One important way to characterize the states having a gauge symmetry spontaneously broken over multibands should be to look at their collective excitation modes. We find that a three-band system has multiple Leggett modes with significantly different masses, which can be classified into different dynamical classes according to whether multiple inter-band Josephson currents add or cancel. This provides a way to dynamically characterize multiband superconductivity while the pairing symmetry is a static property.

PACS numbers: 74.20.-z,03.75.Kk

Introduction — Superconductivity and superfluidity, with their spontaneous broken gauge symmetry, harbor unexpected fascinations. Specifically, the seminal discovery of the iron-based superconductor$^1$ has kicked off renewed interests in multiband superconductivity. There, the gauge-symmetry breaking involves multiple bands, so the ground state is expected to possess the features that can occur only in multiband systems, such as the $s_{±}$ wave pairing proposed for the iron-based superconductor$^2$. Even more interesting are excited states, especially the collective excitations of condensate phases associated with the broken gauge symmetry$^3$. For two-band superconductors, there is a classical 1966 work by Leggett, who has shown that a two-band superconductor accommodates a special collective excitation, now called Leggett’s mode, emerging as an out-of-phase mode between different superfluids$^4$. The Leggett’s mode was experimentally detected in a two-band superconductor, MgB$_2$ (Ref.$^5$) via the Raman scattering$^6$.

However, little is known as to what happens to the collective modes when there are three or more bands. In fact, despite intensive studies on the gap function symmetries in the ground states for various classes of superconductors, dynamics of collective excitations in multiband systems has yet to be systematically investigated. The question is becoming increasingly realistic, since the iron-based superconductors, for instance, have been revealed to have a five-band structure, where three bands contribute to both the Fermi surface and the gap function$^2$, as subsequently experimentally examined$^7$. To study the dynamics of collective modes in multiband systems is thus expected to be a new avenue together with unconventional pairing symmetry.

The purpose of the present paper is to examine, in general, whether a novel class of Leggett’s modes indeed exists specifically in superconductors and superfluids that have three or more bands, which should shed light on dynamics of multiband condensates. Naively, one might expect that the two- and three-band cases may be similar. Here, however, we shall show, on the basis of an effective action for the phase fluctuations, that multiband superfluids having three or more bands are in fact unique in that there exist multiple Leggett’s modes classified by a dynamical class introduced here. The distinction between the dynamical classes come from the presence of multiple inter-band Josephson couplings, whose additive and subtractive combination to the effective action are, respectively, classified as class “even” and “odd.” The two Leggett’s modes in the class odd are predicted to have significantly different masses, which is testable and serves to characterize multiband superconductors.

Formulation — Let us start with a model for multiband superfluidity/superconductivity. We take the simplest possible Bardeen-Cooper-Schrieffer type Hamiltonian density for an $N$-band superfluid, assumed to be neutral here, is given as $\hat{H}(r) = \hat{H}_{\text{kinetic}}(r) + \hat{H}_{\text{pairing}}(r)$ with $\hat{H}_{\text{kinetic}} = \sum_{i=1}^{N} \sum_{\sigma} \epsilon_{i\sigma}(\mathbf{r}) \hat{\psi}_{i\sigma}^\dagger \hat{\psi}_{i\sigma}$ where the dispersion $\epsilon_{i\sigma}(\mathbf{k})$ is assumed to be parabolic with $h = 1$, while $\hat{H}_{\text{pairing}} = -\sum_{i,j=1}^{N} g_{ij} \hat{\psi}_{i\uparrow}^\dagger \hat{\psi}_{j\uparrow} \hat{\psi}_{i\downarrow} \hat{\psi}_{j\downarrow}$. Here $\hat{\psi}_{i\sigma}$ ($i = 1, 2, \ldots, N$) is the field operator for the $i$th band in a superconductor or $i$th atomic species in an atomic gas, and $g_{ij} = (g_{ij})$ the pairing matrix, taken to be positive-definite, and we drop its $\mathbf{k}$-dependence. While $\mathbf{g}$ may come from (the short-range part of) the electron correlation, we ignore the Coulombic part of the interaction, since the mass of Leggett’s modes is not affected by the Anderson-Higgs mechanism, although the group velocity of the mode reflects the Coulomb interaction in superconductors as shown in Ref.$^8$ for $N = 2$. While $\hat{H}_{\text{pairing}}$ with $\mathbf{k}$-dependence dropped, as is done in Leggett’s original treatment, is too simple to examine complicated band structures as in the iron-based superconductors, we should initially know the basic physics for collective excitations in multiband superfluidity/superconductivity in the simplest case.

The grand partition function is given, with the imaginary-time functional integral method,
in terms of a set of auxiliary fields $\Delta^{(i)}$ as

$$Z = Z_0 \int \prod_{i=1}^{N} \mathcal{D} \Delta^{(i)} e^{-S_{\text{eff}}}.$$  

Here the effective action is

$$S_{\text{eff}} = \int_0^\beta \mathbf{d} \tau \sum_{i,j=1}^N \Delta^{(i)}(\mathbf{G}^{-1})_{ij} \Delta^{(j)} - \sum_{i=1}^N \text{Tr} \ln \mathcal{G}_{0,i,i} - \sum_{i,j=1}^N \text{Tr} \ln \mathcal{G}_{i,j}^{-1},$$

where we assume the inverse $\mathbf{G}^{-1}$ is well-defined (i.e., $\det \mathbf{G} > 0$). $Z_0$ is the partition function for the non-interacting system, and $\beta$ the inverse temperature. $\mathcal{G}_i$ is Green’s function in the Nambu representation for the $i$th-band, which satisfies

$$\mathcal{G}_i^{-1} = \mathcal{G}_{0,i,i}(\mathbf{I} - \mathcal{G}_{i,i})^{-1}$$

where $\mathcal{G}_{0,i,i}$ is the free-fermion Green’s function, $\mathbf{I}$ the unit matrix, and $\mathcal{G}_{i,i}$ the inverse of the pairing matrix ($\mathbf{G}^{-1}$), and we shall see that the non-zero off-diagonal elements of $\mathbf{G}^{-1}$ determine the Leggett’s modes.

With this effective action the static gap equation reads

$$\Delta_i = \sum_{j=1}^N g_{ij} \Delta_j N_j \int_0^\infty d\xi \tanh(\beta E_j/2),$$  

where $E_i \equiv \sqrt{\omega_i^2 + |\Delta_i|^2}$, $\omega_i$ a cut-off frequency, and $N_j$ the density of states (DOS) of the $j$th fermion on the Fermi surface. Here, we assume that each of the $\Delta^{(i)}$'s is constant (an s-wave). We can then look at the phase $\varphi^{(i)}_0$ in $\Delta_i = |\Delta_i| e^{i\varphi^{(i)}_0}$. The gap functions on different bands can take either the same or opposite signs, i.e., the phase difference, $\varphi^{(i,j)}_0 \equiv \varphi^{(j)}_0 - \varphi^{(i)}_0$, takes either 0 or $\pm \pi$ and should obviously satisfy $\sum_{i=1}^N \varphi^{(i,i+1)}_0 \equiv 0 \mod 2\pi$ with $\varphi^{(N+1)}_0 \equiv \varphi^{(1)}_0$, as depicted in Fig. 1(a).

Let us derive an effective action for the fluctuations in the superfluid phase to single out the collective dynamics at zero temperature. We first decompose the phase $\varphi^{(i)}_0 + \varphi^{(i)}$, into the equilibrium $\varphi^{(i)}_0$ (as obtained in the mean-field gap equation) and the phase fluctuation $\varphi^{(i)}$. Around the solution of Eq. (1), we obtain an action,

$$V_{\text{interband}} = \int_0^\beta \mathbf{d} \tau \int d\tau V_{\text{interband}} + \sum_{i=1}^N \sum_{m=1}^\infty \text{Tr} \left( \mathcal{G}_{i,m}^{-1} \right)^m / m,$$

where

$$V_{\text{interband}} = \frac{1}{2} \sum_{i<j} \eta_{ij} \lambda_{ij} \left[1 - \cos(\varphi^{(j)}_0 - \varphi^{(i)}_0)\right],$$  

$$\eta_{ij} = \cos(\varphi^{(i,j)}_0 + \kappa_{ij}), \quad \lambda_{ij} = 4 |(\mathbf{G}^{-1})_{ij}| |\Delta_i| |\Delta_j|, \quad \kappa_{ij} = \text{sgn}(\varphi^{(i,j)}_0),$$

comprises a sum of Josephson-couplings between the phases of different superfluid gaps that represents the inter-band Josephson currents caused by the relative phase fluctuations. We mention that the inter-band Josephson couplings are analogous quantities with the standard Josephson couplings but derived in non-perturbative manner. In the above expression, the constraint $\varphi^{(i,j)}_0 = 0$ or $\pm \pi$ is used, and $\kappa_{ij} = 0$ or $\pi$ the sign of $(\mathbf{G}^{-1})_{ij}$, i.e., $e^{i\kappa_{ij}} \equiv -\text{sgn}(\mathbf{G}^{-1})_{ij}$. The primed quantities are gauge-transformed, i.e., $\mathcal{G}'_{0,i}(x;x') \equiv \hat{U}_i(x)\mathcal{G}_{0,i}(x;x')\hat{U}_i^\dagger(x')$, where $\hat{U}_i = e^{-i\varphi^{(i)}_0 - \varphi^{(i)}_0/2}$ and $x \equiv (\tau, r)$, with the Dyson equation transformed into

$$\mathcal{G}'_{i}^{-1} = \mathcal{G}_{0,i}^{-1}(\mathbf{I} - \mathcal{G}_{0,i})^{-1}.$$  

**Parity in the inter-band Josephson couplings** — Let us begin with a trivial two-band ($N = 2$) case, which is relevant to the superconductivity in MgB$_2$. Equation (3) then reduces to

$$V_{\text{interband}} = \left(\eta_{12}\lambda_{12}/2\right)(1 - \cos(\varphi^{(2)}_0 - \varphi^{(1)}_0))$$

with a single inter-band Josephson coupling. The sign of $-(\mathbf{G}^{-1})_{21}$ is equal to that of $g_{12}$. Hence $\kappa_{12} = 0$ when $g_{12} > 0$, for which $\varphi^{(1,2)}_0 = 0$ for $V_{\text{interband}}$ to give a stable gap solution according to Eq. (4). Similarly, $\kappa_{12} = \varphi^{(2)}_0 = \pi$ when $g_{12} < 0$. Thus we always have $\eta_{12} = 1$, which implies that the sign of $g_{12}$ is totally irrelevant to the spectrum of collective modes in the two-band case, as noted in Refs. 4-8.

We now turn to the three-band case with $N = 3$. We have three kinds of the inter-band Josephson currents as schematically depicted in Fig. 1(b). In this case the set of the signs of the couplings $(\eta_{12}, \eta_{23}, \eta_{31})$ can be classified into: (i) all the signs positive, (ii) two positive, one negative, (iii) one positive, two negative, and (iv) all negative. We note that, when two or three $\eta_i$'s are negative, the Hessian matrices associated with $V_{\text{interband}}$ always have negative eigenvalues at $(\varphi^{(1)}_0, \varphi^{(2)}_0, \varphi^{(3)}_0) = (0, 0, 0)$, which implies that the solution of Eq. (1) is not a stable minimum of $S_{\text{eff}}$. We can thus exclude cases (ii) and (iv). Table I.

| class $\eta_{12}, \eta_{23}, \eta_{31}$ | parity of $p_{\varphi_0}$ | parity of $p_{\varphi_0}$ |
|-------------------------------------|------------------------|------------------------|
| even $(1, 1, 1)$                    | even                   | even                   |
| odd $(1, 1, -1)$                    | odd                    | even                   |
| odd $(1, -1, 1)$                    | odd                    | even                   |
| odd $(-1, 1, 1)$                    | even                   | even                   |

**FIG. 1:** Schematic diagrams for $N = 3$ for (a) the differences in the superfluid phases in equilibrium $\varphi^{(i)}_0$ and (b) the inter-band Josephson coupling for the phase fluctuation $\varphi^{(i)}$ around the equilibrium (where arrows represent the phase difference associated with the inter-band Josephson current).
stable solution of Eq. (1) for class odd, where one of \( \Delta_3 \) depends on all the above possibilities for \( \Delta \). Thus the class for reversing \( q \) is given by
\[
q = \begin{cases} 
\pi, & \text{odd class} \\
0, & \text{even class}
\end{cases}
\]
\( \text{even class} \)
\[
p_\xi \equiv \kappa_{12} + \kappa_{23} + \kappa_{31} \mod 2\pi.
\]
Since \( \kappa_{ij} = 0 \) or \( \pi \), we have either \( p_\xi = \pi \) or \( 0 \), which defines the parity "even" and "odd" classes, respectively. For the phases \( \phi_0 = (\phi_0^{(1,2)}, \phi_0^{(2,3)}, \phi_0^{(3,1)}) \), we have four possible cases, \( \phi_0 = (0, 0, 0), (0, \pi, \pi), (0, \pi, -\pi), \text{ or } (0, -\pi, \pi) \) as seen in Fig.[I]a, where we assume \( \phi_0^{(1,2)} = 0 \) without a loss of generality. The first case corresponds to an s-wave with no sign change, while the other sign-reversing s-waves. If we define \( p_{\xi'} \equiv \phi_0^{(1,2)} + \phi_0^{(2,3)} + \phi_0^{(3,1)} \mod 2\pi \), we have always \( p_{\xi'} = 0 \).

In the even class, in which all \( \eta_j \)'s are 1, we find, for all the above possibilities for \( \kappa \) and \( \phi_0 \), that the class even occurs only when \( p_{\xi} \equiv 0 \). On the other hand, the class odd, where one of \( \eta_j \)'s is -1, should satisfy \( p_{\xi} = 1 \). Thus the class for \( \{ \eta_j \} \) are completely characterized by the parity of \( p_{\xi} \) alone, as summarized in Table [II]. We remark that \( \text{Tr} (G_{\ell,0}' K_{\ell}')^m \) appearing in \( S_{\text{eff}} \) does not depend on \( \{ \eta_j \} \), which implies that the effective action is completely distinguished by the dynamical class characterized by the parity of \( p_{\xi} \). Such dynamical classification should always be applicable in the pairing-interaction parameter space when \( N \geq 3 \). In other words, \( \{ \kappa_{ij} \} \), which does not have to coincide with \( \{ \phi_0^{(1,2)} \} \) modulo \( 2\pi \), is no longer a matter of convention unlike the case of \( N = 2 \).

Collective modes — We are now in position to calculate the collective modes. If we expand \( S_{\text{eff}} \) around the stable solution of Eq. (1) for \( \varphi^{(2)}(q) \) with \( q \equiv (i\nu, q) \) and \( \nu = 2\pi/\beta (\ell \in \mathbb{Z}) \) the Matsubara frequency, we have, to the leading order, \( S_{\text{eff}} \approx -\sum_{\ell} \varphi_{\ell}^{(2)}(M_{\ell}/4) \varphi_{\ell} \) in the long-wavelength limit \( (q \to 0) \). Here we have introduced \( \varphi_{\ell} = \ell (\varphi^{(1)}(q), \varphi^{(2)}(q), \varphi^{(3)}(q)) \), and a \( 3 \times 3 \) real symmetric matrix,
\[
M_{\ell} = \begin{pmatrix}
M_{11}(q) + \mu_{11} - \eta_{12}\lambda_{12} & -\eta_{12}\lambda_{11} & -\eta_{31}\lambda_{31} \\
-\eta_{12}\lambda_{12} & M_{22}(q) + \mu_{22} - \eta_{23}\lambda_{23} & -\eta_{23}\lambda_{21} \\
-\eta_{31}\lambda_{31} & -\eta_{23}\lambda_{21} & M_{33}(q) + \mu_{33}
\end{pmatrix},
\]
where \( M_{ii}(q) = N_i \mu_i^2 + \sum_{\ell} (N_i v_{F\xi,i}^2/3) q_{\ell}^2 \) with \( v_{F\xi,i} \) the \( \xi \)th component \( (\xi = x, y, z) \) of the \( i \)th fermion’s Fermi velocity. The diagonal elements involve the contributions from the inter-band Josephson currents, \( \mu_{11} = \eta_{12}\lambda_{12} + \eta_{31}\lambda_{31}, \) etc. The dispersion relations for the collective excitation modes are given by the roots of \( \det M_{\ell} = 0 \). After an analytic continuation \( i\nu \to -\omega \), we obtain the three roots, \( \omega_0, \omega_{\ell_+}, \) and \( \omega_{\ell_-} \). Figure[2] displays the full dispersion. We can give explicit formulae for the three collective modes to the leading order in \( q \) for isotropic systems. The first root \( \omega_0 \) corresponds to the Nambu-Goldstone mode with \( \omega_0 = V|q| + O(|q|^2) \), where \( V^2 = \sum_{i=1}^3 (N_i/N_{\text{tot}}) \langle v_{F\xi,i}^2/3 \rangle \) and \( N_{\text{tot}} = \sum_i N_i \). The other two roots, \( \omega_{\ell_+} \) and \( \omega_{\ell_-} \), are the Leggett’s modes \( \omega_{\ell_\pm} = \pm \bar{v}^2 + v_{\ell}^2 \mp i\nu v_{\ell} \), where \( v_{\ell} = \pm \nu + \eta_{23} v_{\ell_2} + \eta_{31} v_{\ell_3} \). The “mass gap” (the Leggett’s mode frequency at \( \omega = 0 \), i.e., \( \nu_+ = \nu_- \)) is characterized by two quantities: The frequency scale is given by \( \bar{v}^2 = \nu_{12}^2 + \nu_{23}^2 + \nu_{31}^2 \) and \( v_{\ell}^2 = (N_i + N_j) \lambda_{ij}/N_{\text{tot}} \), where \( v_{\ell} = 0 \) corresponds to the frequency of the Leggett’s mode in the two-band model. The difference \( \nu_+ - \nu_- (\approx \sqrt{\Delta - D}) \) is characterized by
\[
D = \frac{4N_{\text{tot}} (\eta_{12}\lambda_{12}\lambda_{31} + \eta_{12}\eta_{23}\lambda_{12}\lambda_{23} + \eta_{23}\eta_{31}\lambda_{23}\lambda_{31})}{\hat{v}^4 N_1 N_2 N_3}.
\]
For \( D \to 1 \) the mass difference \( \nu_+ - \nu_- \) vanishes, whereas for \( D \to 0 \) \( \omega_{\ell_-} \) becomes a gapless mode (i.e., \( \omega_{\ell_-} \to c_- \)). We find that \( \nu_+ - \nu_- \) becomes large due to a cancellation among the terms in the numerator of \( D \) occurs for class odd. The term quadratic in \( |q| \) for the two Leggett’s modes are characterized by \( c_2 \), which involve two velocities, \( \bar{v}^2 = (1 - D)^{-1/2} \sum_{i=1}^3 (\hat{v}_{\ell,i}^2/N_{\text{tot}}) \langle v_{F\xi,i}^2/3 \rangle \) and \( V^2 = \bar{v}^2/3 - V^2 \), with \( v_{\ell}^2 = \sum_{i=1}^3 \hat{v}_{\ell,i}^2 \). In the limit where two bands are decoupled \( (\lambda_{23} = \lambda_{31} = 0) \), we recover the two-band result \( \bar{v}^2 \) with two gapless modes \( (\omega_0, \omega_{\ell_+}) \), and one gapped mode \( (\omega_{\ell_-}) \), along with \( \nu_+ \) and \( \nu_- \) that coincide with those in Ref.[II].

Having formulated the Leggett’s modes, let us see how they reflect the difference in the dynamical classes even and odd. If we look at the simplest case of \( N_1 = N_1/N_{\text{tot}} = \frac{1}{3} \), and \( \bar{v}_{\ell,i}^2 \equiv v_{F\xi,i}^2/\bar{v}^2 = \frac{1}{3} \) (for \( i = 1, 2, 3 \)), for \( \hat{g}_{11} = \hat{g}_{22} = \hat{g}_{33} = \frac{1}{3} \) with \( \hat{g}_{ij} = g_{ij}/Tr \mathcal{G} \), Fig[2] displays typical dispersion relations for \( \omega_0 \) and \( \omega_{\ell_\pm} \) for the two dynamical classes. We immediately notice that the mass difference \( \nu_+ - \nu_- (= \omega_{\ell_-} - \omega_\ell_+) \) at \( |q| = 0 \) is much greater in the class odd than in the class even. Systematic variation of \( \nu_+ - \nu_- \) on an interaction parameter space \( (\bar{g}_{12}, \bar{g}_{13}) \) is shown, first in Fig.[3]a) for the case of two negative (repulsive) and one positive (attractive) inter-band couplings. The allowed parameter region is restricted by the positive-definiteness of \( \mathcal{G}_{12} \). The mass
FIG. 3: (Color online) Color-coded mass difference $\propto \sqrt{1 - \mathcal{D}}$ in the multiple Leggett’s modes plotted on $g_{12}$-$g_{31}$ plane for $g_{ii} = \frac{1}{3}$. We assume identical normal state properties between the three bands. (a) Case of two negative (repulsive) and one positive (attractive) inter-band couplings. Yellow lines represent the boundaries between the even and odd classes. (b) Case of all the three inter-band couplings negative (repulsive), with only the class odd is allowed. In the blank area, the Leggett’s modes become unstable.

The mass difference is close to zero in the central area of the class even region, while it is relatively large in the class odd region. Thus, we recognize that the mass difference of the Leggett’s modes is an indicator of the difference in the dynamical classes. Note, however, that the distinction becomes blurred when the three-band system approaches a two-band behavior, which occurs when one of the off-diagonal elements of $\mathcal{G}^{-1}$ is much greater than the others (e.g., around the corners of the class odd region with a triangular shape), so that there is no jumps at the boundary.

Next, Fig. 3(b) displays the result for the case of all the three inter-band couplings negative (repulsive) with $g_{12}, g_{13}, g_{23} < 0$. Notably, this case always has the class odd throughout. This implies that the mass difference of the Leggett’s modes is lower bounded. The result shows that the bound is $\simeq 0.7$ for $g_{23} = -0.07$ and $g_{ii} = \frac{1}{3}$. Even more interesting, we find that the Leggett’s modes become unstable or ill-defined (within the present treatment which assumes real $\Delta_i$’s) in a narrow but finite region (blank area in Fig. 3(b)) where all three (or two) of $g_{12}, g_{13}, g_{23}$ take similar values. In this case, every two among the three gap functions $\Delta_1, \Delta_2, \Delta_3$ in Eq. (1) want to have opposite signs, but end up with complex values (i.e., the relative phase differences between the gaps deviate from 0 or $\pi$) due to the “frustration”, as pointed out in Ref. 13.

Summary — We have shown the presence of multiple dynamical classes in the $N(\geq 3)$-band superfluidity, which are characterized in terms of the parity of the multiple inter-band Josephson couplings. We have revealed that the mass difference of the Leggett’s modes is greater in the class odd, in contrast to the two-band case where the classification does not exist. So, the behavior of the multiple Leggett’s modes is expected to characterize the dynamics of excitations in multiband superconductors and superfluids. The expressions for the parities for $N = 3$ given here can be extended to $N \geq 4$, with their classification being an interesting future problem. Other future works include an extension of the present discussion to more general, $k$-dependent case for realistic description of multiband superconductors, such as the iron-based superconductors with their material dependence, and an extension to anisotropic pairings. Another intriguing problem is the Leggett’s modes in the case where the gap functions break the time-reversal symmetry in “frustrated” three-band superconductivity. Multiband superfluidity in cold fermionic atomic gases with multiple superfluidities may also be an interesting playing ground where we have a greater tunability due to the Feshbach resonance. How to detect Leggett’s mode, for which Raman spectra have been discussed in Ref. 14–17, is also an important problem.
