Although CDW correlations are a ubiquitous feature of the superconducting cuprates, their disparate properties suggest a crucial role for pinning the CDW to the lattice. Here, we report coherent resonant X-ray speckle correlation analysis, which directly determines the reproducibility of CDW domain patterns in La1.875Ba0.125CuO4 (LBCO 1/8) with thermal cycling. While CDW order is only observed below 54 K, where a structural phase transition creates inequivalent Cu-O bonds, we discover remarkably reproducible CDW domain memory upon repeated cycling to far higher temperatures. That memory is only lost on cycling to 240(3) K, which recovers the four-fold symmetry of the CuO2 planes. We infer that the structural features that develop below 240 K determine the CDW pinning landscape below 54 K. This opens a view into the complex coupling between charge and lattice degrees of freedom in superconducting cuprates.
Holes doped into the Mott insulating parent compounds of the high-temperature superconducting cuprates experience strong interactions with the antiferromagnetic background and with each other, as well as with the lattice in which they reside. The Hubbard Hamiltonian, often used to model the cuprates, predicts that charge density wave (CDW) fluctuations are an intrinsic property of strongly interacting electrons in pristine, undistorted 2D square lattices. CDWs have indeed been observed in essentially all hole-doped cuprates, but with distinct transition temperatures, correlation lengths, and wavevectors. This is epitomized by comparing two very similar cuprates that have slightly different low-temperature crystal structures: La$_2$CuO$_4$ (LSCO 1/8) and LBCO 1/8. LSCO 1/8 has weak CDW correlations and is a bulk superconductor below its transition temperature of $T_c=28$ K, whereas LBCO 1/8 has well-correlated CDW order that almost completely suppresses bulk superconductivity into what is proposed to be a 2D superconducting pair density wave state. As the main difference between these compounds is a subtle change in the crystal structure, it is evident the lattice that hosts the CDW correlations has a dramatic influence on the properties of the CDW and the superconducting ground state.

Multiple types of lattice deformation or disorder are present in cuprates including that of interstitial oxygen atoms, chemical substitutions, as well as local and long-range tilting of the Cu-O octahedra, all of which have been proposed as possible CDW pinning features that stabilize CDW order. One widely discussed lattice deformation in this context is the LTT phase in LBCO, in which octahedral tilts define a preferential direction for stripe pinning within each CuO$_2$ plane. While the LTO phase transition is common for both LBCO and LSCO, the LTT structural transition is a special feature in LBCO that coincides with the CDW formation. Fully understanding this process is, however, hampered by a lack of experimental techniques that are sensitive to the spatial distribution of the CDW order parameter.

This article reports our implementation of coherent resonant X-ray speckle correlation analysis as a tool for probing CDW domain pinning in the cuprates, choosing LBCO 1/8 as the model system due to its LTT structure and particularly large CDW correlation length. We discover strikingly reproducible CDW domain formation upon repeated thermal cycling well above its transition temperature and show that the CDW pinning memory is defined by structures that form at the LTO transition at 236(5) K rather than disorder or the LTT transition at 54(1) K that appears alongside CDW order.

Results

Experimental setup. Although CDW pinning has potential to dramatically change the superconducting ground state, directly observing CDW pinning and tracking its changes with temperature are very challenging tasks. Much of the difficulty is that one must combine a technique that is sensitive enough to detect the CDW domain spatial arrangement, which we will call “textured”, with the ability to reproducibly illuminate the same sample volume over a wide temperature range. Figure 1 shows how we have addressed the problem using coherent resonant X-ray diffraction: a scattering method that measures the interference between scattering from different domains in the CDW texture as a “speckle” pattern. Our innovation, reported here, is to attach a mask with a microscopic pinhole to the sample, which we overfill with the coherent X-ray beam to ensure we illuminate the same sample volume despite possible temperature-induced drifts of the sample position.

CDWs in cuprates modulate the in-plane valance charge density with a period of ~3-4 lattice units along the Cu-O bond direction, and tend to stack out-of-phase from plane-to-plane leading to CDW propagation vectors of $(H, 0, 0.5)$ or $(0, K, 0.5)$, where $H = K = 0.2–0.35$. For these experiments we chose an LBCO 1/8 single crystal which has one of the strongest CDW intensities of any cuprate and aligned it to its Bragg condition at wavevector $Q=(0.236, 0, 1.5)$ (see Methods). We furthermore tuned the X-ray energy to the Cu $L_3$-edge resonance around 931 eV in order to enhance our sensitivity to the weak CDW. In this condition the incident X-ray angle is $\theta_i = 88^\circ$ with respect to the [001] sample surface and the detector angle is $\theta_d = 119^\circ$. Such an approach has been used extensively to study the average CDW properties. The very high coherent flux (10$^{13}$ photons/s) at the 23-ID-1 beamline at the National Synchrotron Light Source II (NSLS II) opens up the possibility of observing coherent interference between the domains of a weakly scattering order parameter, such as that of cuprate CDWs. This was configured to produce a beam of ~20 μm at the sample overfilling the 10 μm pinhole in the Au mask attached to the sample (see Methods).

Pinned domains within the ordered state. Figure 2a plots a detector image at the CDW Bragg condition, which is zoomed in panels b–g. The extent of the observed peak (in this case $\times 10^{-3}$ Å$^{-1}$) is inversely proportional to the CDW correlation length (or domain size) similar to what is seen in conventional scattering. The speckle modulations on top of the peak envelope arise from coherent interference between different CDW domains. The average size and elongated shape of the speckles on the
CDW domain memory. Speckle images were taken at 24 K successively before and after the sample temperature was cycled to \( T_{\text{cycle}} \) as we illustrate in Fig. 3b (see Supplementary Fig. 7 for a larger field of view). After cycling to \( T_{\text{cycle}} = 180 \) K, a temperature well above the CDW transition temperature, the speckle patterns are strikingly similar [see panels (i) and (ii)]. However, as the sample was heated to higher temperatures, the degree of reproducibility dropped, and by \( T_{\text{cycle}} = 320 \) K, their positions completely changed as seen in panels (ii) to (iv).

In order to compare speckle positions quantitatively, and identify the onset temperature of this change, we calculated the normalized cross-correlation function. Speckle images were background subtracted as described in Supplementary Note 1. These images are then represented as \( M \times N \) matrices \( A_{m,n} \) and \( B_{m,n} \) where \( m \) and \( n \) are row-column indices. Cross-correlations matrices are calculated via

\[
A_{m,n} \ast B_{m,n} = \sum_{m'=-M}^{M} \sum_{n'=-N}^{N} A_{m',n'} B_{m+m',n+n'}. 
\]

Here, \( A_{m,n} \) and \( B_{m,n} \) were taken to be \( M = 200 \times N = 200 \)-pixel images under the CDW peak measured before and after thermally cycling the sample, which include \( \sim 30-50 \) speckles. When \( A_{m,n} \) and \( B_{m,n} \) have the same or similar speckle patterns, the correlated intensity features a peak that we sum over to obtain a single normalized speckle cross-correlation coefficient \( 33-35 \)

\[
\xi = \left( \frac{\sum_{\text{speckle}} A_{m,n} \ast B_{m,n}}{\sum_{\text{speckle}} A_{m,n} \ast A_{m,n} \sum_{\text{speckle}} B_{m,n} \ast B_{m,n}} \right)^{1/2}. 
\]
repeated, nominally equivalent, measurements for this which coincides with the LTO structural phase transition. The red box error function \( f_i \) of the Cu transition at \( 240(3) K \), which coincides with the LTO structural phase transition. The onset temperature of de-correlation was the cross-correlation matrix, corresponding to just over one

\[ \sum_{\text{speckle}} \sum_{\text{ domains}} \sum_{\text{ peaks}} \]

In this equation, \( \sum_{\text{speckle}} \) denotes summing over the peak in the cross-correlation matrix, corresponding to just over one speckle (~4 x 16 pixels) in size. The value is normalized by dividing by the auto-correlations of \( A_{m,n} \) and \( B_{m,n} \), such that two identical images have \( \xi = 1 \). In Fig. 4, we show \( \xi \) for various cycle temperatures showing a transition from high to low speckle reproducibility well above the CDW ordering temperature. We fit \( \xi \) versus \( T_{\text{cycle}} \) using an error function, which provides a reasonable phenomenological description of the shape of the transition. The onset temperature of de-correlation was \( 240(3) K \), which coincides with the LTO structural phase transition at \( T_{\text{LTO}} = 236(5) K \). This transition involves rotations of the Cu–O octahedra around the \( (110)_{\text{LTT}} \) direction and since nearest-neighbor octahedra rotate in opposite directions, the unit cell volume increases by a factor of two, with \( a_o \approx b_o \approx \sqrt{2} a \). Below this threshold the majority of the speckles reproduce with \( \xi = 0.84(9) \); above the transition \( \xi = 0.21(4) \), which corresponds to the value expected in a random domain distribution (Supplementary Note 2). We further confirmed that different regions within the speckle pattern shown in Fig. 2a and data taken through another pinhole reproduce the same phenomenology within error bars.

**Discussion**

These data establish that the CDW domains are strikingly reproducible upon temperature cycling well above the LTT and CDW transitions. The CDW is pinned at low temperatures, which is the usual behavior for a system with a long CDW correlation length as this can be accomplished by even a weak pinning force. This is, however, not a priori certain and the CDW in chromium has been reported to be dynamic down to low temperatures. It further appears that the reproducibility threshold here is associated with the LTO transition. This differs from what might have been anticipated based on the fact that the CDW appears at the LTT transition temperature, which would suggest the reproducibility threshold should match this temperature. We go on to discuss this intriguing result.

An analysis of hard X-ray Bragg diffraction data suggests that the typical LTO domain width is ~700 nm (Supplementary Note 3); we expect the LTT domain width to be comparable. In these experiments we illuminate a 10 x 10 \( \mu m^2 \) area of the sample with coherent X-rays, which will contain of order 200

**Fig. 4 CDW memory.** Normalized speckle cross-correlation coefficient, \( \xi \), of data before and after temperature cycling to different values of \( T_{\text{cycle}} \). Images of \( 200 \times 200 \) detector pixels were used for this calculation. An error function fit gives a de-correlation onset temperature of \( 240(3) K \), which coincides with the LTO structural phase transition. The red box indicates the temperature where all the speckle images were sampled for this figure. Error bars are estimated by taking the standard deviation of repeated, nominally equivalent, measurements.

LTT domains. All the CDW signal from this area contributes to the interference that determines the speckles. Within a given CuO\(_2\) layer, only half of the twin domains will contribute to a given CDW diffraction peak because of the unidirectional ordering within the LTT structure; the other half of the twin domains will contribute to a CDW peak rotated by 90°, i.e. at (0, 0.23, 1.5) rather than (0.23, 0, 1.5). Hence, in order for the speckle pattern to reproduce after cycling through the LTO-LTT transition, the domain pattern must reproduce precisely.

Now, the speckle pattern reproduces with cycling, but only if we use \( T_{\text{cycle}} < 240(3) K \). This temperature matches the LTO–HTT transition. So if we cycle into the HTT phase, the resulting CDW speckle pattern in the LTT phase changes. This indicates that LTO domain boundaries play a crucial role in propagating the CDW domain memory.

How does the CDW domain memory created at LTO–HTT transition translate through LTT? Based on strain considerations, LTO domain boundaries are expected to occur along the (100)\(_{\text{LTT}}\) lattice directions, as confirmed by TEM imaging. Electron structural studies of LBO demonstrated that the LTT and LTO tilt patterns can be conceptualized as superpositions of one another. Such superposition-based arguments naturally justify the observation that LTT-like tilts occur at LTO domain boundaries in the cuprates. Moreover, this supports the idea that LTT twin boundary locations can be inherited from the LTO twin boundary configuration. From the experimental results and the discussion above, we infer that the LTO twin domain pattern must change in a significant way on cycling into the HTT phase and that this process limits the observed CDW memory effect.

This is a remarkable result, but it is just the start. One might have expected a random nucleation of CDW domains on each cycling, which would change the speckles. The CDW order, with a period of ~4\( a \), has a four-fold degeneracy with respect to how it aligns within a CuO\(_2\) layer of the LTT structure. The experiment, on the other hand, shows that the phase of the CDW order with respect to the lattice must be reproduced precisely each time. The CDW correlation length is just 24 nm (at low temperature), which is much smaller than the structural domain size. That implies that defects within a structural domain must locally pin the phase of the CDW order. Disorder and structural distortions are present in almost all cuprates and have been discussed extensively in connection with CDW pinning in the cuprates. In \( La_{2-x}Ba_xCuO_4 \) the most prominent form of disorder is La/Ba cation substitution, with locations that are independent of temperature. This may act in concert with the domestic boundaries to pin the local CDW phase.

Another significant observation is that, within the CDW phase, the speckle locations do not change with temperature (see Fig. 2), despite the fact that the CDW correlation length varies with temperature. This can be explained by uniform expansion of CDW domains around their pinning centers on cooling, as speckle locations are primarily dependent on the locations of the domains and largely insensitive to their size (Supplementary Note 4).

Almost all cuprates show some form of orthorhombic structural symmetry breaking, so the CDW memory effects discovered here may well be shared by many different cuprate species. Testing whether other cuprates, including those without a LTT phase, show similar behavior, and whether lattice pinning and the stability of CDW ordering are related will be important in future work. We further emphasize that the experimental configuration presented here, in which sample drift problems are avoided by attaching a mask directly to the sample, is also applicable to applied current or laser excitation, as well as to the magnetic field-dependent behavior studied previously in magnetic alloys. This complements what can be achieved with scanning tunneling
spectroscopy, which has superior spatial resolution, but is limited to cleaved surfaces. The use of coherence and resonant X-ray scattering further opens the possibility to study charge, spin and orbital order parameters in other quantum materials with better resolution than is possible with current microdiffraction techniques.

In conclusion, we present the first application of coherent resonant soft X-ray speckle correlation analysis to study the CDW domain hysteresis in LBCO 1/8. We uncover remarkably reproducible CDW domain formation upon temperature cycling far above the 54 K CDW transition, before the CDW pattern is almost completely reconfigured by cycling above 240(3) K. The CDW order, which is associated with the dramatic suppression of superconductivity in this sample, experiences a pinning landscape that is determined by structural domains that form at the LTO phase transition. Our results open a new route to study the complex interplay between lattice and charge degrees of freedom in quantum materials at cryogenic temperatures.

Methods
Sample preparation. Single crystals of LBCO 1/8 were grown using the floating zone method, and characterized extensively in previous studies, all indicating excellent sample quality. A 2 μm gold (Au) film was evaporated onto a free-standing 200 nm Si3N4 membrane. Arrays of 10 μm asymmetric pinholes were drilled into the film using a focused ion beam yielding the shape shown in Fig. 1c. Although any stable shape is adequate for speckle correlation analysis, we chose to make a two-lobe structure. This decision was taken to break circular symmetry, which should improve the prospects for obtaining real-space images via Bragg coherent diffraction imaging in the future. Such attempts have thus far been unsuccessful. This assembly was pressed onto the LBCO single crystal with poly methyl methacrylate (PMMA) as a glue. The excess PMMA that was then removed using reactive ion etching. The resulting sample was imaged in a JEOL 7600F scanning electron microscope (Fig. 1b, c). In this paper, we index the crystal using the HTT unit cell where a = b = 3.78 Å and c = 13.28 Å. Correlation length here is defined as a/HWHM where HWHM is the half width at maximum of the peak in reciprocal lattice units (r.l.u.).

Coherent X-ray scattering. Data were taken at the Coherent Soft X-Ray (CSX) 23-ID-1 beamline at the NSLS II which is optimized to deliver high coherent flux at the sample. The beam was energy-dispersed in the vertical plane with a grating and focused onto a 20 μm x 340 μm pixel size placed 340 mm from the sample. Images were read out every 5 s for a total collection time of ~10 min. A temperature ramp rate of 3 K min−1 was used for all the temperature cycles with an average waiting time of 5 min at the cycling temperature.
