We adopt the distant-observer approximation and measure the power spectrum in $(k_\parallel, k_\perp)$ space, where subscripts ‘$\parallel$’ and ‘$\perp$’ denote perpendicular and parallel components to the line-of-sight.

The density fluctuation field is constructed by assigning the dark matter particles to $1024^3$ grids for the fast Fourier transformation (FFT) using the cloud-in-cell (CIC) method. We use bins in $k$ and $μ$ for the following analysis. $k$ is divided in $Δk = 0.01h\text{Mpc}^{-1}$ linearly equally spaced bins from $k = 0.01h\text{Mpc}^{-1}$ to $0.2h\text{Mpc}^{-1}$ and $μ$ is in 20 linear-bins from 0 to 1 with equal spacing. The averages of measured 2D power spectra in $(k, μ)$ coordinate are shown in Fig. 1. The Gaussian variance is used to derive errors for each bin shown as error bars in Fig. 1. $σ[\tilde{P}_{\text{ob}}(k, μ)] = \tilde{P}_{\text{ob}}(k, μ)\sqrt{2/N(k, μ)}$ where $N(k, μ)$ is number of modes in $(h^{-1}\text{Mpc})^3$ in Fourier space.

The overall amplitude of $\tilde{P}(k_i, μ_j)$ at $μ → 0$ is solely determined by $P_{gg}^{\text{lin}}(k_i)$. And the running of $\tilde{P}(k_i, μ_j)$ along $μ$ direction is determined by $P_{gg}^{\text{lin}}(k_i)$ about the pivot point of $\tilde{P}(k_i, μ_j = 0)$. Distinct contributions of $P_{gg}^{\text{lin}}$ and $P_{gg}^{\text{non-lin}}$ to the observed spectra lead us to simultaneously decompose both through data fitting to the observed $\tilde{P}(k_i, μ_j)$ in $k$ and $μ$ dimension. Additionally, non-perturbative effect is externally parameterized using $σ_v$ appearing in $G^X$, while the higher order loop corrections are expressed using the given linear spectra parameters of $P_{gg}^{\text{lin}}$ and $P_{gg}^{\text{non-lin}}$. Here parameterised one-dimensional velocity dispersion $σ_v$ is set to be a scale-independent free parameter.

We find best-fit parameter space of $P_{gg}^{\text{lin}}(k_i)$, $P_{gg}^{\text{non-lin}}(k_i)$ and $σ_v$ by minimizing $\chi^2$

$$\chi^2 = \sum_{i=i_{\text{min}}}^{i_{\text{max}}} \sum_{p=1}^{20} \sum_{q=1}^{20} [\tilde{P}_{\text{ob}}(k_i, μ_p) - \tilde{P}_{\text{fit}}(k_i, μ_p)] \times \text{Cov}_{pp}^{-1}(k_i) [\tilde{P}_{\text{ob}}(k_i, μ_q) - \tilde{P}_{\text{fit}}(k_i, μ_q)] ,$$

(16)

where $k_{\text{min}}$ is fixed to be $k_{\text{min}} = 0.01h\text{Mpc}^{-1}$, and best $k_{\text{max}}$ is determined in the following subsections. Off-diagonal elements of the covariance matrix are nearly negligible and those diagonal elements are written as

$$\text{Cov}_{pp}^{-1}(k_i) = \frac{1}{σ[\tilde{P}_{\text{ob}}(k_i, μ_p)]^2} .$$

(17)

We repeat this procedure for each 60 realization, and report the averages of best-fit values.

B. Decomposition of linear density–density spectra

We present the result of decomposition of $P_{gg}^{\text{lin}}$. Linear spectra of $P_{gg}^{\text{lin}}$ are determined at a few first bins about $μ = 0$ in which the orientation of correlated two point pairs is transverse. The observed $\tilde{P}_{\text{ob}}$ at those $μ$ bins are nearly equivalent to density–density spectra itself. The procedure to decompose $P_{gg}^{\text{lin}}$ is immune from all line-of-sight contamination described in Sec. III. Therefore density–density spectra are measured in high precision at arbitrary scale of $k$. But what we are interested in is measuring linear spectra of $P_{gg}^{\text{lin}}$. Unless the non-linear contribution in the decomposed $P_{gg}$ are separated, cross-correlation between density and velocity fields is not guaranteed to be perfect.

FIG. 1: The observed spectra of $\tilde{P}(k, μ)$ are presented at scales $0.03h\text{Mpc}^{-1} < k < 0.11h\text{Mpc}^{-1}$. Blue triangles represent averaged $\tilde{P}(k, μ)$ at given $k–μ$ bins from 60 realizations. The error bars are dispersions of measured values of 60 realizations divided by $\sqrt{60}$. 

The closure approximation in Eq. (11) is applied for extracting linear information out of measured $P_{\delta\delta}$. This approximation breaks down at specific scale of $k$. The upper bound of $k$ is investigated to uncover the limit of the closure approximation for density fields.

We use measured $P_{\delta\delta}(k, \mu)$ up to $k = 0.2 \, h \, \text{Mpc}^{-1}$ at $z = 0.35$. Then there are 400 measured $P_{\delta\delta}(k, \mu)$ at each realization of simulated maps. Those measured data are fitted by the parameter space of $(20P_{\delta\delta}^{\text{lin}} \cdot 20P_{\delta\delta}^{\text{lin}}, \sigma_v)$. In order to handle a large parameter space, we adopt Markov chain Monte Carlo (MCMC) methods which are a class of algorithms for sampling from probability distributions around equilibrium points.

Dashed curve in Fig. 2 represents the fiducial $P_{\delta\delta}^{\text{lin}}(k)$ in logarithmic scale. Black circle points in the top panel represent measured $P_{\delta\delta}(k_i)$ when non-linear correction terms of $\delta P_{ij}$ in Eq. (11) are nullified. Fractional errors against linear spectra of density fields are shown in the bottom panel of Fig. 2. Non-linearity of density fields in measured $P_{\delta\delta}(k_i)$ is observed when $k \geq 0.1 \, h \, \text{Mpc}^{-1}$. Measured $P_{\delta\delta}^{\text{lin}}(k_i)$ deviates from $P_{\delta\delta}^{\text{fid}}(k)$ by 10% at $k = 0.2 \, h \, \text{Mpc}^{-1}$. Blue triangle points represent measured $P_{\delta\delta}(k_i)$ including $\delta P_{ij}$. Seen at fractional error bars in the bottom panel, linear spectra of $P_{\delta\delta}^{\text{lin}}(k)$ are well reproduced within a couple of percentage uncertainties through $k = 0.2 \, h \, \text{Mpc}^{-1}$. The closure approximation in Eq. (11) for density fields is proved to be trustable at least by this limit of $k$.

Cross-correlation coefficient between density and velocity fields is not parameterized in this paper. Instead, we claim to probe linear spectra of density and velocity fields using this closure approximation. Our test for linearity of measured density spectra in this subsection is important to proceed next step of probing coherent motion spectra.

Additionally, measuring $P_{\delta\delta}^{\text{lin}}(k)$ is also precious information to probe distance measures. The important information about the evolution of the universe is imprinted on the large-scale structure of the universe. The broadband shape of the power spectrum provides the information about the horizon scale at the epoch of the matter–radiation equality. Although much of this information has been faded away due to the nonlinear process, the possible extension of distance measure detectability at bigger $k$ is worth being investigated in the following works.

C. Decomposition of coherent motion spectra

Results of $P_{\delta\delta}^{\text{lin}}$ decomposition are presented in this subsection. The running of $P_{\delta\delta}$ along the $\mu$ direction is caused by $P_{\delta\delta}^{\text{lin}}$, and pivoted from $P_{\delta\delta}$ at $\mu = 0$. The observed $P_{\delta\delta}$ are maximally affected by peculiar velocity when the orientation of correlation is radial, while minimally affected at transverse orientation of correlation. In the limit of $\mu \rightarrow 1$, $P_{\delta\delta}$ is significantly contaminated by
all non–linear smearing effects described in Sec. I. Hence, we develop an appropriate statistical tool to bridge the improved theoretical model to real datasets.

The statistical methodology to treat non–linear correction terms is described in Sec. II B in detail. In this method, the higher order loop correction terms are given theoretically, but the uncertainty due to FoG effect is phenomenologically parameterized. At scales in which the first order term of FoG dominates, the assumption of FoG effect is valid through fitting $\sigma_v$ with datasets. But beyond this quasi–linear cut–off, our statistical model is broken down. The decomposition of $P_{\Theta\Theta}^{\text{lin}}$ in our analysis is limited by the uncertainty of FoG effect at higher orders.

Using the simulated maps at $z = 0.35$, we find this upper bound of $k$ scales in which our assumption is valid. We test two different upper bounds of $k_{\text{max}} = 0.11 \, h \, \text{Mpc}^{-1}$ and $0.15 \, h \, \text{Mpc}^{-1}$. The blue triangle points in Fig. 3 represent the decomposed $P_{\Theta\Theta}^{\text{lin}}$ using $k_{\text{max}} = 0.11 \, h \, \text{Mpc}^{-1}$. The fiducial spectra are well decomposed.

The best fit $\sigma_v$ is $3.7 \, h^{-1} \, \text{Mpc}$ with $k_{\text{max}} = 0.11 \, h \, \text{Mpc}^{-1}$ which corresponds to about 10% non–perturbative contribution to $P_{\Theta\Theta}$ at $\mu = 1$. The detailed functional form of FoG is not crucial in our statistical method, because most FoG functions agree at the first order approximation. The decomposed $P_{\Theta\Theta}^{\text{lin}}(k)$ is not much dependent on types of FoG function, such as Gaussian or Lorentzian, in this test. Hereafter, Gaussian function is chosen for describing FoG effect.

When we increase $k_{\text{max}}$ beyond $k_{\text{max}} = 0.11 \, h \, \text{Mpc}^{-1}$, the measured $P_{\Theta\Theta}^{\text{lin}}(k)$ becomes underestimated [30]. The black circle points in Fig. 3 represents decomposed $P_{\Theta\Theta}^{\text{lin}}(k)$ with $k_{\text{max}} = 0.15 \, h \, \text{Mpc}^{-1}$. This test indicates that the unknown higher order terms of FoG effect become dominating above $k = 0.11 \, h \, \text{Mpc}^{-1}$. Beyond $k_{\text{max}} = 0.11 \, h \, \text{Mpc}^{-1}$, the first order approximation of FoG effect is not valid, and the decomposed $P_{\Theta\Theta}^{\text{lin}}$ start to be biased.

We compare fractional errors of decomposed $P_{\Theta\Theta}^{\text{lin}}(k)$ with the theoretical estimation using Fisher matrix analysis [13]. We do not marginalize the Fisher matrix with FoG effect. The estimated errors using $k_{\text{max}} = 0.11 \, h \, \text{Mpc}^{-1}$ are presented as thin blue curves in Fig. 3. When $P_{\Theta\Theta}^{\text{lin}}(k)$ is not correlated much with FoG effect at smaller $k$ of $k < 0.05 \, h \, \text{Mpc}^{-1}$, the observed and estimated errors agree to each other. But when $P_{\Theta\Theta}^{\text{lin}}(k)$ is affected much by FoG effect at $k \rightarrow 0.1 \, h \, \text{Mpc}^{-1}$, the observed fractional errors increase. The correlation between $P_{\Theta\Theta}^{\text{lin}}(k = 0.10 \, h \, \text{Mpc}^{-1})$ and $\sigma_v$ is presented in Fig. 4 using one realization of simulated maps out of 60. This high correlation causes the increasing fractional errors about a factor of 3.

Results in Fig. 4 present the contribution of higher–order polynomials in Eq. 10. The decomposed $P_{\Theta\Theta}^{\text{lin}}$ will be overestimated or underestimated without $A$ or $B$. The fractional errors in the bottom panel of Fig. 4 show the results, when higher–order polynomials are not
FIG. 6: Measured spectra of $P_{lin}^{\text{rot}}(k_i)$ are presented at higher redshift at $z = 1$, $z = 2$ and $z = 3$ in the top, middle and bottom panels respectively.

considered at all. It is the case of common practice using the simple combination of Kaiser’s model and FoG effect. We show that it is not sufficient for the future precision wide–deep surveys.

Additionally, we test our method against higher redshift data at $z = 1$, 2 and 3 in Fig. 6. The upper bounds of $k_{\text{max}}$ for these redshifts are larger than the low redshift of $z = 0.35$ as expected, since the damping scale of FoG effect becomes rather milder at higher redshift. We found that the linear velocity spectra $P_{\text{lin}}^{\text{rot}}$ are precisely measured up to $k_{\text{max}} = 0.12$, 0.14 and 0.18 $h$ Mpc$^{-1}$ at $z = 1$, 2 and 3, respectively.

IV. DISCUSSION

The decomposition results shown in previous section rely on an idealistic assumption that the non-linear corrections to the redshift-space power spectra, $\delta P_{ij}$, $A$ and $B$, are known a priori for the fiducial cosmology. Since these corrections must be computed for a given set of cosmological parameters, they might be sensitive to the underlying cosmological model and the decomposed power spectra could be biased if we adopt the wrong cosmological priors. In this section, we discuss the impact of wrong cosmological assumption on the decomposition of power spectra.

In principle, the on-going and upcoming CMB experiments will provide a way to precisely determine a set of cosmological parameters, from which we can compute the non-linear corrections. Because of the parameter degeneracies, however, the CMB observation alone cannot fully specify the cosmological model. This is indeed one of the main reasons why the precision measurements of the redshift-space distortions and/or baryon acoustic oscillations are highly desired to unlock the nature of late-time cosmic acceleration. Hence, a large statistical error of the cosmological parameters would cause an erroneous estimation of the non-linear corrections that potentially leads to a biased decomposition of the coherent motion spectra. To quantify the size of this, we consider wrong cosmological models, in which the density parameter of the dark energy $\Omega_v$ differs from the fiducial value by 3, 5 and 10%, keeping the equation-of-state parameter of dark energy fixed. To be precise, we adopt slightly larger values of $\Omega_v$, while we fix the spatial curvature $\Omega_k$, the spectral index $n_s$, the normalization of fluctuation amplitude at CMB scales $A_s$, and some combinations of the parameters, $\Omega_m h^2$ and $\Omega_b h^2$, since these are expected to be tightly constrained by the CMB observations. Then, we compute the non-linear corrections to the redshift-space power spectrum, and repeat the same analysis as examined in previous section.

Fig. 7 shows the decomposition results of the coherent motion spectra at $z = 0.35$. Here, we plot the fractional errors of the resultant spectra in the cases adopting larger values of $\Omega_v$. As anticipated, there appears a clear systematic trend that as increasing $\Omega_v$, the coherent motion spectra tend to deviate from the fiducial spectrum. Nevertheless, apart from $k \sim 0.1 h$ Mpc$^{-1}$, the resultant size of the bias is rather small. This is because we are basically looking at the scales where the contribution of the corrections terms is small, and even the 10% change of the cosmological parameter gives a little effect on the non-linear corrections. Also, a slight mismatch of the non-linear corrections can be partly absorbed into the FoG damping factor, which further reduces the impact of wrong prior assumptions. Since the uncertainty of the future constraint on $\Omega_v$ will not be as large as 10%, the results shown in Fig. 7 may be regarded as a very good news, suggesting that the coherent motion spectra would be decomposed successfully in a less biased manner.

V. CONCLUSION

We have presented an improved prescription to reconstruct coherent motion spectra from the matter power spectrum in redshift space, properly taking account of the non–linear effects of both the structure growth and redshift distortions. Statistical analysis is presented to bridge theoretical models of redshift distortion to real dataset. Based on the perturbation theory treatment, non–linear correction terms of higher-order polynomials and non–linear growth functions are appropriately included in the reconstruction analysis. Those contributions are proved to be influential even at linear scales, and measurements of coherent motion spectra are misled without it. On the other hand, non–perturbative correction term such as FoG effect is parameterized. Those
FIG. 7: Fractional errors of measured spectra of $P_{lin}(k_i)$ are presented at $z = 0.35$ using diverse templates at different cosmological models. Results with templates of $\Omega_v$ larger by 3%, 5% and 10% than true $\Omega_v$ are shown at top, middle and bottom panels respectively.

all knowns and unknowns in our analysis successfully reproduce fiducial spectra of coherent motion up to some limited scales. Although it is still steps away to achieve complete and practical observational tools measuring coherent motion spectra, results show that our analysis method righteous path to be developed to meet real world.
