INTRODUCTION

The most commonly reported adverse events following COVID-19 vaccinations are pain and swelling at the injection site, fever, myalgia, headache, and chills. Apart from these, there have also been reports of few rare and life-threatening adverse reactions like thrombosis with thrombocytopenia syndrome, Guillain-Barré syndrome, vasculitis, autoimmune hepatitis, inflammatory myopathies, and myocarditis, which are now thought to be caused by immune-mediated mechanisms. With 6.08 million doses of COVID-19 vaccine being administered daily (as of 5 July 2022), the reporting of such rare adverse events is essential not only for a better understanding of its pathogenesis but also to aid clinicians in promptly recognizing the symptoms and for effective management.

CASE REPORT

A 53-year-old man presented himself with severe pain and soreness in his left upper arm and generalized myalgia. The pain started 2 days after the first dose of the ChAdOx1 nCoV-19 Corona Virus Vaccine (COVISHIELD) into his left deltoid muscle. The pain initially developed in the left upper arm, followed by the right upper arm and bilateral calf muscles (left more than right). The pain gradually increased, restricting his daily activities, following which he presented himself to our hospital, on the 11th day of vaccination. He had difficulty walking and moving his left arm at the time of presentation. He also reported generalized muscle weakness, more pronounced in the proximal upper and lower limbs than the distal ones. The patient was healthy and asymptomatic prior to the vaccination. There was no history of heavy manual labour or vigorous
exercise before the onset of symptoms. There was no malaise or fever. There was no history of any skin rash, breathlessness, dry cough, or joint pain. He was non-diabetic and non-hypertensive, with no history of any connective tissue disorders or allergic reactions to drugs or vaccines. There has been no evidence of COVID-19 infection in the past.

On local examination, there was no swelling or erythema. There was tenderness over the left deltoid muscle and bilateral calf muscles, more so on the left side. The power in the proximal muscle groups of the left upper limb was 3/5 and that of the distal was 4/5, whereas for the proximal and distal lower limb muscle groups on the left side, the power was 3/5. Both proximal and distal muscle groups of the right upper and lower limbs showed power of 5/5 (assessed by the Medical Research Council Scale). Sensory examination was normal. Reflexes were preserved.

Serologic testing yielded mildly increased serum creatine kinase (187 U/L, reference range 40–171 U/L) and alanine transaminase (50 U/L, reference range 10–40 U/L) concentrations. Serum bilirubin, aspartate aminotransferase (AST), gamma glutamyl transpeptidase (GGT), alkaline phosphatase (ALP), and C-reactive protein levels were normal. Urine analysis excluded myoglobinuria.

Suspecting skeletal muscle damage, MRI of all the limbs was suggested. On MRI, edema was observed in the left deltoid muscle with a thin layer of subfascial fluid adjacent to the muscle belly (Figure 1). Deltoid muscle architecture was preserved. Subtle edema was also noted in the medial head of the left gastrocnemius muscle, with the edema fluid tracking along the intermuscular plane between the gastrocnemius and soleus (Figure 2). No collection or abscess was seen. MRI of the right arm and leg was normal. Based on the findings, a diagnosis of COVID-19 vaccine-associated myositis was made. EMG, muscle biopsy, and immunological workup could not be carried out as the patient did not give consent.

The patient was advised to rest and take nonsteroidal anti-inflammatory drugs (NSAIDs) for 1 week. Steroids or IVIg were not given, as the symptoms were relatively mild, and the muscle enzymes were only mildly elevated. On the first follow-up after 1 week (18th day of vaccination), the pain and tenderness had reduced considerably. The power in the left upper and lower limb muscle groups was 5/5. However, the difficulty in walking persisted. Repeat serum creatine kinase after 5 weeks (45th day of vaccination) was normal (121 U/L, reference range 40–171 U/L). A repeat MRI was not carried out, as the patient significantly improved after initial management.

3 DISCUSSION

ChAdOx1 nCoV-19 is a recombinant, replication-deficient chimpanzee adenovirus vector which encodes the SARS-CoV-2 Spike (S) glycoprotein. When administered, it causes the genetic material of part of the coronavirus to
be expressed, thereby stimulating neutralizing antibody and cellular immune responses.

Autoimmunity associated with vaccines can be attributed to the cross-reactivity between antigens or to the effect of adjuvants. ASIA (Autoimmune/inflammatory Syndrome Induced by Adjuvants) is a complex occurrence referring to the autoimmune manifestations that appear to be caused by adjuvants and may be related to specific HLA phenotypes, the development of autoantibodies, or even evolve into a rheumatological disorder. ASIA is characterized by inflammatory musculoskeletal, neurocognitive, and/or constitutional symptoms on exposure to an external stimulus and improves when the stimulus is withdrawn. Cases of autoimmune thyroid disease including subacute thyroiditis, Hashimoto’s thyroiditis, and Graves’ disease have been reported after the first and second doses of COVID-19 vaccines. Few of the other reported cases of ASIA following COVID-19 vaccines include optical neuritis, transverse myelitis, autoimmune encephalitis, sensory neuropathy, and polyarthritis autoimmune rheumatoid arthritis. K Gupta et al. recently reported a case of inflammatory myositis in a 46-year-old female, following the second dose of Covishield. The patient presented with low-grade fever and joint pain, and laboratory tests revealed elevated AST, ALT, LDH, and inflammatory markers. CT chest showed features of interstitial lung disease. MRI showed features of inflammation in bilateral thigh muscles. CK was elevated, and the myositis profile was positive for anti-Jo-1 and anti-Ro-52 antibodies.

It is known that COVID-19 can lead to myositis and rhabdomyolysis due to immune hyperactivation and excessive cytokine release. The antibodies against SARS-CoV-2 spike glycoproteins cross-reacting with structurally similar host proteins (molecular mimicry) have been suggested as a possible cause for this acute autoimmune response. Other proposed mechanisms include cytokine-mediated autoinflammation, CD8 T-cell overactivation, formation of antigen–antibody complexes, and structural deformity of myocytes caused by intake of viral antigen. It has been suggested that the COVID-19 vaccination could also trigger such a response. However, the exact mechanism remains unclear. The clinical features suggestive of COVID-19-induced myositis include proximal muscle weakness, myalgia, features of muscle inflammation in

**TABLE 1**  Table showing published reports of myositis and rhabdomyolysis following ChAdOx 1 nCoV 19 vaccination

| Author | Clinicals | Biochemical parameters | Imaging | Management |
|--------|-----------|------------------------|---------|------------|
| Present report. | 53-year-old male, severe left upper arm pain, generalized weakness and myalgia 2 days after first dose. | Mildly elevated CK and ALT. | MRI: edema and perifascial fluid in left deltoid and left gastrocnemius muscles. | Rest, NSAIDs. |
| D.J. Theodorou et al. 2021, Greece. | 56-year-old female, severe left upper arm pain 8 days after second dose. | Elevated serum CK. | MRI: diffuse edema and intense focal enhancement of left deltoid. | Rest, cryotherapy, compression, and NSAIDs. |
| Maramattom et al. 2021, India. | 74-year-old male and 75-year-old female, fever, tachycardia, arthralgia, and myalgia 2 days after first dose. 80-year-old female, fever, fatigue, and tachycardia 2 days after first dose. | Elevated AST and ALT, normal CK. Myositis panel negative. Elevated LDH, AST and ALT, normal CK. Myositis panel negative. | 18 FDG-PET CT: FDG avid vessels in lower limbs (vasculitis). MRI: Patchy STIR hyperintensity involving bilateral lower limb muscles. 18 FDG-PET CT: Diffuse patchy minimally increased FDG avidity in skeletal muscles. MRI: Multiple patchy areas of STIR hyperintensity involving bilateral lower limb muscles. | Oral prednisolone +/- mycophenolate mofetil. Oral prednisolone +/- Methylprednisolone. |
| M Capassoni et al. 2021, Italy. | 37-year-old female, skin rash, muscle weakness, and foot pain 4 days after vaccination. | Positive ANA, elevated aldolase. Imaging not done. Histology: neutrophilic pustular dermatitis. EMG: Myositis in the tibialis anterior muscle. | | Methylprednisolone infusion and subsequent oral tapering. |
| S.-T. Huang, T.-J. Lee, K.-H. Chen et al. 2022, Taiwan. | 44-year-old male, generalized myalgia, progressive weakness, and brown urine 2 weeks after second dose. Bilateral forearm and gastrocnemius muscles tense and tender. | Markedly elevated CK and severe metabolic acidosis. Myositis panel positive. | CT: bilateral retroperitoneal fluid collection and swelling and edema of psoas muscles. | Emergent fasciotomy over four limbs, Methylprednisolone, Cyclophosphamide. Patient died of sepsis and multiorgan failure on day 17. |
MRI, dermatomyositis, and rhabdomyolysis evidenced by elevated CK and myoglobinuria.  

The Government of United Kingdom’s “COVID-19 Vaccine AstraZeneca analysis print” reports one case of autoimmune myositis, 59 cases of myositis, six cases of polymyositis, and seven cases of dermatomyositis. These cases are reported during the period from 4th January 2021 to 13th July 2022. Theodorou et al.15 have reported a case like ours, with a 56-year-old woman presenting with myalgia and progressive muscle weakness that started 8 days after the second dose of COVID-19 vaccination. Her symptoms were limited to the left upper arm, where the vaccination was given. Myositis was diagnosed based on elevated CK and typical MRI findings. In our case, in addition to the edema at the injection site, edema was also observed in the ipsilateral calf muscle, which could not be explained otherwise. These features were suggestive of a generalized myositis. Maramattom et al.16 have recently reported three similar cases, all of which showed features of inflammatory myositis on MRI, while one patient showed features of vasculitis in addition to myositis on biopsy. Interestingly, the CK levels were normal in all the three cases. A comparison of these cases and few other published reports of ChAdOx1 nCoV-19-related myositis ranging from mild to fatal reactions is given in Table 1. 

A similar case of myositis with mildly elevated CK has been reported by Ramalingam et al17 following the second dose of mRNA vaccine. Laboratory tests revealed CK 236 U/L (reference range 35–232 U/L) and Aldolase 20.9 U/L (reference range 1.5–8.1 U/L). MRI showed diffuse cellulitis and myositis of the deltoid and supraspinatus muscles. The patient underwent local incision and drainage, along with antibiotic and steroid therapy. A summary of few other reported cases of myositis following other types of COVID-19 vaccinations is given in Table 2.

**CONCLUSION**

Most of the ChAdOx1 nCoV-19 vaccine-associated adverse events are mild and self-limiting. Prolongation or worsening of symptoms necessitate further evaluation. In our case, the myositis was mild, and the patient’s condition improved with rest and NSAIDs. Given the mild nature of the illness, many such cases may not even be reported. Evaluation of such patients with basic laboratory tests and imaging and
follow-up will help in early diagnosis and management, preventing complications and reducing overall patient expense and better understanding of the unprecedented effects of this novel vaccine. Although such rare adverse events can be seen following the vaccination, it is not a deterrent factor for the ongoing vaccination programme.
