Abstract

AKARI/Infrared Camera (IRC) Point Source Catalog provides a large amount of flux data at S9W (9 μm) and L18W (18 μm) bands. With the goal of constructing Star-Formation Rate (SFR) calculations using IRC data, we analyzed an IR selected GALEX-SDSS-2MASS-AKARI/IRC/Far-Infrared Surveyor sample of 153 nearby galaxies. The far-infrared fluxes were obtained from AKARI diffuse maps to correct an underestimation for extended sources raised by the point-spread function photometry. SFRs of these galaxies were derived by the spectral energy distribution fitting program CIGALE. In spite of complicated features contained in these bands, both the S9W and L18W emission correlate with the SFR of galaxies. The SFR calibrations using S9W and L18W are presented for the first time. These calibrations agree well with previous works based on Spitzer data within the scatters, and should be applicable to dust-rich galaxies.

Key words: infrared: galaxies — ISM: dust, extinction — stars: formation

1. Introduction

Star-formation activity is fundamental to studies on the formation and evolution of galaxies. Numerous efforts have been made to find reliable and convenient star-formation rate (SFR) indicators (e.g., Kennicutt 1998; Hirashita et al. 2003; Bell 2003; Hopkins et al. 2003; Calzetti et al. 2007). Among most frequently used indicators, the ultraviolet (UV) and the optical recombination lines (e.g., Hα, Pα) give direct measures of light from young stars. However, UV and Hα emissions are strongly affected by dust extinction (Kennicutt 1998) and Pα as well as other optical recombination lines were also shown to underestimate SFRs for galaxies with high luminosity (Rieke et al. 2009). On the other hand, since dust absorbs UV/optical light and re-emits the bulk of the energy into a far-infrared (FIR) band (25 μm–350 μm), FIR emission can efficiently trace SFRs for dusty galaxies. However, FIR emission is unable to trace the dust-unobscured radiation, and includes part of radiation from old stellar populations. Therefore, the energy-balance method combining the FIR- and UV-derived SFRs were used to complement the emission from young stars not traced by FIR (e.g., Buat & Xu 1996; Meurer et al. 1999; Gordon et al. 2000; Buat et al. 2005). Although this method could trace SFRs with considerable accuracy, it is difficult to obtain the total dust emission, especially for high-redshift objects.

The MIR monochromatic fluxes were also investigated as SFR indicators. The MIR emission is contributed by several components, including polycyclic aromatic hydrocarbon (PAH) features (prominent at 6.2, 7.7, 8.6, 11.3, 12.7, and 17 μm), the continuum by stochastic heating of very small grains, silicate absorption at 9.7 and 18 μm, molecular hydrogen lines, and fine-structure lines (Leger & Puget 1984; Léger et al. 1989; Desert et al. 1990; Draine & Li 2007; Smith et al. 2007; Treyer et al. 2010). The MIR–SFR relation was intensively studied using Spitzer IRAC 8 μm and MIPS 24 μm photometry data and spectral data (e.g., Förster Schreiber et al. 2004; Calzetti et al. 2005, 2007; Kennicutt et al. 2009; Rieke et al. 2009; Treyer et al. 2010). Nevertheless, there is still a debate about the reliability of MIR indicators because of the complicated features it contains. Attempts to combine the optical and IR indicators show that this combination could trace the SFR effectively, and notably reduce the scatter (e.g., Calzetti et al. 2007; Zhu et al. 2008; Kennicutt et al. 2009). However, factors of the combination are different in each work.

The recently released AKARI/IRC Point Source Catalogue Version β-1 (IRPCSC hereafter) provides positions and fluxes of all-sky surveys at the S9W (9 μm) and L18W (18 μm) bands (Ishihara et al. 2010). For numerous MIR data, it would be useful if there is a benchmark of SFR measurement. Compared with the Spitzer 8 and 24 μm bands, the AKARI IRC S9W and L18W bands cover wider wavelength ranges, including silicate absorption features at both bands and emission contributed by large PAH molecules at the L18W band. This work is done to investigate whether and to what degree these AKARI broadband MIR data could trace SFRs, and how much...
Searching in the SIMBAD database, most of galaxies in our sample are normal star-forming galaxies. Only 15 galaxies are classified as AGNs (including Seyfert 1 and Seyfert 2 galaxies). All of the galaxies in our sample are nearby ones. The distribution of the redshift is shown in figure 1.

2. Data

2.1. Construction of the Multiwavelength Sample

We cross-identified IRCSC with multiwavelength data constructed by Takeuchi et al. (2010) to obtain a sample including MIR photometric measurements. The original sample was based on a selection by IRAS-PSCz (Saunders et al. 2000) and AKARI/Far-Infrared Surveyor (FIS) Bright Source Catalog (FISBSC hereafter) data (I. Yamamura et al. 2008; Yamamura et al. 2009), which means that all of these galaxies have considerable fluxes at FIR. Then, these galaxies were cross-matched with observations by GALEX, 2MASS, and SDSS. Fluxes at the UV band were obtained by performing specific aperture photometry so as not to shred GALEX images. A detailed description of the original sample can be found in Takeuchi et al. (2010).

IRCS presents flux data at 9 μm and 18 μm that have an effective bandwidth of 4.10 μm and a detection limit of 50 mJy, and 9.97 μm and 90 mJy, respectively (Ishihara et al. 2010). After cross-identification, there were 162 galaxies with a flux of either 9 μm or 18 μm. However, nine galaxies were found to have inconsistent fluxes at the GALEX, SDSS, or 2MASS band according to their SEDs, possibly due to measurement errors or misidentification of objects caused by the inhomogeneous resolution of each observation; they were thus omitted from our sample. We also discarded one galaxy with a too-small redshift (z ~ 0.0008). A summary of the samples is listed in table 1. Searching in the SIMBAD database, most of galaxies in our sample are considered as AGNs.

![Redshift distribution of our sample. The filled area denotes AGNs.](https://academic.oup.com/pasj/article-abstract/63/6/1207/1456689)

Table 1. Brief summary of the sample.

| Survey     | Band   | Wavelength (μm) | Number of sources |
|------------|--------|----------------|-------------------|
| GALEX      | FUV, NUV | 0.153, 0.231   | 153               |
| SDSS       | u, g, r, i, z | 0.355, 0.469, 0.617, 0.748, 0.893 | 153               |
| 2MASS      | J, H, Ks | 1.244, 1.655, 2.169 | 153               |
| IRAS*      | band-1, 2, 3, 4 | 12, 25, 60, 100 | 153               |
| AKARI IRC  | S9W    | 9              | 126               |
| AKARI IRC  | L18W   | 18             | 106               |
| AKARI FIS  | N60, Wide-S, Wide-L, N160* | 65, 90, 140, 160 | 153               |

* Data were not used for the SED fitting described in section 3.

2.2. The Re-Estimation of AKARI FIR Data

The FISBSC flux density for extended sources would be no longer accurate because of the point-source extraction procedure. In our sample, a considerable part of galaxies is the extended source. Therefore, it is questionable whether the catalog data of these sources are reliable. This is confirmed by making a comparison between FISBSC fluxes and IRAS co-added fluxes (figure 2), which were specially calculated for extended sources (Saunders et al. 2000). In order to investigate the dependence of the FISBSC flux on the extension of the galaxy, the sample was divided into three subsamples according to the size of the galaxy (table 2). The lines in figure 2 give predictions of the difference between two different bands by Dale and Helou (2002, DH hereafter) one-parameter constrained SED templates. The parameter α is related to the IRAS flux ratio, f60/f100. The log(f60/f100) in our sample ranges from -0.60 to 0.25, and most of the galaxies have log(f60/f100) between -0.5 and 0.0, corresponding to an α value of between 2.625 and 1.375. Accordingly, the model predictions with α = 1.375, 2.625, and the median value 2.0
Fig. 2. Comparison between the FIS catalog flux and the IRAS flux. Galaxies in different subsamples are shown by different sizes (large open circles, large; small open circles, medium; dots, small). The DH models with three different $\alpha$ are shown by different lines (dashed, $\alpha = 1.375$; solid, $\alpha = 2.0$; dash-dotted, $\alpha = 2.625$).

Table 2. Criteria to divide the sample.

| Subsample | Criteria                     |
|-----------|------------------------------|
| Small     | $a < 40''$ and $b < 40''$    |
| Medium    | $a > 40''$ or $b > 40''$     |
| Large     | $a > 40''$ and $b > 40''$    |

* Criteria to divide the sample into three subsamples. The length of major axis $a$ and minor axis $b$ of each galaxy was obtained from the SDSS image; 40'' was taken as the separating value, considering the PSF size of AKARI/FIS.

are illustrated in figure 2. Table 3 presents the median value of $\log(f_{\text{AKARI}}/f_{\text{IRAS}})$ for each subsample. Compared with the model-predicted values, there are clear discrepancies between FISBSC and IRAS data, especially for 60–65 $\mu$m and 90–100 $\mu$m. Also note that the large galaxies show greater discrepancies than the small ones, indicating that the point-spread function (PSF) photometry is less reliable for larger galaxies, because a considerable part of their fluxes is left behind by the relatively small beam size.

Aiming to obtain more reliable flux data, the photometry of the diffuse maps provided by the AKARI group was conducted using SExtractor. The obtained “AUTO” fluxes were also compared with IRAS co-added fluxes.

In the 90 $\mu$m band, the result shows a great improvement on the consistency with the IRAS flux according to the DH model (figure 3 and table 3) for all galaxies in our sample. At the 65 and 140 $\mu$m bands, the consistency is improved for those galaxies in “Medium” and “Large” subsamples, whereas the dispersion increases for the galaxies in “Small” subsamples. Less improvement is found for the 140 $\mu$m band, which can be explained by the relatively larger PSF FWHM at this band, ~60'', as compared with ~39'' for the 65 and 90 $\mu$m bands (Kawada et al. 2007). At the 160 $\mu$m band, neither fluxes derived from the diffuse maps nor those from the IRCPSC are satisfying, which is due to the poor quality of this band; thus, 160 $\mu$m data were not used in the following work. Therefore, we kept the IRCPSC flux values for “Small” sources at the 65 and 140 $\mu$m bands, and applied fluxes derived from diffuse maps to the other sources. In addition, fluxes derived from AKARI diffuse maps showed notably smaller measurement errors than the IRAS fluxes, greatly improving the data quality. Considering that the IRAS fluxes provide information similar to that given by the AKARI bands, we omitted IRAS fluxes when fitting the SEDs.
Table 3. Comparison between the AKARI and IRAS fluxes.\textsuperscript{a}

|                  | Catalog | Map       | Model    |
|------------------|---------|-----------|----------|
|                  | L       | M         | S        | L       | M         | S         | $\alpha = 1.375$ | $\alpha = 2$  | $\alpha = 2.625$ |
| $\log\left(f_{65}/f_{60}\right)$ | -0.18   | -0.09     | -0.03    | -0.10   | -0.12     | -0.01     | 0.00            | 0.03         | 0.04            |
| $\log\left(f_{90}/f_{100}\right)$ | -0.33   | -0.27     | -0.24    | -0.13   | -0.12     | -0.11     | 0.05           | 0.00         | -0.04           |
| $\log\left(f_{140}/f_{100}\right)$ | -0.09   | -0.04     | -0.09    | 0.03    | 0.01      | -0.02     | -0.30          | -0.11        | 0.02            |
| $\log\left(f_{160}/f_{100}\right)$ | -0.20   | -0.17     | -0.32    | 0.01    | 0.00      | 0.07      | -0.45          | -0.20        | -0.02           |

The mean values of the difference between the AKARI and IRAS fluxes according to the AKARI FISBSC fluxes (Catalog), fluxes derived from diffuse maps (Map), and DH model prediction (Model) are listed for each subsample of galaxies (‘L’, ‘M’, and ‘S’ represent large, medium, and small groups in table 2, respectively).

Fig. 3. Comparison between the FIS diffuse map flux and the IRAS flux. The symbols have the same meaning as in figure 2.

Note that the MIR data provided by IRCPSC were little affected by an extension of the source, since it applies “AUTO” fluxes by SExtractor, which are suitable for both point sources and extended sources.

3. SFR Calculation

The SED fitting program CIGALE (Noll et al. 2009) was used to calculate the SFR for our sample. CIGALE was developed to derive highly reliable galaxy properties by fitting the UV/optical SEDs and the related dust emission at the same time; i.e., the stellar population synthesized models are connected with infrared templates by the balance of the energy of dust emission and absorption. A detailed description of CIGALE can be found in Noll et al. (2009), Buat et al. (2011), and Giovannoli et al. (2011). Here, we give a short introduction to the main features.

CIGALE allows one to use the stellar SEDs from models given either by Maraston (2005) or by Fioc and Rocca-Volmerange (1997, PEGASE). The difference between these models is the contribution of the thermally pulsating asymptotic giant branch (TP-AGB) stars. In PEGASE models,
the contribution from TP-AGB stars is low (Maraston et al. 2006). Maraston (2005) increases the contribution from TP-AGB stars by adopting the “fuel consumption” approach. Maraston et al. (2006) shows that the insufficient consideration of TP-AGB stars overestimates the stellar mass by 0.2 dex, and worsens the consistency with IR observation data at a redshift of $z \sim 2$. At lower redshifts, it is found that using different models little affects the results (Rettura et al. 2006; Eminian et al. 2008). Therefore, the models from Maraston (2005) were preferred in this work. The Kroupa initial mass function (IMF) (Kroupa 2001) was used to calculate the complex stellar populations (CSPs).

This code provides two scenarios of star formation. One is “box models” with a constant SFR; the other is “$\tau$ models”, for which SFR decreases exponentially with a typical decay time, $\tau$. SFR is presently calculated as $\text{SFR}_{\text{box}} = M_{\text{gal}}/\tau$ for “box models” and $\text{SFR}_{\tau} = M_{\text{gal}}/\tau(e^{\tau(t)} - 1)$ for “$\tau$ models”, where $M_{\text{gal}}$ is the galaxy mass (Noll et al. 2009). CIGALE also allows one to apply different scenarios for young and old populations. The input star-formation history here is a constant burst star-formation history for young stellar populations, and an exponentially decreasing one for old stellar populations. Thus, SFRs were calculated using the formula $f_{\text{SP}} \cdot \text{SFR}_{\text{box}} + f_{\text{SP}} \cdot \text{SFR}_{\tau}$, where $f_{\text{SP}}$ and $f_{\text{SP}}$ are the fractions of young stellar populations and old stellar populations, respectively.

The attenuation curve adopted by CIGALE is based on a law given by Calzetti et al. (2000), with a modification of the slope and/or adding a UV bump. The modification of the slope is controlled by the factor $(\lambda/\lambda_Y)^{\delta}$; i.e., by changing $\delta$, the slope of the attenuation curve can be modified. We only considered a modification of the slope of the attenuation law here, and no bump was introduced. CIGALE allows one to consider different effects of attenuation for old and young stellar populations by adding a reduction factor, $f_{\text{att}}$, of the dust attenuation for the old stellar populations as an input parameter. For the IR part, CIGALE uses DH models, which is described in section 2. Then, the dust emission was calculated, and by balancing the energy emitted and absorbed, the short- and long-wavelength parts of the model were connected.

To compute the output parameters, the code provides two methods: “sum” and “max”. The former calculates the probability distribution functions (PDFs) by taking sums of the probability of the models in given bins of parameter space, which might cause an unintentional bias when the input parameter values are badly chosen. The latter introduces a fixed number of equally sized bins for each parameter, and searches the maximum probability of models in each bin. Then, these maximum probabilities are taken as weights for individual bins to calculate the expectation value of the parameter. The advantage of this method is that it alleviates the dependence on the choice of parameters (see Noll et al. 2009 for detail). Therefore, we applied the “max” method in this work.

The input parameters applied in this study were adopted from Buat et al. (2011) in order to obtain a stable and reliable output. Since CIGALE is unable to trace the unobscured emission of an AGN, for Seyfert 1 galaxies the output decreases reliability (Buat et al. 2011). For dust-obscured AGNs, CIGALE provides models to fit the SED, and can avoid introducing any severe bias. Therefore, five Seyfert 1 galaxies were rejected in our sample, and other AGNs were marked during analysis. In order to keep the accuracy of derived SFRs, galaxies with relatively large discrepancies between observation and output spectra (reduced $\chi^2 > 10$) were discarded as being unreliable. At first running, there were 25 such galaxies. By updating the SDSS data using Navigator of SDSS DR7/8 instead of the original pipeline data from SDSS DR7, the reduced $\chi^2$ values of 17 galaxies decreased to less than 10.$^3$ Four of the eight remaining galaxies left had very poor quality of AKARI diffuse maps. The four other galaxies had large extension and brightness, which could cause incomplete flux derivation or saturation in the optical plates. Considering that the number was small ($\sim 6\%$), these eight galaxies and five out of the 17 galaxies were discarded. Therefore, reliable SFRs were derived for 140 galaxies, out of which there are 112 with available $9\mu m$ fluxes and 97 with $18\mu m$ fluxes.

$^3$ There is no modification for other sources which are fitted well.
3.1. The Reliability of the Results

For a SED fitting, the accuracy of the output depends on the input parameter. To give proper estimates of the SFRs, the robustness of the results must be tested. A straightforward way to check the reliability of the output of CIGALE is to use a sample of mock galaxies with comprehensively known physical parameters. Mock galaxies can be generated following a recipe in Giovannoli et al. (2011): (1) Run CIGALE on the data of real galaxies. For each galaxy, a best model is produced by \( \chi^2 \) minimization. Then, from these models, the fluxes at each band can be estimated. (2) Add to each flux a random relative error, which is normally distributed with \( \sigma = 0.1 \). Thus, we obtain a mock catalog with flux information at every photometric band used in this study. The last step is to run the code on the mock catalog and then to compare the output parameters with the exact values provided by the best model. The result of the comparison is shown in figure 4. We only present the result concerning SFRs because in this work the SFR is the only parameter that needs to be of concern. Figure 4 shows that the two quantities are well related, indicating the SFRs derived here are reliable.

As discussed in Noll et al. (2009), CIGALE could provide stable results of SFRs as long as one constraint beyond the PAH band is given. We ran CIGALE with and without MIR data to examine the influence on SFR by MIR photometric data. The result shows that adding the MIR data or not adding has almost no influence on the resulting value of SFR (figure 5), while not using FISBSC data causes large uncertainties to the output, consistent with the conclusion of Noll et al. (2009) using the SINGS sample.

4. Result and Discussion

Apparently, the luminosities at 9 \( \mu m \) and 18 \( \mu m \), \( L_9 \) and \( L_{18} \), both correlate with SFRs (figures 6 and 7); the Spearman’s correlation coefficients are 0.943 for the \( L_9 \)--SFR relation and 0.956 for the \( L_{18} \)--SFR relation.\(^5\) Linear regressions following the method provided by Kelly (2007) give

\[
\log \frac{\text{SFR}}{M_\odot/\text{yr}} = (0.99 \pm 0.03) \log \frac{L_9}{L_\odot} - (9.02 \pm 0.32) \quad (1)
\]

and

\[
\log \frac{\text{SFR}}{M_\odot/\text{yr}} = (0.90 \pm 0.03) \log \frac{L_{18}}{L_\odot} - (8.03 \pm 0.30). \quad (2)
\]

The scatters of the data points about the regression lines of equations (1) and (2) are approximately the same, with \( \sigma = 0.18 \text{dex} \) for 9 \( \mu m \) and 0.20 \text{dex} for 18 \( \mu m \). These tight correlations also hold for the surface densities of luminosities and SFRs (figures 8 and 9). The correlation coefficients are 0.961 for 9 \( \mu m \) and 0.945 for 18 \( \mu m \). The areas of galaxies were calculated from \( g \)-band images of SDSS. The regression gives

\[
\log \frac{\Sigma_{\text{SFR}}}{M_\odot \text{yr}^{-1} \text{kpc}^{-2}} = (1.02 \pm 0.03) \log \frac{\Sigma_9}{L_\odot \text{kpc}^{-2}} - (9.30 \pm 0.19), \quad (3)
\]

with \( \sigma = 0.18 \), and

\[
\log \frac{\Sigma_{\text{SFR}}}{M_\odot \text{yr}^{-1} \text{kpc}^{-2}} = (0.98 \pm 0.04) \log \frac{\Sigma_{18}}{L_\odot \text{kpc}^{-2}} - (8.89 \pm 0.25), \quad (4)
\]

with 0.22.

Figures 6 and 7 show that AGNs share a MIR--SFR relation similar to normal star-forming galaxies, although the radiation mechanism of AGNs is different from that of normal galaxies. The slopes of the \( \log L_9 \)--log SFR and \( \log L_{18} \)--log SFR

---

\(^{4}\) In this paper, \( L_\lambda \) refers to \( \nu L_\nu \) at wavelength \( \lambda \).

\(^{5}\) Pearson’s correlation coefficient is 0.944 for \( L_9 \)--SFR relation and 0.951 for \( L_{18} \)--SFR relation.
relations derived here are almost equal to one, indicating that the MIR–SFR relations are close to linear.

4.1. Comparison with SFR Calibrations from Spitzer Data

Spitzer 8 μm and 24 μm data were investigated as SFR tracers by several authors (e.g., Wu et al. 2005; Pérez-González et al. 2006; Calzetti et al. 2007; Relaño et al. 2007; Zhu et al. 2008; Rieke et al. 2009). The 24 μm fluxes were found to be tightly related to the emission of the warm dust, and thus more intensively investigated, whereas the 8 μm–SFR relation is more complicated, strongly depending on such as the metallicity, size, and star-formation history (Calzetti et al. 2007); therefore, there are fewer calibrations.

The main difference between the AKARI and Spitzer filters is their bandwidths. Due to the wider band, the AKARI 9 μm and 18 μm fluxes are more affected by silicate absorption, PAH, and molecular hydrogen line emissions (figure 10). In order to check the reliability of our calibrations, the SFRs derived from equations (1) and (2) were compared with those given by Spitzer calibrations. The work to compare was chosen to keep the luminosity range close to the present sample (table 4). The calibrations given by Wu et al. (2005) and Zhu et al. (2008) are based on an equation given by Kennicutt (1998) in which the Salpeter IMF was used. The use of the Salpeter IMF will cause smaller SFRs by ~0.18 dex than some other IMF with a more shallow slope at low masses (Rieke et al. 2009). Therefore, this effect was corrected for the results of Wu et al. (2005) and Zhu et al. (2008).

4.1.1. Comparison between SFRs derived from 9 μm and from 8 μm

Spitzer 8 μm fluxes were computed from the output spectra of the CIGALE and filter response curves of the Spitzer IRAC and MIPS. Since the 8 μm fluxes used in the calibration (given in table 4) were the dust emission with the stellar contribution subtracted following the recipe of Helou et al. (2004), the 3.6 μm flux was also calculated to compute the stellar composition contained in 8 μm, and thus 8 μm dust emission could be obtained (hereafter, we refer to 8 μm dust emission as 8 μm emission for conciseness). Note that here the stellar contribution is very small, which can only affect the result by ~0.02 dex. The obtained flux is then converted to SFR by formula given by previous work (table 4). The results are plotted in figure 11 (typical 1σ uncertainty for the galaxy of median luminosity is ~0.5 dex). The statistical information of the comparison is given in table 5.

The discrepancy between our sample and Wu et al. (2005) may be due to several reasons. Wu et al. (2005) listed factors such as the accuracy of the fiber aperture corrections, the validity of the estimation of the obscuration in galaxies by using the Balmer decrement, and the possible contamination to radio and MIR emission from obscured weak AGNs. The larger capacity of our sample [79 for 8 μm in Wu et al. (2005) compared with 112 in our sample] and the wider coverage of 9 μm band may also cause such a difference. Another possible reason is that the oversimplification of PAH emission...
Table 4. SFR calculations based on Spitzer data. The luminosity is expressed in $L_\odot$ and SFR in $M_\odot$/yr.

| Work               | SFR calculation                                                                 |
|--------------------|--------------------------------------------------------------------------------|

| Rieke et al. (2009)| $\text{SFR} = 7.8 \times 10^{-10} L_{24}$ for $6 \times 10^8 \leq L_{24} \leq 1.3 \times 10^{10} L_\odot$ |
|                   | $\text{SFR} = 7.8 \times 10^{-10} L_{24} \times (7.76 \times 10^{-11} L_{24})^{0.048}$ for $L_{24} > 1.3 \times 10^{10} L_\odot$ |

* For galaxies with $12 + \log(O/H) > 8.35$, i.e., “high metallicity” galaxies in Calzetti et al. (2007).

Table 5. Regressions between SFRs from 9\,$\mu$m and those from 8\,$\mu$m.*

| 8\,$\mu$m calibration | $a$     | $b$     | Correlation coefficient | $(\log \text{SFR(8}\,\mu\text{m)} – \log \text{SFR(9}\,\mu\text{m)})$ |
|-----------------------|---------|---------|-------------------------|--------------------------------------------------|
| Wu et al. (2005)      | $-0.17 \pm 0.02$ | $1.05 \pm 0.03$ | 0.968 | $-0.14 \pm 0.18$ |
| Zhu et al. (2008)     | $-0.20 \pm 0.02$ | $0.90 \pm 0.02$ | 0.968 | $-0.25 \pm 0.16$ |

* Regressions between SFRs derived from AKARI 9\,$\mu$m and those from Spitzer 8\,$\mu$m. $\log \text{SFR(8}$\,$\mu$m) = $a + b \log \text{SFR (9}$\,$\mu$m) and the mean value of the difference: $(\log \text{SFR(8}$\,$\mu$m) – $\log \text{SFR(9}$\,$\mu$m)).

in DH models underestimates the 8\,$\mu$m flux, and therefore gives smaller SFRs. However, this level of discrepancy is well within the scatters in equation (1).

The discrepancy between Wu et al. (2005) and Zhu et al. (2008) is because Zhu et al. (2008) included 8\,$\mu$m-weak H II galaxies with lower MIR luminosity (Zhu et al. 2008). Since no such galaxies were included in present sample, it is reasonable that the present result agrees well with Wu et al. (2005).

4.1.2. Comparison between SFRs derived from 18\,$\mu$m and 24\,$\mu$m

For a 18\,$\mu$m–24\,$\mu$m SFRs comparison, more reference calibrations are available (table 4). The 24\,$\mu$m fluxes were also derived from the output spectra of the SED fitting by CIGALE.

The statistical information of the comparison is given in table 6. The converted SFRs are plotted in figure 12. Since the SFRs derived from Wu et al. (2005) are quite similar to those from Zhu et al. (2008), and the luminosity range in Wu et al. (2005) is closer to this work, the results from Zhu et al. (2008) are omitted for the sake of brevity.

The results of Wu et al. (2005) and Zhu et al. (2008) agree well with our result after a correction of the IMF. Rieke et al. (2009) assembled SED templates for local luminous and ultraluminous infrared galaxies, and combined the result of Dale et al. (2007) and Smith et al. (2007) to produce templates.
at lower luminosities. Their result is applied to galaxies with 24 $\mu$m luminosity greater than $6 \times 10^8$ $L_\odot$, corresponding to log SFR = $-0.33$, which is shown by the dotted line in figure 12. The present result agrees very well with Rieke et al. (2009) above the limit.

Our result is slightly higher than that given by Calzetti et al. (2007). A possible reason is that the result of Calzetti et al. (2007) was derived for H II clouds by Pa $\alpha$ emission, which might be poorly applied to galaxy-wide calculations, because the diffuse MIR or Pa $\alpha$ emissions in the whole galaxy are not included (Alonso-Herrero et al. 2006; Calzetti et al. 2007; Kennicutt et al. 2007; Rieke et al. 2009).

4.2. Combination of FUV and MIR Indicators

At lower IR luminosity, the IR indicator may fail to trace part of the UV photons from young stars due to the increased transparency of the ISM. A combination of unobscured FUV and MIR luminosities, (FUV + $\alpha$MIR), may efficiently compensate for the lost energy, and could trace the SFR linearly (Zhu et al. 2008). However, upon converting SFRs to dust obscuration corrected FUV fluxes by equation (1) from Kennicutt (1998), we found that $\alpha = 2.53$ and 3.33 have a scatter of 0.17 dex for 9 $\mu$m and 0.20 dex for 18 $\mu$m, respectively. The scatter is not reduced significantly. This fact indicates that the origin of the scatter in MIR–SFR diagram is complicated: not only the untraced UV photons, but also other unknown factors, such as the variation of the physical conditions within each galaxy, the distribution of dust and photo dissociation regions (PDRs), etc.

4.3. Metallicity

We attempted to investigate the gas-phase metallicity range of our sample by searching in the metallicity database measured by Tremonti et al. (2004) for SDSS galaxies. Unfortunately, the $12 + \log(O/H)$ values are given for only 33 galaxies (all higher than 8.75). Therefore, we applied a compromised method: to investigate the stellar mass, $M_*$, of our sample. Measured by CIGALE, the stellar mass, $M_*$, of all the galaxy in the sample is larger than $10^{8.5} M_\odot$. Thus, from mass–metallicity relation given by Tremonti et al. (2004),

$$12 + \log(O/H) = -1.492 + 1.847(\log M_*) - 0.08026(\log M_*)^2,$$

the metallicity $12 + \log(O/H)$ for our sample is higher than 8.4. This is not surprising because the initial sample from Takeuchi et al. (2010) is IR selected, which means a considerably high luminosity in IR and thus sufficient dust content and relatively high metallicity range. Thus, the MIR–SFR relations derived here could only be extrapolated to other high-metallicity galaxies. The situation for low-metallicity galaxies is rather complicated; since the opacity of the galaxy decreases, MIR would be unable to trace most of the UV/optical photons and thus lose the ability as an SFR indicator (Calzetti et al. 2007).

4.4. AGNs

Although AGNs have distinct features from normal galaxies regarding various physical properties, they share the same trend in the MIR–SFR figures. A possible reason is that the contribution from the AGN component is minor (from SED fitting, less than 15%); therefore, the host-galaxy component dominates the spectrum. To investigate the effect of AGNs on MIR emission, we plot the average SEDs for AGNs and normal galaxies in figure 13. On average, AGNs are brighter than normal galaxies at all bands, while with a lower MIR/90 $\mu$m ratio (table 7). There are two possible reasons: (1) silicate

\begin{table}[h]
\centering
\caption{Regression between SFSs from 18 $\mu$m and those from 24 $\mu$m.}
\begin{tabular}{lcc}
\hline
24 $\mu$m calibration & $a$ & $b$ & Correlation coefficient & (log SFR(24 $\mu$m)–log SFR(18 $\mu$m)) \\
\hline
Wu et al. (2005) & $-0.02 \pm 0.02$ & $1.00 \pm 0.02$ & 0.982 & $-0.01 \pm 0.12$ \\
Calzetti et al. (2007) & $-0.23 \pm 0.02$ & $1.00 \pm 0.02$ & 0.982 & $-0.23 \pm 0.12$ \\
Zhu et al. (2008) & $-0.02 \pm 0.02$ & $0.96 \pm 0.02$ & 0.982 & $-0.05 \pm 0.11$ \\
Rieke et al. (2009) & $-0.14 \pm 0.02$ & $1.14 \pm 0.02$ & 0.982 & $-0.04 \pm 0.17$ \\
\hline
\end{tabular}
\end{table}

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{fig13}
\caption{Average SED (dashed lines) and the SED normalized at 90 $\mu$m (solid lines) of AGNs (solid symbols) and normal galaxies (open symbols).}
\end{figure}

\begin{table}[h]
\centering
\caption{MIR to 90 $\mu$m flux ratio of AGNs and normal galaxies.}
\begin{tabular}{lccc}
\hline
Galaxy & $\log(f_{9}/f_{90})$ & $\log(f_{18}/f_{90})$ & $\log(f_{9}/f_{18})$ \\
\hline
AGN & $-1.69$ & $-1.35$ & $-0.34$ \\
Normal & $-1.35$ & $-1.19$ & $-0.16$ \\
\hline
\end{tabular}
\end{table}
absorption occurs more strongly in AGNs; (2) PAH molecules are destroyed by the harsh radiation field in AGNs. The latter is more convincing. Studies show that small PAH molecules contributed to shorter wavelength MIR emission are destroyed more easily than large ones contributed to longer wavelength MIR emission (Smith et al. 2007; Treyer et al. 2010, and reference therein), which is consistent with the lower 9 \( \mu \)m flux value than 18 \( \mu \)m in figure 13. Nevertheless, these differences between AGNs and normal galaxies are only on their average level, which could not be used to distinguish AGNs and normal galaxies in individual cases.

5. Conclusion

We combined AKARI/IRC 9 \( \mu \)m and 18 \( \mu \)m data with a previous sample to construct a FIR selected multiwavelength sample with MIR photometric measurements. The FIR data of AKARI/FIS in the original sample were re-estimated by photometry of AKARI diffuse maps to correct the bias of PSF photometry for extended sources. Then, the SEDs of the sample were fitted by CIGALE, and the SFRs were obtained. Regression analysis was conducted to investigate MIR–SFR relations. SFRs converted from AKARI MIR fluxes were compared with those from the Spitzer MIR fluxes to test the reliability of AKARI MIR–SFR calibrations. From the analysis, we draw the following conclusions:

1. Both 9 \( \mu \)m and 18 \( \mu \)m luminosities correlate with SFRs, and thus could be converted into SFRs.
2. A combination of FUV and MIR luminosities barely reduces the scatters, indicating that the unobscured UV photons are not the only reason of the variation of MIR–SFR relation.
3. A comparison of the SFRs derived from equations (1) and (2) with the ones derived from Spitzer MIR–SFR relations shows that the silicate absorption included in the S9W (9 \( \mu \)m) and L18W (18 \( \mu \)m) bands little affects the results. The discrepancies, if any, are well within the uncertainties.
4. AGNs in the sample show no discrepancy with normal galaxies in the MIR–SFR diagrams. The smaller average MIR fluxes for AGNs than normal galaxies might indicate that the small PAH molecules are destroyed by harsh radiation from AGNs.

In summary, for IR selected galaxies the rest frame 9 \( \mu \)m and 18 \( \mu \)m emissions are efficient tracers of SFRs, and the equations derived here should be applicable to other dust-rich galaxies.

This work is based on observations with AKARI, a JAXA project with the participation of ESA. FTY, TTT, and KLM are partially supported by a Grand-in-Aid for the Global COE Program “Quest for Fundamental Principles in the Universe: from Particles to the Solar System and the Cosmos” from the Ministry of Education, Culture, Sports, Science and Technology (MEXT). TTT has been supported by Program for Improvement of Research Environment for Young Researchers from Special Coordination Funds for Promoting Science and Technology, and a Grant-in-Aid for the Scientific Research Fund (20740105) commissioned by the MEXT of Japan. VB and DB have been supported by the Centre National des Etudes Spatiales (CNES) and the Programme National Galaxies (PNG). JIP is supported by the grant AYA2007-67965-C03-02, from the Spanish MICINN. This work makes use of the SIMBAD database, operated at the Centre de Données astronomiques de Strasbourg (CDS), Strasbourg, France. We acknowledge Y. Doi for preparing diffuse maps for our sample and Y. Matsuoka for helpful advice and comments. We also thank an anonymous referee for constructive suggestions to improve this paper.
