ABSTRACT

The *Escherichia coli* MelR protein is a transcription activator that autoregulates its own promoter by repressing transcription initiation. Optimal repression requires MelR binding to a site that overlaps the melR transcription start point and to upstream sites. In this work, we have investigated the different determinants needed for optimal repression and their spatial requirements. We show that repression requires a complex involving four DNA-bound MelR molecules, and that the global CRP regulator plays little or no role.

INTRODUCTION

Repressors play an important role in the complex web of regulatory interactions that control transcription in *Escherichia coli*. Many repressors bind to sites that overlap key promoter elements and down-regulate promoter activity by preventing the binding of RNA polymerase (1). At some promoters, efficient down-regulation requires the repressor to be bound at tandem operators. In a number of instances, these operators are separated by more than 100 bp and it has been suggested that bound repressors interact, forming a repression loop in the intervening DNA (2,3). One of the best-studied examples is the AraC protein, an arabinose-trigerred transcription factor (4). In the absence of arabinose, transcription of the araC gene is repressed by two AraC molecules that bind to two DNA sites (O2 and I1) that flank the araC promoter and are separated by 210 bp (5). In this paper, we present a study of similar complex repression by a transcription factor that is related to AraC, the *E. coli* K-12 MelR protein, which represses transcription of its own gene, melR.

MelR is a member of the AraC-XylS family of bacterial gene regulatory proteins (6) and our previous studies have shown that MelR, together with the cyclic AMP receptor protein, CRP, regulates expression of the melAB operon that encodes products essential for melibiose metabolism (7). Melibiose triggers the formation of an activatory complex of four MelR molecules and one CRP dimer at the melAB promoter (8,9). In this complex, MelR binds to two pairs of DNA sites, sites 2 and 2’ and sites 1 and 1’, and CRP binds between the two pairs of sites (Figure 1A). This complex cannot form in the absence of melibiose because MelR, whilst binding to sites 2, 1 and 1’, is unable to occupy site 2’.

Expression of MelR is controlled by the melR promoter, which drives initiation of a divergent transcript from 237-bp upstream of the melAB transcript start point (10,11). Transcription of melR is completely dependent on cAMP-CRP binding to a DNA target that overlaps the promoter -35 region, and is autoregulated by MelR binding to a fifth target site, site R, that overlaps the melR promoter transcript start (Figure 1A). Like many members of the AraC-XylS family, MelR consists of an N-terminal ligand-binding domain connected, via a flexible linker, to an ~100 amino acid C-terminal DNA-binding domain (12,13). The DNA-binding domain, that is the defining feature of all AraC-XylS family regulators (6,14), contains two helix–turn–helix motifs which, when bound at operator targets, recognize different base sequences in adjacent major grooves in a specific orientation (15). The orientation of MelR binding at sites 2 and 2’ and sites 1 and 1’ has already been determined experimentally (16) and here we have investigated the orientation of MelR bound at site R.

Previously, we found that optimal MelR-dependent repression of the melR promoter occurs in the absence of melibiose, and requires MelR-binding site 2, centred between base pairs −174 and −175 (i.e. position

EcoRI–HindIII TB20 fragment carrying the *E. coli* *mel* operon regulatory region, described by Kahramanoglou *et al.* (13), illustrated in Figure 1A, together with the shorter TB10 derivative that lacks sequences upstream of the *melR* promoter. Derivatives of the TB20 fragment are illustrated in the figures and the complete base sequence of each fragment from the EcoRI site to the HindIII site is shown in Figure 1 of the online Supplementary Data. All DNA sequences were checked by the University of Birmingham Functional Genomics Service (http://www.genomics.bham.ac.uk/). By convention, in this paper, sequences are numbered with respect to the transcription start point of the *melR* promoter with upstream and downstream locations denoted by minus and plus prefixes, respectively. EcoRI–HindIII fragments carrying the *melR* promoter were cloned into pRW50, a broad host range low copy number *lac* expression vector (18), to create *melR* promoter::*lac* fusions. Plasmid pRW50 and derivatives were maintained in host strains with 35 μg/ml tetracycline. Experiments to measure effects of MelR *in vivo* used pJW15, which carries the wild-type *melR* gene, and an empty control pJW15Δ*melR* (13,19). Plasmid pJW15 and derivatives were maintained in host strains with 80-μg/ml ampicillin. The derivative of pJW15 encoding Val273 MelR is described in Grainger *et al.* (20). For *in vitro* experiments, *melR* promoter fragments were cloned into plasmid pSR that was maintained in host strains with 80-μg/ml ampicillin (21).

**Construction of promoter fragments**

Different promoter fragments were constructed by using PCR or megaprimer PCR (22). Table 1 of the online Supplementary Data lists the base sequence of all the oligo primers that were used in these constructions.

Starting with the TB20 fragment cloned in pSR, PCR was used to construct the shorter TB22 and T23 fragments using primers D51247 and D21970 for TB22, and D51248 and D21970 for TB23. The TB20 5C, 13G and 13T derivatives were constructed by megaprimer PCR using primers D51247 and D21970 for TB22, and D51248 and primer D21970 for TB23. The TB20 5C, 13G and 13T derivatives were maintained in host strains with 35 μg/ml tetracycline. Experiments to measure effects of MelR *in vivo* used pJW15, which carries the wild-type *melR* gene, and an empty control pJW15Δ*melR* (13,19). Plasmid pJW15 and derivatives were maintained in host strains with 80-μg/ml ampicillin. The derivative of pJW15 encoding Val273 MelR is described in Grainger *et al.* (20). For *in vitro* experiments, *melR* promoter fragments were cloned into plasmid pSR that was maintained in host strains with 80-μg/ml ampicillin (21).

**Materials and methods**

**Strains, plasmids and promoters**

In this work, we used the WAM1321 Δ*lac* Δ*melR* Δ*melA* strain of *E. coli* K-12 (13). The starting point was the −174.5, upstream of the *melR* transcript start point (17). By analogy with the action of AraC at the *araC* promoter, it was suggested that repression might simply be due to loop formation between two MelR molecules bound at site R and site 2 (17). Hence, in this work, we used *in vivo* and *in vitro* methods to investigate the determinants needed for MelR-dependent repression of the *melR* promoter. We show that the simple looping model is not applicable and that repression involves four bound MelR molecules, and we argue for a repression complex rather than a repression loop.
EcoRI–NcoI fragment was used together with a downstream NcoI–HindIII fragment generated using primers D21970 and D55274. For the +5 derivative, the same D31961/D55280 EcoRI–NcoI fragment was used together with a downstream NcoI–HindIII fragment generated using primers D21970 and D55276. To make the +41 and +91 inserts, first a derivative of TB22 carrying NcoI and SalI sites downstream of site 1 was constructed. To do this, a megaprimer was made using D56893 and D21970. The megaprimer was then used as a primer together with D31961 to generate the TB22 derivative. The TB22 +41 and TB22 +91 fragments were then constructed by insertion of blocks of sequence amplified from pBR322 and cloned as NcoI–SalI fragments. These fragments were generated after PCR using D56890 and D56891 (for +41) or D56892 (for +91). The TB28 fragment was generated by ligating upstream EcoRI–NcoI and downstream NcoI–HindIII fragments together. The upstream fragment was generated using primers D31961 and D58647 with TB22 cloned in pSR as a template. The downstream fragment was generated using primers D56848 and D21970 with TB22 +91 cloned in pSR as a template.

Measurement of promoter activities in vivo

Assays were performed in WAM1321 Δlac ΔmelR ΔmelA cells containing melR promoter:lac fusions on pRW50 derivatives, into which the different fragments carrying the melR promoter had been cloned. The cells also carried pJW15 encoding wild-type or mutant melR, or the control ‘empty’ vector plasmid, pJWAmelR, with no melR insert. Note that, in pJW15, melR is transcribed from the melR promoter, but that the upstream limit of melR promoter sequence is at position –59 upstream of the melR promoter transcript start (11,19). Thus, the melR promoter is not efficiently repressed by MelR, and MelR is over-expressed. Cells were grown in minimal medium, with fructose as a carbon source, as in our previous work (10), and the Miller method (23) was used to quantify β-galactosidase expression.

Purification and labelling of MelR for Fe-BABE experiments

MelR carrying a single cysteine at residue 269 was over-expressed, purified and labelled with Fe-BABE, and used in footprinting experiments, exactly as described by Grainger et al. (16). 32P end-labelled DNA fragments were used at a final concentration of 10 nM in buffer containing 60 mM HEPES, pH 8.0, 1.25 μM potassium glutamate and 40 μg/ml herring sperm DNA. Incubations contained 0.75 μM labelled MelR, 75 nM CRP and 200 μM cyclic AMP.

In vitro transcription, DNAase I footprinting and electromobility shift assays

These experiments were performed as described by Belyaeva et al. (8) using MelR purified by the method of Caswell et al. (24). For in vitro transcription experiments, caesium chloride purified supercoiled pSR plasmid carrying the TB22 or TB23 EcoRI–HindIII melR promoter inserts was used. Ten-nanomolar template was pre-incubated with purified CRP (200 nM; gift from Dr Georgina Lloyd) and cAMP (200 μM) and purified E. coli holo RNA polymerase (20 nM; purchased from Epicentre Biotechnologies, Madison) in 40 mM Tris-acetate pH 7.9, 10 mM MgCl2, 1 mM DTT, 100 mM KCl and 50 μg/ml BSA, either with or without 100 nM purified MelR. Transcription was started with the addition of 200 μM ATP, CTP and GTP, 10 μM 32P-labelled UTP and 100 μg/ml heparin and labelled RNA products were analysed on sequence gels. Transcripts were quantified using ImageQuant software.

For electromobility shift assays, we used EcoRI–HindIII fragments that had been purified from pSR carrying the TB22 or TB28 inserts and end-labelled with γ32P ATP at the HindIII end (19). For DNAase I footprinting, we used AattII–HindIII fragments that had been purified from pSR, carrying the TB22 or TB28 EcoRI–HindIII inserts, and end-labelled with γ32P ATP at the HindIII end. Different concentrations of MelR were pre-incubated for 5 min at 37°C with 4 nM of the DNA fragment in buffer containing 20 mM HEPES pH 8.0, 5 mM MgCl2, 50 mM potassium glutamate, 1 mM DTT, 0.5 mg/ml BSA and 0.05 mg/ml herring sperm DNA. Samples were treated with 3 μl of DNAase I (0.15 × 10−3 U/μl) for 5 min at 37°C and reactions were quenched with 10 vol of stop solution (0.3 M sodium acetate pH 5.2 and 10 mM EDTA). After phenol–chloroform treatment and ethanol precipitation, samples were re-suspended in gel-loading buffer (40% deionized formamide, 5 M urea, 5 mM NaOH, 1 mM EDTA, 0.025% bromophenol blue and 0.025% xylene cyanole), heated for 2 min at 90°C and then loaded on a 6% polyacrylamide sequencing gel. Footprints were scanned and quantified using Bio-Rad Quantity One software. To compare the affinity of MelR for site R in the TB22 and TB28 fragments, we measured the intensity of bands which result from cleavage at three different positions in site R, where cleavage is reduced by MelR binding. Intensities were measured in footprints obtained at different MelR concentrations, and lane-to-lane variation was accounted for by normalization to the intensities of bands at positions -35 and -65, that are unaffected by MelR binding. Comparison of the apparent concentration of MelR required for 50% protection at site R in the two fragments gives an estimate of relative binding affinities.

Atomic force microscopy (AFM) of MelR–DNA complexes

The DNA fragment used was generated by digestion of pSR carrying the TB22 EcoRI–HindIII fragment with SspI and NdeI. The fragment was purified using a Qiagen gel extraction kit and was eluted with 8 mM Tris–HCl, pH 8.5. MelR protein, purified by the Caswell method (24), was dialysed into buffer containing 50 mM Tris pH 7.6 and 600 mM NaCl, and complexes were formed by incubating 25 nM DNA fragment and 1 nM MelR in buffer containing 40 mM Tris pH 8.0, 0.1 M KCl, 50 mM NaCl and 0.5 mM EDTA for 10 min at room temperature. Samples (10 μl) were then deposited onto a freshly cleaved mica disk that had been treated with 2 mM NiCl2 (25). After incubation for 30 s, the surface was slowly rinsed with water and then allowed to dry under a gentle flow of nitrogen gas. Imaging was carried out with a Digital
Instruments Nanoscope IIIa Multimode AFM with a type E scanner (Veeco, Santa Barbara, CA, USA) in tapping mode. The cantilevers used were silicon-tapping probes with a spring constant of 34.4–74.2 N/m (Olympus, OMCL-AC160TS). The tapping set point was adjusted to minimize probe–sample interactions.

**RESULTS**

**Measurement of melR promoter activity: repression by MelR**

The starting point of this work was the TB20 EcoRI–HindIII fragment that covers the intergenic region between the divergent *E. coli* melR and melA genes and the translation start points. This fragment, together with the TB22, TB23 and TB10 truncated derivatives (Figure 1A), was cloned into pRW50, a lac expression vector, to generate melR promoter::lac fusions. To measure MelR-dependent repression of melR promoter activity, the pRW50 derivatives carrying the TB20, TB22, TB23 or TB10 fragments were transformed into WAM1321 ΔmelR Δlac cells containing either pJW15, encoding melR, or empty control vector, pJWΔmelR and β-galactosidase activities were measured. The results, illustrated in Figure 1B, show that, with the TB20 fragment cloned in pRW50, MelR causes a >5-fold reduction in β-galactosidase expression. Similar repression is seen with the TB22 fragment, in which melAB promoter sequences upstream of MelR-binding site 2 have been removed. In contrast, and in full agreement with the previous results of Wade et al. (17), the longer deletion in the TB23 fragment, that removes MelR binding site 2, results in a sharp reduction in the repression of the melR promoter by MelR. This reduced repression is unchanged by the longer deletion in the TB10 fragment.

Next, we attempted to reproduce MelR-dependent repression of the melR promoter in vitro. To do this, the TB22 and TB23 fragments were cloned into plasmid pSR such that the melR promoter was placed upstream of the bacteriophage λ oop factor-independent terminator. The recombinant plasmids were incubated with purified RNA polymerase holoenzyme and the activator, CRP, and radiolabelled nucleoside triphosphates were added. Analysis of the RNA products, shows that two discrete RNA species were produced (Figure 2). These correspond to the plasmid-encoded RNA-1 (108 nt) and a longer 138 base transcript starting at the promoter and Figure 2A shows the proposed 18-bp terminator. Note that the production of the 138 base RNA, but not RNA-1, is dependent on the inclusion of CRP in the assay (control experiments not shown). The experiment illustrated in Figure 2 shows that MelR has little or no effect on the synthesis of RNA-1 but represses synthesis of the transcript from the melR promoter. In accord with the in vivo assays (Figure 1B), repression is greater with the TB22 template, which includes MelR-binding site 2, than with the TB23 template.

**Orientation of MelR bound at site R**

Wade et al. (17) showed that MelR-binding site R is essential for MelR-dependent repression of the melR promoter, and Figure 3A shows the proposed 18-bp binding sequence compared to the consensus (7). In another study (16), it was found that base pairs 5 and 13 of the consensus sequence make important contacts with the side chains of amino acids N222 and R273, respectively, in the first and second helix–turn–helix motifs of the MelR DNA-binding domain. To confirm the location of site R and its orientation, three derivatives of the TB20 fragment, carrying base substitutions at position 5 or position 13 of the proposed site R sequence, were constructed (Figure 3A). MelR-dependent repression of the melR promoter carried by each derivative was then measured, as above. Results illustrated in Figure 3B show that the 5C substitution, which removes the consensus G base at position 5, reduced MelR-dependent repression. Furthermore, though the base at position 13 is the non-consensus A, substitution with a T also reduces MelR-dependent repression. In contrast, MelR-dependent repression is enhanced by the 13G change which introduces a consensus G.
biochemical approaches. First, we exploited the observation that the RV273 substitution in helix–turn–helix 2, permits MelR to recognize binding targets with a T at position 13 (20). Results from Figure 3C show that Val273 MelR gives a small enhancement in repression of the melR promoter carrying the 13T substitution in site R, compared to wild-type MelR. In contrast, repression of the 5C derivative is reduced with Val273 MelR. These data are consistent with a model in which helix–turn–helix 2 of MelR contacts the downstream part of site R, with residue 273 interacting with the base pair at position 13.

As expected, two sets of bands are observed. These result from hydroxyl radicals generated by Fe-ABE attached to residue 269 of purified MelR. For this experiment, 0.75 μM of MelR labelled with Fe-ABE was incubated with 10-nM DNA fragment, either without (lane 1) or with (lane 2) 10 mM melibiose (see Materials and methods section). The DNA fragment was purified from a restriction digest of plasmid pSR carrying the TBI0 melR promoter fragment and end-labelled at the HindIII site downstream of the melR promoter. The gel was calibrated with a Maxam–Gilbert G+A reaction (lane M). The location of MelR-binding site R is shown by vertical box and calibrations correspond to positions with respect to the melR transcript start point. (B) The figure shows the base sequence around the melR transcript start point (+1). The locations of DNA cleavage, resulting from hydroxyl radicals generated by Fe-ABE attached to residue 269 of MelR are indicated by stars. The 18-bp MelR-binding site R is enclosed by a box.
TB210, TB211 and TB222, respectively). The results are averages from promoter, the activity of MelR is expressed as a % of the activity from pJW15 that encodes MelR (+MelR: black filled bars), or the control indicated.

To investigate the possibility that the activator CRP is required for repression of the melR promoter by MelR, we constructed derivatives of the TB20 fragment carrying mutations that inactivated either or both DNA sites for CRP, and measured MelR-dependent repression (Figure 5A). Thus, TB201 is a derivative of TB20 in which the DNA site for CRP located between MelR site 1 and site 2 (CRP1) is inactivated. Results illustrated in Figure 5B show that MelR-dependent repression of the melR promoter is unaffected when CRP binding at this target is prevented. It is more complicated to investigate the DNA site for CRP located 41-bp upstream of the melR transcript startpoint (CRP2) because its inactivation leads to loss of melR promoter activity (11). Hence, we constructed the TB210 fragment, in which the melR promoter –10 hexamer element was changed from 5′ CATAAT 3′ to the consensus 5′ TATAAT 3′. This change confers partial CRP independence on the melR promoter (data not shown) and also causes a small reduction in MelR-dependent repression. We then constructed the TB211 fragment in which the CRP2 site was inactivated, and TB222, in which both DNA sites for CRP were inactivated (Figure 5A). Results illustrated in Figure 5B show that the MelR-dependent repression of the melR promoter in the TB210 fragment is unchanged in the TB211 and TB222 derivatives. This indicates that CRP binding plays little or no role in MelR-dependent repression of the melR promoter.

Other determinants for MelR-dependent repression of the melR promoter

To investigate the effects of altering the spacing between MelR-binding site R and the upstream sites, derivatives of the TB22 fragment with 5- or 10-bp deletions, or with 5-, 41- or 91-bp insertions were constructed (see Figure 6A and Materials and methods section). MelR-dependent repression of the melR promoter in each of the new constructs was measured as above and the results are illustrated in Figure 6B. The data show that repression is reduced by deletion of 5-bp but is restored in the 10-bp deletion construct. Similarly, repression is reduced by insertion of 5-bp but is restored, at least partially, by the 41- or 91-bp insertions. In our previous study (17), we reported that repression of the melR promoter by MelR was unaffected by point mutations in either site 1 or site 1′. However, it was subsequently found that, whilst these point mutations weakened MelR binding at these targets, their occupation by MelR was not prevented (Mohamed El-Robh, unpublished results). Hence, the TB28 fragment, in which both site 1 and site 1′ were replaced by unrelated sequence, was constructed (see Figure 6A and methods section). Results illustrated in Figure 6B show that MelR-dependent repression of the melR promoter in the TB28 fragment is reduced. This suggests that occupation of sites 1 and 1′ by MelR plays a role in repression.

CRP is not needed for MelR-dependent repression of the melR promoter

To investigate the possibility that the activator CRP is required for repression of the melR promoter by MelR, we constructed derivatives of the TB20 fragment carrying mutations that inactivated either or both DNA sites for CRP, and measured MelR-dependent repression (Figure 5A). Thus, TB201 is a derivative of TB20 in which the DNA site for CRP located between MelR site 1 and CRP1 is inactivated. Results illustrated in Figure 5B show that MelR-dependent repression of the melR promoter is unaffected when CRP binding at this target is prevented. It is more complicated to investigate the DNA site for CRP located 41-bp upstream of the melR transcript startpoint (CRP2) because its inactivation leads to loss of melR promoter activity (11). Hence, we constructed the TB210 fragment, in which the melR promoter –10 hexamer element was changed from 5′ CATAAT 3′ to the consensus 5′ TATAAT 3′. This change confers partial CRP independence on the melR promoter (data not shown) and also causes a small reduction in MelR-dependent repression. We then constructed the TB211 fragment in which the CRP2 site was inactivated, and TB222, in which both DNA sites for CRP were inactivated (Figure 5A). Results illustrated in Figure 5B show that the MelR-dependent repression of the melR promoter in the TB210 fragment is unchanged in the TB211 and TB222 derivatives. This indicates that CRP binding plays little or no role in MelR-dependent repression of the melR promoter.

Other determinants for MelR-dependent repression of the melR promoter

To investigate the effects of altering the spacing between MelR-binding site R and the upstream sites, derivatives of the TB22 fragment with 5- or 10-bp deletions, or with 5-, 41- or 91-bp insertions were constructed (see Figure 6A and Materials and methods section). MelR-dependent repression of the melR promoter in each of the new constructs was measured as above and the results are illustrated in Figure 6B. The data show that repression is reduced by deletion of 5-bp but is restored in the 10-bp deletion construct. Similarly, repression is reduced by insertion of 5-bp but is restored, at least partially, by the 41- or 91-bp insertions. In our previous study (17), we reported that repression of the melR promoter by MelR was unaffected by point mutations in either site 1 or site 1′. However, it was subsequently found that, whilst these point mutations weakened MelR binding at these targets, their occupation by MelR was not prevented (Mohamed El-Robh, unpublished results). Hence, the TB28 fragment, in which both site 1 and site 1′ were replaced by unrelated sequence, was constructed (see Figure 6A and methods section). Results illustrated in Figure 6B show that MelR-dependent repression of the melR promoter in the TB28 fragment is reduced. This suggests that occupation of sites 1 and 1′ by MelR plays a role in repression.

In vitro studies of MelR binding at the melR promoter

Our results show that MelR-dependent repression of the melR promoter is contingent on MelR binding to site R and is somehow modulated by MelR binding to upstream sites 2, 1 and 1′. Hence an electromobility shift assay (Figure 7) and a DNAase I footprinting assay (Figure 8) were used to investigate the occupation of the different binding sites at the TB22 and TB28 promoters by purified MelR.
The electromobility shift assay shows that MelR forms more stable complexes at the TB22 promoter than at the TB28 promoter (Figure 7). With the TB22 fragment, three clear shifted bands are observed. DNAase I footprinting (Figure 8) suggests that these bands are due to the successive occupation of MelR-binding sites 1 and 1', site 2 and site R. With the TB28 fragment, two weaker bands are seen (Figure 7). DNAase I footprinting shows that these result from MelR binding at site 2 and at site R, and quantification of scans of the gel shows that MelR binding to site R is weakened by at least 2-fold.

In the next experiments, we used AFM to visualize the binding of purified MelR to its targets in the TB22 promoter fragment, to attempt to establish whether DNA loop formation is a feature of the MelR binding. To do this, we exploited an 821-bp SspI–NdeI restriction fragment (Figure 9), which contains the 251-bp TB22 EcoRI–HindIII fragment (Figure 1A) with a short 190-bp extension upstream of the EcoRI site and a longer 380-bp segment downstream from the HindIII site. A mixture containing purified MelR and the DNA fragment was deposited onto a nickel chloride-treated mica surface and imaged by AFM using a cantilever in tapping mode. DNA fragments and MelR–DNA complexes were visualized, and typical examples are shown in Figure 9 (with more examples and data in Figure 2 of the online Supplementary Data). The cluster of the binding sites 2, 1 and 1' is at a distance from site R that would allow clear visualization of a DNA loop, but no sign of such loops was apparent in any of the 100 images of complexes that we examined. Instead, DNA-bound MelR appears as distinct oval foci at a distance of 59–64 nm from one end of the DNA fragments. While the length of the shorter DNA arm was approximately the same in all complexes, the length of the longer DNA arm appeared shorter in a third of the complexes. In the examples shown in Figure 9, the longer arm is 205 nm in one complex and 158 nm in the

The electromobility shift assay shows that MelR forms more stable complexes at the TB22 promoter than at the TB28 promoter (Figure 7). With the TB22 fragment, three clear shifted bands are observed. DNAase I footprinting (Figure 8) suggests that these bands are due to the successive occupation of MelR-binding sites 1 and 1', site 2 and site R. With the TB28 fragment, two weaker bands are seen (Figure 7). DNAase I footprinting shows that these result from MelR binding at site 2 and at site R, and quantification of scans of the gel shows that MelR binding to site R is weakened by at least 2-fold.

In the next experiments, we used AFM to visualize the binding of purified MelR to its targets in the TB22 promoter fragment, to attempt to establish whether DNA loop formation is a feature of the MelR binding. To do this, we exploited an 821-bp SspI–NdeI restriction fragment (Figure 9), which contains the 251-bp TB22 EcoRI–HindIII fragment (Figure 1A) with a short 190-bp extension upstream of the EcoRI site and a longer 380-bp segment downstream from the HindIII site. A mixture containing purified MelR and the DNA fragment was deposited onto a nickel chloride-treated mica surface and imaged by AFM using a cantilever in tapping mode. DNA fragments and MelR–DNA complexes were visualized, and typical examples are shown in Figure 9 (with more examples and data in Figure 2 of the online Supplementary Data). The cluster of the binding sites 2, 1 and 1' is at a distance from site R that would allow clear visualization of a DNA loop, but no sign of such loops was apparent in any of the 100 images of complexes that we examined. Instead, DNA-bound MelR appears as distinct oval foci at a distance of 59–64 nm from one end of the DNA fragments. While the length of the shorter DNA arm was approximately the same in all complexes, the length of the longer DNA arm appeared shorter in a third of the complexes. In the examples shown in Figure 9, the longer arm is 205 nm in one complex and 158 nm in the

The electromobility shift assay shows that MelR forms more stable complexes at the TB22 promoter than at the TB28 promoter (Figure 7). With the TB22 fragment, three clear shifted bands are observed. DNAase I footprinting (Figure 8) suggests that these bands are due to the successive occupation of MelR-binding sites 1 and 1', site 2 and site R. With the TB28 fragment, two weaker bands are seen (Figure 7). DNAase I footprinting shows that these result from MelR binding at site 2 and at site R, and quantification of scans of the gel shows that MelR binding to site R is weakened by at least 2-fold.

In the next experiments, we used AFM to visualize the binding of purified MelR to its targets in the TB22 promoter fragment, to attempt to establish whether DNA loop formation is a feature of the MelR binding. To do this, we exploited an 821-bp SspI–NdeI restriction fragment (Figure 9), which contains the 251-bp TB22 EcoRI–HindIII fragment (Figure 1A) with a short 190-bp extension upstream of the EcoRI site and a longer 380-bp segment downstream from the HindIII site. A mixture containing purified MelR and the DNA fragment was deposited onto a nickel chloride-treated mica surface and imaged by AFM using a cantilever in tapping mode. DNA fragments and MelR–DNA complexes were visualized, and typical examples are shown in Figure 9 (with more examples and data in Figure 2 of the online Supplementary Data). The cluster of the binding sites 2, 1 and 1' is at a distance from site R that would allow clear visualization of a DNA loop, but no sign of such loops was apparent in any of the 100 images of complexes that we examined. Instead, DNA-bound MelR appears as distinct oval foci at a distance of 59–64 nm from one end of the DNA fragments. While the length of the shorter DNA arm was approximately the same in all complexes, the length of the longer DNA arm appeared shorter in a third of the complexes. In the examples shown in Figure 9, the longer arm is 205 nm in one complex and 158 nm in the
other, and more examples are shown in Supplementary Figure 2. We noticed that the foci due to MelR binding were consistently bigger in the complexes with the shortened arm. In the images shown in Figure 9, the MelR focus is $15 \times 33$ nm across the shortest and longest axes of the oval in the complex with the shortened arm (right hand panel), compared to $9 \times 12$ nm in the other complex (centre panel). The simplest explanation for these observations, that is consistent with the location of sites in the DNA fragment (Figure 9), is that one type of complex contains 3 MelR molecules bound at sites 2, 1 and 1’ (centre panel), whilst the other contains 4 MelR molecules bound at sites 2, 1, 1’ and R (right panel). Thus there is an apparent progressive shortening of the end-to-end contour length of the DNA from the naked DNA to the MelR-2-1-1’ complex and to the MelR-2-1-1’-R complex. The shortening appears to be due to compaction of the DNA between bound MelR molecules rather than to looping. Note a loop formed from the DNA between MelR bound at sites 2, 1, 1’ and bound at site R would have a diameter of $\sim 13$ nm and this is well within the range of sizes visualized in other studies that used the same methodology (29–31).

**DISCUSSION**

At the *E. coli* arabinose operon regulatory region, transcription is repressed by the binding of two AraC molecules at two targets that are in the same orientation and separated by 210 bp, and a repression loop forms (4,5). Our aim in this work was to ascertain if such a simple model applied to MelR-dependent repression of the *melR* promoter. Our principal conclusion is that optimal repression does require MelR binding at distant targets, but it is more complicated, involving four molecules of MelR.

Expression of the *E. coli* K-12 *melAB* genes, which encode products essential for melibiose metabolism, depends on transcription activation by MelR and CRP, and is triggered by melibiose (7,9). Expression of the *melR* gene depends on transcription activation by CRP, whose activity depends on cyclic AMP (11). In conditions where CRP is active, but melibiose is absent, MelR is made and occupies binding sites 2, 1, 1’ and site R, but it cannot occupy site 2’ and activate the *melAB* promoter, and hence the system is ‘poised’ (8). In this situation, MelR autoregulates its own expression by binding to site R and repressing its own promoter, and this repression is reinforced by upstream binding of MelR. The simplest model is that repression is dependent on the formation of a complex involving more than one molecule of MelR and we have found that optimal repression requires the binding of MelR at sites R, 2, 1 and 1’, but not the binding of CRP at its targets. Since each target site accommodates one MelR monomer, and since MelR exists in solution as a monomer–dimer equilibrium (Mohamed el-Robh, unpublished data) we suppose that the final repressing complex is a dimer of MelR dimers.

We previously suggested that a MelR dimer simultaneously occupies site R and site 2, creating a repression loop and the effects of different insertions and deletions on MelR-dependent repression of the *melR* promoter (Figure 6) are consistent with this (17). However, we now argue for a repression complex rather than a repression loop, and, taken together, our results suggest that this complex involves MelR bound at sites 1 and 1’, as well as at site 2 and site R. Our AFM imaging data suggest...
that DNA regions between the MelR-binding sites remain associated with the MelR–DNA complexes rather than forced to loop out of the complexes. The nature of this DNA packaging in the MelR–DNA complexes is not clear and might involve MelR-induced DNA bending (32) or wrapping (33), but whatever its nature, the intervening DNA remains accessible to attack by DNAase I (Figure 8). Note that others have argued for repression by complexes rather than by simple loops, and the best example is that of the E. coli GalR repressor at the gal operon regulatory region, where ‘repressomes’ have been visualized (29,34). Thus, our results may have implications for understanding the pathway of DNA at other regulatory regions, such as the E. coli chbB regulatory region (35,36), where multiple bound factors are required for repression.

SUPPLEMENTARY DATA

Supplementary Data are available at NAR Online.

ACKNOWLEDGEMENTS

This work was supported by the Wellcome Trust, the UK BBSRC and the Darwin Trust of Edinburgh. We thank Stephanie Allen and Clive Roberts for use of the AFM, Georgina Lloyd for providing purified cyclic AMP receptor protein and for advice with in vitro transcription experiments, and Christine Webster for excellent technical support. Funding to pay the Open Access publication charges for this article was provided by the Wellcome Trust.

Conflict of interest statement. None declared.
