Synanthropic rodents as possible reservoirs of shigatoxigenic *Escherichia coli* strains

INTRODUCTION

Shigatoxigenic *Escherichia coli* (STEC) strains are worldwide zoonotic pathogen responsible for different cases of human disease including hemolytic uremic syndrome (HUS). Transmission of STEC to humans occurs through the consumption of food and water contaminated by faeces of carriers and by person-to-person contact. The objective of this study was two-fold: (1) to investigate whether synanthropic rodents are possible reservoirs of STEC in the urban area and (2) whether a particular genus out of synanthropic rodent is the principal carrier of STEC. One hundred and forty-five rodents were captured in Buenos Aires City. Screening for *stx1/stx2* and *ribO157* was done by PCR from the confluence zone. STEC isolates were further characterized with biochemical tests by standard methods. Additional virulence factors (*eae*, *ehx*, and *saa*) were also determined by PCR. Forty-one of the rodents were necropsied and sample of kidney and small and large intestine were taken for histopathological diagnosis. The samples sections were stained with hematoxylin-eosin, and observed by light microscopy to evaluate the systemic involvement of these species in natural infections. STEC was isolated from seven out of 27 suspect animals at screening. The following genotypes were found in the STEC strains: *stx1/stx2/ehxA (1)*, *stx2 (4)*, *stx2/ehxA (1)*, *stx2/ehxA/eae (1)*. Neither gross nor microscopic lesions compatible with those produced by Shiga toxin were observed in the studied organs of necropsied rodents. The bivariate analysis including the 145 rodent's data showed that the isolation of STEC is associated positively to *Rattus* genus. This synanthropic species may play a role in the transmissibility of the agent thus being a risk to the susceptible population. Their control should be included specifically in actions to dismiss the contamination of food and water by STEC in the urban area, as additional strategies for epidemiological control.

MATERIALS AND METHODS

STUDY DESIGN

A non-probabilistic sampling by convenience was carried out in Buenos Aires City. One hundred and forty-five rodents were captured using live traps (Sherman and cage traps). The traps were placed in parks at intervals of five meters, varying in number.
according to the surface and the characteristics of each site of capture. The traps remained active for four consecutive nights and they were checked daily in the morning.

The inclusion criteria for the sample from the rodent population of Buenos Aires City were “animals from parks which were captured alive.” We studied the population groups that were validated by relevant epidemiological characteristics. The animals were classified according to genus and species. Each rodent was anesthetized to be weighed, measured, sexed, and their reproductive status was recorded. They were also sampled by two rectal swabs.

The study was approved by the Institutional Animal Care and Use of Experimental Animals, CICUAL, Faculty of Veterinary Science, University of Buenos Aires.

DETECTION OF stx+ AND ISOLATION OF STEC STRAINS

The samples were examined according to standard procedures for isolation of O157:H7 STEC and non-O157 STEC previously described (Bentancor et al., 2007). Briefly, for O157 STEC detection the samples were inoculated in 5 ml of cefixime-tellurite (CT) triptéine soy broth (TBS) for enrichment and incubated 18 h at 37°C. The cultures were streaked onto Sorbitol MacConkey Agar (CT-SMAC) and incubated overnight. Detection of non-O157 was performed inoculating the samples in 5 ml of Go Taq (Promega) DNA polymerase in 1 × buffer according to the manufacturer’s instructions, and finally 6 μl of the template from sample. PCR was performed in a Mastercycler Gradient Eppendorf under the following conditions: 5 min at 94°C, followed by 30 cycles of: 45 s at 94°C, 30 s at 56°C, 30 s at 72°C and a final step of 7 min at 72°C, maintaining it at 4°C until analysis. 10 μl of each PCR product obtained were electrophoresed on 2% agarose gels and stained with ethidium bromide.

Positive samples at screening from the confluence zone were considered suspect. Each suspect sample was evaluated for the presence of stx+ strains up to 50 CFU.

According to the results obtained by PCR, animals were classified into positive (positive screening with isolation of a stx+ strain), suspect (positive screening without isolation) and negative (pathogen was not detected at screening).

BIOCHEMICAL CHARACTERIZATION AND IDENTIFICATION OF VIRULENCE FACTORS

STEC isolates were further characterized as E. coli after gram staining, oxidase, catalase, glucose oxidation-fermentation, indole, methyl red (MR), Voges Proskauer (VP), Simmons citrate, fermentation of sugars (lactose, sucrose, cellobiose, sorbitol, raffinose, dulcitol, rhamnose) H2S production, yellow pigment, β-glucuronidase activity, lysine decarboxylase, ornithine decarboxylase, and mobility assessment (Mac Faddin, 2003). RapidID ONE System 20 test (Remel) was also done, and additional virulence factors (saa, eae, elxA) were determined by PCR (Paton and Paton, 1998a, 2002).

HISTOPATHOLOGY

Necropsy of captured animals was performed to determine if STEC carriers had any injury. We looked for gross changes. Kidney, small, and large intestine were removed for histopathological diagnosis. The samples were fixed for 48 h in 10% buffered formalin and processed routinely. Sections of paraffin-embedded tissue were stained with hematoxylin-eosin and evaluated by light microscopy.

STATISTICAL ANALYSIS

The data obtained from each rodent were analyzed with EpiInfo 3.2 (CDC-WHO). We performed bivariate analysis (Chi-squared) and estimated OR and 95% confidence interval for significant variables.

RESULTS

Rodents captured belonged to the following species: Deltamys kempi (n=4), Mus musculus (n=66), Oligoryzomys flavescens (n=16), Rattus norvegicus (n=31), Rattus rattus (n=28).

PCR analysis was performed for all the rodents captured (145 animals). Twenty-seven out of 145 animals were suspected at PCR screening from the confluence area: Deltamys kempi (0/4), Mus musculus (10/66), Oligoryzomys flavescens (1/16), Rattus norvegicus (6/31); Rattus rattus (10/28) (Table 2).

Isolation of stx+ strains was obtained in seven cases out of 27 suspect samples: Mus musculus (1/66), Rattus norvegicus (2/31), and Rattus rattus (4/28). Each isolated strain was identified as Escherichia coli by conventional bacteriological test and by RapidID ONE System 20 test. All the isolates were detected as non-O157 strains by PCR.

The following genotypes were found in the STEC strains: stx1/stx2/ehxA (1), stx2 (4), stx2/ehxA (1), stx2/ehxA/ea (1).

Forty-one out of 145 animals evaluated (five positive, four suspect and 32 negative) were necropsied. Neither gross nor microscopic lesions compatible with those produced by Shiga toxin were not observed in the studied organs.

The bivariate analysis including the 145 rodent data showed no association between STEC carriers and all studied variables.

DISCUSSION

Very little is known about the occurrence of STEC in synanthropic rodents. This study differs from others studies which captured rodents and searched for O157 STEC in sampling methods and procedures for isolation of strains (Hancock et al., 1998; Čizek et al., 1999), in our case the presence of O157 was not detected in these samples.

We isolated STEC strains in seven out to 27 suspect animals. This low number of isolates could be related to the number of CFU evaluated in positive animals at PCR screening from the confluence zone. We analyzed 50 CFU from each suspect animal to avoid underestimated rodent species. It is possible that a low proportion of STEC in the suspect samples determinate a low recovery. On the other hand, sampling methods could be the cause of the low efficiency of isolation according to the low sample obtained.

Although rodents from different species were suspected at PCR screening, we observed a higher proportion in individuals of the Rattus genus. This fact is important because rodents from Rattus genus live in urban areas, overlaying their territory with men, feeding on waste and stowed food which can pollute. The growth of this population is related to their availability to food and water. When we discriminated these individuals by species, the study of carriage in R. norvegicus was lower than in R. rattus, opposed to the findings of different researchers who have not detected R. rattus as a carrier of STEC (Čizek et al., 1999; Nielsen et al., 2004). Differences between R. rattus and R. norvegicus could not be explained.

In Argentina the epidemiology of HUS included sporadic cases, opposite to large outbreaks of food borne diseases described in others countries. Synanthropic species as other sources deserve to be evaluated to mitigate the endemic presentation of the disease.

The capture of these animals was performed in the urban area, mainly in parks. Although the population of rats of Buenos Aires City is not determinate, larger sample with animals that come from other urban areas would be needed to establish whether there are differences between species in the urban cycle.

In the present study, one strain isolated genotype had stx1 and all strains carried stx2. The stx2 is strongly associated with increased risk of HUS (Rivas et al., 2006). However, none of

| Rodent evaluated | N0 STEC suspicious carrier at screening | Isolation of stx+ strain | Escherichia coli bacteriological identification | O157 serogroup | Genotype |
|------------------|--------------------------------------|-------------------------|-----------------------------------------------|----------------|----------|
| Rattus norvegicus| 31 6                                  | 2                       | 2                                             | 0              | 0 2 0 0 0 |
| Rattus rattus    | 28 10                                 | 4                       | 4                                             | 0              | 1 4 1 3 0 |
| Mus musculus     | 66 10                                 | 1                       | 1                                             | 0              | 0 1 0 0 0 |
| Deltamys kempi   | 4 0                                   | NA                      | NA                                            | NA             | NA NA NA NA NA |
| Oligoryzomys flavescens | 16 1 | 0                       | NA                                            | NA             | NA NA NA NA NA |

NA, not applicable.
the isolated strains was from the O157 serogroup, which is most frequent as HUS producer.

The animals captured had no signs of disease; neither gross changes nor microscopic lesions compatible with those produced by Shiga toxin were observed in the studied organs. At the present time, lesions in rodents have been described in animal models which were inoculated orally or gastrointestinal with STEC, or by injection with Stx alone or with lipopolysaccharide component on the outer membrane of this bacterium (Obata, 2010). The absence of lesions may be due to Stx production, amount of Stx receptor (globotriaosylceramide, Gb3) in host cells and their sensitivity to Stx or complex biochemical aspects of the Gb3 membrane microenvironment (Obregí, 2010). Anyway, healthy synanthropic rodents could serve as a reservoir of STEC as occurs in other animal species (Beutin et al., 1993). On the other hand the possibility that the animals consumed contaminated food and could be colonized transiently by STEC could not be excluded. It is difficult to estimate the time of excretion of STEC in wild animals that do not survive in captivity to determine if their carrier status is due to a transient colonization or whether we are in presence of a new reservoir of STEC. In order to obtain a finally conclusion about their role as reservoirs, larger sample would be need.

The results of the present study represent the first finding of STEC in R. rattus and show STEC no-O157 is circulating in different synanthropic rodent species of the urban area.
