Preoperative alpha-fetoprotein slope is predictive of hepatocellular carcinoma recurrence after liver transplantation

Kathy Han BSc, George N Tzimas MD, Jeffrey S Barkun MD, Peter Metrakos MD, Jean I Tchervenkov MD, Nir Hilzenrat MD, Phil Wong MD, Marc Deschênes MD

BACKGROUND: Liver transplantation (LT) offers a possible cure for patients with hepatocellular carcinoma (HCC) and cirrhosis. However, tumour progression while on the waiting list and tumour recurrence after LT are common. The prognostic significance of various pre- and postoperative variables were investigated in regard to tumour recurrence, with an emphasis on the slope of preoperative serum alpha-fetoprotein (AFP) levels.

PATIENTS AND METHODS: Data from 48 patients who had HCC diagnosed preoperatively and underwent LT at the McGill University Health Centre (Montreal, Quebec) were reviewed retrospectively, and possible risk factors for tumour recurrence were examined.

RESULTS: Univariate analysis revealed a positive correlation between the preoperative AFP slope and vascular invasion (P=0.045), total tumour diameter at explant (P=0.040), Cancer of the Liver Italian Program score (P=0.017) and recurrence-free survival (P=0.028). Of the preoperative variables examined, only the preoperative AFP slope was identified as an independent predictor of tumour recurrence by multivariate analysis. Receiver operating characteristic analysis showed that the best discriminant cut-off value, calculated as the value of the maximized likelihood ratio, was preoperative AFP slope greater than 50 µg/L per month. At this cut-off, sensitivity was 36%, and specificity was 97%. Patients with a preoperative AFP slope greater than 50 µg/L per month had a much worse one-year recurrence-free survival rate than those with a preoperative AFP slope 50 µg/L per month or less (40% versus 90%, P<0.001).

CONCLUSIONS: These results suggest that the preoperative AFP slope is an important predictor of HCC recurrence after LT and should be examined in future studies of patients receiving LT for HCC.

Key Words: Alpha-fetoprotein slope; Hepatocellular carcinoma; Liver transplantation; Tumour recurrence

Hepatocellular carcinoma (HCC) is the fifth most common cancer worldwide (1) and its incidence has increased substantially in North America, Europe and Japan over the past 30 years (2-4). HCC results in approximately 500,000 deaths annually (1). Cirrhosis, mainly caused by hepatitis B and C viruses, and alcohol, is the dominant risk factor for HCC (4). Liver transplantation (LT) offers a possible cure for selected patients with HCC and cirrhosis, because it simultaneously removes both the tumour and the underlying cirrhosis (4).

With the steadily increasing waiting time for LT induced by the relative shortage of donors, an HCC has the opportunity to grow in size. Patients are therefore often offered the possibility of receiving preoperative adjuvant treatments in an attempt to delay progression and decrease the risk of recurrence. However, available treatments, such...
Han et al

as transarterial chemoembolization (TACE), intra-arterial chemotherapy, radiofrequency ablation and percutaneous ethanol injection, have a controversial impact on survival (5). Given the shortage of donors, it is thus important to examine factors that may predict the best results from LT to optimize the allocation of organs and survival rates.

Many studies have shown that the total tumour diameter in the explanted liver correlates with the risk of tumour recurrence (6-8). Because of the prolonged waiting time and the limited accuracy of imaging techniques, it is not unusual that the ultimate total tumour load of the explanted liver is more than had been previously predicted with preoperative imaging. Besides imaging, another readily available preoperative test is the serum alpha-fetoprotein (AFP). AFP is a widely used tumour marker for the detection, surveillance and monitoring of HCC. Although a significant proportion of HCCs secrete elevated levels of AFP, serum AFP levels can remain low (less than 20 µg/L) in up to 40% of cirrhotic patients who are not hepatitis B virus carriers (9,10). While some studies suggest that an elevated serum AFP level at the time of diagnosis is associated with poorer prognosis, others have failed to show such a correlation (11). Instead of focusing on single static values of AFP, we investigated the possible prognostic significance of the slope of serial AFP values measured during the waiting time before LT. We thus conducted a retrospective study of 48 patients who had HCC and underwent LT to examine possible risk factors for HCC recurrence, with emphasis on whether a correlation exists between the slope of pre-LT AFP measurements and various pathological and clinical outcomes.

PATIENTS AND METHODS

All patients who received LTs and were diagnosed with HCC at the McGill University Health Centre (Montreal, Quebec) between November 1991 and April 2003 were identified through the McGill University Transplantation Database. The diagnosis of HCC was confirmed in all cases by the histological findings of the explanted liver. Of the 76 patients identified, 13 were excluded because only a single preoperative AFP value had been obtained and, thus, the AFP slope could not be calculated. Two of the 13 patients developed recurrence. Patients whose tumours had not been identified preoperatively were defined as incidental (n=15), and were considered separately because the prognosis of the group is known to be better (6,12). The following data were collected for the remaining 48 nonincidental cases: age, sex, ethnic background, etiology of liver disease, Model End-Stage Liver Disease (MELD) score, pretransplantation treatment with TACE, percutaneous ethanol injection or intra-arterial chemotherapy, preoperative AFP values, results of the last imaging study before LT (number of lesions, total tumour diameter and portal vein thrombosis), the explant histology (number of lesions, total tumour diameter, tumour differentiation and vascular invasion), and the Cancer of the Liver Italian Program (CLIP) score (13). The MELD score reported in the present study reflects the liver disease itself (international normalized ratio, bilirubin and creatinine), without correction for HCC (14). Mortality data were assessed as of July 3, 2003. Subgroup analyses were also performed on patients according to whether the tumours had met the Milan criteria (n=9) (15).

Between 1997 and 2002, patients with HCCs exceeding the Milan criteria (ie, single tumour greater than 5 cm, or more than three small tumours) had been enrolled in a protocol where they had received TACE with carboplatin, iodized oil and gelatin pellets for three cycles (four to six weeks apart). Those on the waiting list for more than two months after three treatments received a fourth TACE treatment. Also between 1997 and 2002, patients on the LT wait list with a small single tumour received percutaneous ethanol injections.

Calculation of the preoperative AFP slope

Preoperative AFP levels were measured using the Centaur Automated Chemiluminescence System (Bayer Diagnostics, USA) for each patient, and individual slopes were plotted with AFP levels on the y axis and time on the x axis. The AFP slope was calculated using the ‘SLOPE’ function of Microsoft Excel 2002 (Microsoft Co, USA). All available AFP levels were included in the model, with the exception of four patients in whom the AFP slopes were biphasic (ie, increasing slope, then dramatically decreasing slope or vice versa). For those four patients, the AFP slope pattern closest to the time of transplantation was used in the subsequent analysis. For example, if a patient initially had a decreasing AFP pattern, but then an increasing AFP pattern closer to the time of transplantation, the positive AFP slope was used. While on the waiting list, the patients’ AFP levels had been scheduled every three months. However, depending on the patients’ compliance and time on the waiting list, the number of data points and interval between AFP measurements were not necessarily the same for all patients. A median of four data points (range two to 11) were used to calculate the AFP slopes. The median interval between individual AFP measurements was 42 days (interquartile range 90 days).

Statistical analysis

The relationship between the preoperative AFP slope and various postoperative variables and the type of preoperative treatment was examined using the Mann-Whitney U or Kruskal-Wallis test. Univariate and multivariate Cox regression analyses were performed to identify risk factors for tumour recurrence and survival using StatsDirect, version 2.3.1 (StatsDirect Ltd, United Kingdom). The receiver operating characteristic (ROC) curve was constructed using Analyse-it software (Analyse-It Software, Ltd, United Kingdom). The optimal cut-off was determined by the preoperative AFP slope that yielded the greatest maximum likelihood ratio. Survival curves were generated using the Kaplan-Meier method and differences between curves were tested using the log-rank test. P<0.05 was considered statistically significant.

RESULTS

Patient and tumour characteristics

The characteristics of all 48 patients and the subgroup of patients (n=29) who met the Milan criteria are summarized in Table 1. The median waiting time for LT was 30 days (range one to 1167 days). For many years, in Quebec, patients with HCC have been given waiting list priority for LT, even before implementation of the MELD score. The median MELD score was 24.4 (range 20 to 45). As of July 3, 2003, the median follow-up time was 3.7 years (range 0.3 to 11.6 years). Overall, a total of 17 recipients (35.4%) had died, whereas 11 recipients (22.9%) had developed HCC recurrence. Of the 29 patients who had met the Milan criteria, nine (31.0%) had died and four (13.8%) had developed HCC recurrence. The majority of the HCCs were moderately differentiated. Lymph nodes were identified in 24 explanted livers, and all of them were found to be lymph node negative through examination or resection at time of transplant.
Characteristics of patients and tumours

| Characteristics                          | All nonincidental cases (n=48) | Nonincidental cases that met the Milan criteria (n=29) |
|------------------------------------------|-------------------------------|-------------------------------------------------------|
| Age, years (mean ± SD)                  | 61±7                          | 60±7                                                  |
| Sex, male/female                        | 42/6                          | 23/6                                                  |
| Asian/non-Asian                          | 5/43                          | 4/25                                                  |
| Etiology of liver disease               |                               |                                                       |
| Hepatitis B virus                       | 12 (25.0)                     | 6 (20.7)                                              |
| Hepatitis C virus                       | 22 (45.8)                     | 14 (48.3)                                             |

| Moderately differentiated               | 31 (64.6)                     | 19 (65.5)                                             |
| Poorly differentiated                   | 5 (10.4)                      | 2 (6.9)                                               |

Except for the section on ‘Preoperative treatment for hepatocellular carcinoma (HCC)’, all other sections add up to 100%. *Some patients received more than one type of therapy; †Fourteen patients whose tumours exceeded the Milan criteria were initially treated with transarterial chemoembolization while on the waiting list between 1997 and 2002. Following treatment with transarterial chemoembolization, five patients’ tumours met the Milan criteria (according to the last preoperative imaging study).

Findings at the last imaging study before LT and tumour characteristics at explant are summarized in Table 1. The last preoperative imaging study was performed a median of 39 days (range one to 183 days) before LT. In other series (16-18), radiological findings were not able to accurately predict the number of lesions, nor the total tumour burden ultimately found at explant.

Preoperative AFP levels and slopes

The timing of preoperative AFP measurements and actual levels, as well as the number of patients with positive, zero and negative slopes are presented in Table 2. Three patients’ AFP levels remained normal (less than 10 µg/L), yet all three patients developed HCC recurrence. Only one of them met the Milan criteria. Two of these patients had a positive slope whereas the other had a slightly negative slope.

| Variables                        | P       |
|----------------------------------|---------|
| Meets Milan criteria             | 0.660   |
| Preoperative treatment           | 0.542   |
| Tumour differentiation*          | 0.171   |
| Number of lesions*               | 0.743   |
| Vascular invasion*               | 0.045   |
| Total tumour diameter (>7 cm versus >7 cm)* | 0.040   |
| Cancer of the Liver Italian Program score (0–2 versus 3–5) | 0.017   |
| Tumour recurrence                | 0.028   |

P<0.05 is considered to be significant. *Based on the pathology report.

The relationship between the preoperative AFP slope and various postoperative variables, and the type of pretransplantation treatment was examined by univariate analysis (Table 3). The preoperative AFP slope was found to be associated with a total tumour diameter at explant greater than 7 cm, vascular invasion, high CLIP score and HCC recurrence after LT. In contrast, there was no association between the last preoperative AFP level and tumour recurrence. The difference between the median of the last preoperative AFP level in patients with a recurrence (63 µg/L) compared with those without a recurrence (18 µg/L) was not statistically significant (P=0.54).

Cox regression analysis

Univariate Cox regression analysis was performed on possible factors associated with HCC recurrence, including the radiological and histological variables listed in Table 1, as well as the last preoperative AFP level and the preoperative AFP levels listed in Table 2. Of these 48 patients, total tumour diameter greater than 7 cm (based on the pathology reports), vascular invasion and the preoperative AFP slope were the only significant predictors of HCC recurrence (Table 4). Stratification of the AFP slope (greater than 0 µg/L per month, greater than 50 µg/L per month and greater than 100 µg/L per month) revealed a positive correlation between the magnitude of the slope and the risk of HCC recurrence in univariate analysis (Table 4). Factors found...
to be significant by univariate analysis were subsequently included as covariates in multivariate analysis using Cox’s proportional hazard regression (Table 5). Cox’s models were fit separately for AFP slopes greater than 0 µg/L per month, greater than 50 µg/L per month and greater than 100 µg/L per month. When AFP slope greater than 0 µg/L per month was used, vascular invasion and total tumour diameter greater than 7 cm (based on the pathology reports) were introduced as covariates, only AFP slope greater than 0 µg/L per month and total tumour diameter greater than 7 cm were independent predictors of HCC recurrence. When AFP slope greater than 50 µg/L per month was included instead of AFP slope greater than 0 µg/L per month, AFP slope greater than 50 µg/L per month and total tumour diameter greater than 7 cm were found to be independently associated with greater recurrence rates. Finally, inclusion of AFP slope greater than 100 µg/L per month as a covariate in place of AFP slope greater than 0 µg/L per month, resulted in AFP slope greater than 100 µg/L per month and total tumour diameter greater than 7 cm as independent factors influencing the risk of HCC recurrence (Table 5).

ROC analysis showed that the best discriminant cut-off value, calculated as the value of the maximized likelihood ratio, was AFP slope greater than 50 µg/L per month (Figure 1A). At this cut-off, sensitivity was 36%, specificity was 97%, positive predictive value was 80%, and negative predictive value was 84%. Figure 1B shows the recurrence-free survival of all LT recipients, and survival according to the value of the preoperative AFP slope (greater than 50 µg/L per month, or 50 µg/L per month or less). The one-year recurrence-free survival rate of patients with preoperative AFP slope greater than 50 µg/L per month was less than one-half in patients with AFP slope 50 µg/L per month or less (40% versus 90%, P<0.001).

### Subgroup analyses

A separate analysis was performed on patients whose tumours preoperatively met the Milan criteria (n=29). Among this subgroup of patients, on univariate analysis, only total tumour diameter greater than 7 cm (based on the pathology reports), AFP slope greater than 50 µg/L per month and AFP slope greater than 100 µg/L per month were found to be statistically significant by univariate analysis and were subsequently included as covariates in multivariate analysis using Cox’s proportional hazard regression (Table 5).
significant as predictors for HCC recurrence (Table 5). When multivariate Cox regression analysis was carried out on total tumour diameter greater than 7 cm (based on the pathology reports) and AFP slope greater than 100 µg/L per month, both were independent predictors of HCC recurrence. The optimal cut-off shown on the ROC analysis was also AFP slope greater than 50 µg/L per month (Figure 1C). At this cut-off, sensitivity was 50%, specificity was 96%, positive predictive value was 67%, and negative predictive value was 92%. The one-year recurrence-free survival rate of patients with preoperative AFP slope greater than 50 µg/L per month was almost one-third in patients with AFP slope 50 µg/L per month or less (33% versus 91%, P=0.002) (Figure 1D).

**Incidental cases (data not shown)**
The data for incidental cases (n=15) were not shown because realistically, it would not be feasible to monitor the preoperative AFP slope for patients who were not diagnosed with HCC.
DISCUSSION

We evaluated the prognostic value of the preoperative serum AFP slope compared with other preoperative variables often recorded in the assessment of patients with HCC undergoing LT. Although imaging techniques have improved over the period of the present study (12 years), when we examined patients who underwent LT after 1996 separately, the radiological variables were still not found to be good predictors of HCC recurrence. In fact, the only preoperative variable predictive of HCC recurrence was the preoperative AFP slope. Our finding that the preoperative AFP slope was a prognostic factor for recurrence was further validated by the direct relationship between the preoperative AFP slope and vascular invasion, total tumour diameter at explant (both postoperative variables) were included as covariates in multivariate analysis, it is not currently possible to accurately determine these preoperatively, and they are thus not applicable as preoperative selective criteria. In our current study, the only preoperative variable that is predictive of HCC recurrence is the preoperative AFP slope. The optimal AFP slope cut-off was determined based on the value of the maximized likelihood ratio. Although our sensitivity is not high, the specificity and negative predictive values are high. Ideally, the optimal AFP slope cut-off would have a high specificity, so as to not deny patients the right to an LT, should their risk of HCC recurrence be low. Future larger studies are needed to confirm the optimal AFP slope cut-off for predicting HCC recurrence.

CONCLUSION

As the incidence of HCC, the demand and waiting time for LT continue to increase, it is important to identify prognostic levels less than or equal to 20 µg/L and those with AFP levels greater than 1000 µg/L. Shorter survival was also associated with AFP levels greater than 8.5 µg/L (24), 20 µg/L (25) and 400 µg/L (13), and while Figueras et al (26) and Shetty et al (27) found AFP levels greater than 300 µg/L to be associated with recurrence, Mazzalferro et al (15) did not observe such correlation. The innovative finding in the present study is that, although the absolute preoperative value of AFP is not a predictor, the slope of the preoperative AFP levels is a very strong independent predictor of HCC recurrence.

The present study has a few shortcomings. The retrospective nature of the current study is a weakness, because it may be subjected to bias or confounding variables. In addition, while a median waiting time of 30 days for the entire cohort may appear short, patients with HCC have traditionally been given waiting list priority for LT in Quebec. The median waiting time is prolonged to 136 days for patients who underwent LT after 2000, reflecting the recent shortage of organs. However, our short wait time may become more relevant as Canada moves toward using a MELD-like system for prioritizing organ allocation.

The three-year recurrence-free survival rate of patients with nonincidental tumours is 75%. While this may seem low, our cohort contains some patients whose tumours did not meet the Milan criteria. In fact, in Figure 1D, the incidence of nonincidental cases is higher than the 60% recorded by the International Tumour Registry (6). Moreover, the five-year recurrence-free survival rate of those who met the Milan criteria is 85%, which is comparable with that of other studies (15,28). Our patient population is not homogeneous because of the use of pre-LT treatment between 1997 and 2002. Over that period, we had been carrying out a study to determine the efficacy of TACE in patients with tumours exceeding the Milan criteria (29). Subgroup analyses, however, show that whether we analyzed tumours outside of the Milan criteria, or those tumours that met the Milan criteria, the preoperative AFP slope is still strongly predictive of tumour recurrence. The preoperative AFP slope is also an independent predictor of HCC recurrence both for patients who did and did not receive preoperative therapy. Although preoperative therapy may be a confounder in the present study (as it may affect the AFP level), this is actually desirable. For patients who respond to preoperative therapy, decreasing AFP slope may be a better predictor of HCC recurrence than treatment response itself.

While vascular invasion and total tumour diameter at explant (both postoperative variables) were included as covariates in multivariate analysis, it is not currently possible to accurately determine these preoperatively, and they are thus not applicable as preoperative selective criteria. In our current study, the only preoperative variable that is predictive of HCC recurrence is the preoperative AFP slope. The optimal AFP slope cut-off was determined based on the value of the maximized likelihood ratio. Although our sensitivity is not high, the specificity and negative predictive values are high. Ideally, the optimal AFP slope cut-off would have a high specificity, so as to not deny patients the right to an LT, should their risk of HCC recurrence be low. Future larger studies are needed to confirm the optimal AFP slope cut-off for predicting HCC recurrence.

CONCLUSION

As the incidence of HCC, the demand and waiting time for LT continue to increase, it is important to identify prognostic
factors for postoperative HCC recurrence to allocate organs efficiently. Despite technological advancement, the accuracy of preoperative imaging studies has remained limited. The present study shows that the preoperative AFP slope, which is easily obtained clinically, can be a useful preoperative predictor of tumour recurrence following LT. This predictor variable should be examined in future studies of outcome following LT for HCC.
