The appendiceal abscess is a common complication of acute appendicitis and usually is located in the right lower quadrant of the abdomen. An epigastric appendiceal abscess has never been reported at an unusual location.

We experienced an unusual case of a 49-year-old man with an epigastric appendiceal abscess. Initially, this abscess was suspected to be a pancreatic abscess. Abdominal CT scan and barium enema demonstrated a hyperrotated cecum with an appendiceal abscess in the left upper quadrant of the abdomen. An gastroscopy revealed a small fistula-like lesion with purulent coating at the bulging posterior gastric wall. The abscess resolved spontaneously. We believe that the abscess drained into the stomach through a small fistula between the stomach and abscess cavity. There was no recurrence for over 6 months.

Key Words: Epigastric appendiceal abscess

INTRODUCTION

Appendiceal abscesses represent 2.3% of all the cases of acute appendicitis and usually present a mass in the right lower quadrant. Occasionally, abscesses develop in the right subhepatic space, right subdiaphragmatic space and right pararenal space or liver. However, an appendiceal abscess located in the epigastric space has never been reported. The management of appendiceal abscess is controversial. Recently, the ultrasonic or CT guided percutaneous puncture technique has offered an alternative to conventional surgical treatment. We experienced a patient with an epigastric appendiceal abscess, demonstrated by abdominal CT scan and barium enema, which resolved spontaneously.

CASE REPORT

A 49-year-old man was referred to our institution for further evaluation and management of an intraabdominal abscess with the air-fluid level located outside of the greater curvature of the stomach, demonstrated on the abdominal CT scan checked 5 days before the referral (Fig. 1). He experienced left upper quadrant abdominal pain with fever and chills for 15 days without any preceding trauma and was managed at a private clinic without improvement of symptoms. Upon abdominal examination, an adult fist-sized, ill-defined, round, nonmovable and tender mass was palpated at the left epigastrum. No abnormalities were observed in CBC, urinalysis, stool examination, serum amylase and liver chemistry. We treated the patient with intravenous antibiotics and bed rest. On the second day of hospitalization, a gastroscopy was performed which showed a bulging external mass effect with adherent purulent material and mucosal friability around a fistula-like lesion at the posterior wall of the mid-gastric body (Fig. 2). We took biopsy specimens which showed
necrotic tissues along with an intact gastric mucosa.

On the third day of hospitalization, a barium enema was performed and showed a hyperrotated cecum in the left upper quadrant and nonvisualization of the appendix with mucosal irregularity and focal luminal narrowing at the surrounding distal transverse colon on prone position film consistent with a hyperrotated cecum and appendiceal abscess (Fig. 3).

On the fifth day of hospitalization, after conservative management, the tender mass subsided. A follow-up gastroscopy showed a focal regenerating edematous mucosa without the bulging effect noted in the initial examination (Fig. 4). A follow-up CT scan disclosed the abscess pocket had subsided with surrounding inflammatory change only (Fig. 5). The patient was discharged on the tenth day of hospitalization and has remained well for over 6 months.

**DISCUSSION**

The palpable mass associated with acute appendicitis may consist of phlegmon or abscesses of various sizes. 2-3% of the patients with appendicitis who are admitted to the hospital have abdominal masses and appendiceal abscesses represent 50-89% of the patients with an appendiceal mass. Complicating abscesses
have been reported in 2.3% of all cases of acute appendicitis. 

The main manifestations of acute appendicitis are fever, a palpable mass and leukocytosis. Patients often have a palpable mass in the right lower quadrant (the "appendix mass"). Rarely does the abscess form in the right subhepatic space, right subdiaphragmatic space, liver or posterior pararenal space distant to the right lower quadrant. Therefore, the value of aggressive radiologic work-up and follow-up cannot be overemphasized in suspected appendiceal abscesses, especially those present in locations remote from the appendix. Jordan has reported that the distinction between an appendiceal mass and an appendiceal abscess could not be made by considering the patient's duration of symptoms, temperature and white blood cell count when the patient was admitted. Careful follow-up, routine barium enema study, ultrasonography and abdominal CT scanning would prevent misdiagnosis and delayed treatment. Ultrasonography has made it possible to distinguish an abscess from the phlegmon without operation and the abdominal CT scan has proven to be of considerable clinical value in characterizing periappendiceal inflammatory masses and in determining the relative size of the liquefied versus nonliquefied component.

Despite extensive clinical experiences, the surgical management of appendiceal abscesses remains controversial. However, most authors agree that the initial treatment must be conservative management, including bed rest, nasogastric suction, systemic antibiotics and drainage, rather than early surgery. Initial conservative management with intravenous antibiotics, with or without percutaneous drainage of the abscess, is prudent, safe and effective and shows a high success rate (80-90%) and low morbidity rate (15%) compared to the high complication rate of early surgery (15-50%). Guided percutaneous drainage is an effective alternative to surgical drainage. Nonoperative treatment and, if possible, ultrasonic percutaneous drainage of a verified abscess are safe procedures with few complications and late sequelae. Recently, the ultrasonic percutaneous puncture technique has offered an almost atraumatic alternative to conventional surgical treatment. Also, CT guided percutaneous abscess drainage is an effective alternative to surgery.

The recurrence of appendicitis after conservative treatment is between 4-80% or 0-20%. Sixty-six percent of the recurrent cases occurred within 2 years of the initial attack. The abscess often spontaneously resolves or drains into the intestine with a low recurrence rate. Our case exhibited fever, chills and an epigastric abscess. At first, we suspected a pancreatic abscess because of its location, and managed initially with antibiotics and planned percutaneous drainage. However, the radiological studies, especially the CT scan and the barium enema, revealed an appendiceal abscess in the left upper quadrant of the abdomen due to a hyperrotated cecum.

The abscess resolved spontaneously, and we think that the abscess drained into the stomach through a small fistula between the stomach and abscess cavity. The patient has remained well for over 6 months.
