Abstract

In this study was developed a natural process using a biological system for the biosynthesis of nanoparticles (NPs) and possible removal of copper from wastewater by dead biomass of the yeast Rhodotorula mucilaginosa. Dead and live biomass of Rhodotorula mucilaginosa was used to analyze the equilibrium and kinetics of copper biosorption by the yeast in function of the initial metal concentration, contact time, pH, temperature, agitation and inoculum volume. Dead biomass exhibited the highest biosorption capacity of copper, 26.2 mg g⁻¹, which was achieved within 60 min of contact, at pH 5.0, temperature of 30 °C, and agitation speed of 150 rpm. The equilibrium data were best described by the Langmuir isotherm and kinetic analysis indicated a pseudo-second-order model. The average size, morphology and location of NPs biosynthesized by the yeast were determined by scanning electron microscopy (SEM), energy dispersive X-ray spectroscopy (EDS) and transmission electron microscopy (TEM). The shape of the intracellularly synthesized NPs was mainly spherical, with an average size of 10.5 nm. The X-ray photoelectron spectroscopy (XPS) analysis of the copper NPs confirmed the formation of metallic copper. The dead biomass of Rhodotorula mucilaginosa may be considered an efficiently bioprocess, being fast and low-cost to production of copper nanoparticles and also a probably nano-adsorbent of this metal ion in wastewater in bioremediation process.

Introduction

The biosynthesis of NPs is viewed as a new fundamental building pillar of nanotechnology. Nanobiotechnology has revolutionized the production of nanomaterials which are environmentally safe products. Physico-chemical methods employ toxic chemicals and energy intensive routes, which make these choices eco-hazardous and preclude their use for biomedicine and clinical applications [1]. Therefore, environment friendly protocols need to be developed for the synthesis of nanomaterials. Copper NPs have potential industrial applications, including their use as wood preservatives, gas sensors, catalytic processes, high temperature superconductors and solar cells, among others [2,3,4]. The synthesis of different NPs by microorganisms such as prokaryotes (bacteria and actinomycetes) and eukaryotes (yeast, fungi and plant) has been reported in the literature [5–6]. Yeasts are preferred for the synthesis of nanomaterials due to their traditional use for biodegrading metals from mineral ores [7–8]. Wastewater from copper mining often contains high concentrations of this toxic metal produced during its extraction, beneficiation, and processing. Bioremediation of toxic metals such as copper through biosorption has received a great deal of attention in recent years not only as a scientific novelty, but also because of its potential industrial applications. This approach is competitive, effective, and cheap [9]. In this respect, studies have demonstrated the multi-metal tolerance of Rhodotorula spp, which may be of potential use for the treatment heavy metal-bearing wastewater [10]. Consequently, there has been considerable interest in developing methods for the biosynthesis of copper NPs as an alternative to physical and chemical methods. A literature review [11] revealed only few studies on the biosynthesis of copper NPs using fungi and none of the studies has used the yeast Rhodotorula mucilaginosa (R. mucilaginosa). On the other hand, several studies have investigated the biosynthesis of copper NPs using bacteria, for example, Hasan et al. [12], Ramanathan et al. [13], Singh et al. [14] among others. This work had the objective to enlarge the scope of biological systems for the biosynthesis of copper NPs and bioremediation. We explored for the first time the potential of the yeast R. mucilaginosa, for the removal and conversion of copper ions to copper NPs. Thus the goals of uptake and of a natural process to the production of copper NPs, have been achieved in the present study using dead biomass of R. mucilaginosa.

Materials and Methods

Ethics Statement

The company Vale S.A., owner of Sossego Mine, located in Canaã, Pará, in the Brazilian Amazon region, through the director...
of the Vale Technology Institute, Dr Luiz Eugenio Mello authorized the establishment and dissemination of the study featured in this research article, allowing the collection of material (water from pond of copper waste) supervised by company employees, whose material led to the isolation of the fungus under study. This field study did not involve manipulation of endangered or protected species by any government agency.

Growth and maintenance of the organism
The yeast R. mucilaginosa was isolated from the water collected from a pond of copper waste from Sossego mine, located in Canãa das Garajás, Pará, Brazilian Amazonia region (06°26’S latitude and 50°4’W longitude). The R. mucilaginosa was maintained and activated in YEPD agar medium (10 g yeast extract L−1, 20 g peptone L−1, 20 g glucose L−1 and 20 g agar L−1) and the media compounds were obtained from Oxoid (England) [15].

Analysis of copper (II) tolerance
Copper tolerance of the isolated yeast was determined as the minimum inhibitory concentration (MIC) by the spot plate method [16]. For this purpose, YEPD agar medium plates containing different copper concentrations (50 to 3000 mg L−1) were prepared and inocula of the tested yeast were spotted onto the metal and control plates (plate without metal). The plates were incubated at 25°C for at least 5 days. The MIC was defined as the lowest concentration of the metal that inhibits visible growth of the isolate.

Evaluation of copper NPs retention by the yeast
Preparation of the adsorbate solutions. All chemicals used in the present study were of analytical grade and were used without further purification. All dilutions were prepared in double-deionized water (Milli-Q Millipore 18.2 MΩcm−1 resistivity). The copper stock solution was prepared by dissolving CuCl2·2H2O (Carlo Erba, Italy) in double-deionized water. The working solutions were prepared by diluting this stock solution.

Biomass preparation. The yeast cells were grown in 500 mL Erlenmeyer flasks containing 100 mL YEPD broth (10 g yeast extract L−1, 20 g peptone L−1, 20 g glucose L−1). The flasks were incubated on a rotary shaker at 150 rpm for 20 h at 27°C. The biomass was harvested by centrifugation. Once harvested, the biomass was washed twice with double-deionized distilled water and was used directly for the experiment, corresponding to live biomass. For the production of dead biomass, an appropriate amount of live biomass was autoclaved.

Experimental design of the effects of physico-chemical factors on the efficiency of adsorption of copper NPs by the yeast. The effect of pH (2–6), temperature (20–60°C), contact time (5–360 min), initial copper concentration (25–600 mg L−1), and agitation rate (50–250 rpm) on the removal of copper was analyzed using analysis of variance models [17] with Bonferroni’s multiple comparisons method for adjustment of p-values. These experiments were optimized at the desired pH, temperature, metal concentration, contact time, agitation rate and biosorbent dose (0.05–0.75 g) using 45 mL of a 100 mg L−1 of Cu (II) test solution in plastic flask.

Sorption experiments were carried out using several concentrations of copper (II) prepared by appropriate dilution of the copper (II) stock solution. The pH of the solutions was adjusted using HCl or NaOH aqueous solutions. The desired biomass dose was then added and the content of the flask was shaken for the desired contact time in a shaker at the required agitation rate. The reaction mixtures were filtered by vacuum filtration through a Millipore membrane. The filtrate was analyzed for metal concentrations by flame atomic absorption spectrophotometer (AAS). The efficiency (R) of metal removal was calculated using following equation:

\[ R = \frac{(C_i - C_e)}{C_i} \times 100 \]

where \( C_i \) and \( C_e \) are initial and equilibrium metal concentrations, respectively. The metal uptake capacity, \( q_e \), was calculated using the following equation:

\[ q_e = \frac{V(C_i - C_e)}{M} \]

where \( q_e \) (mg g−1) is the biosorption capacity of the biosorbent at any time, M (g) is the biomass dose, and V (L) is the volume of the solution.

Sorption isotherms. The equilibrium data were fitted using the two most commonly adsorption models, Langmuir and Freundlich [18]. The biosorption was analyzed by the batch equilibrium technique using the following sorbent concentrations of 25–600 mg L−1. The linearized Langmuir isotherm model is:

\[ \frac{C_e}{q_e} = \frac{1}{(q_m b)} + \frac{C_e}{q_m} \]

where \( q_m \) is the monolayer sorption capacity of the sorbent (mg g−1), and b is the Langmuir sorption constant (L mg−1). The linearized Freundlich isotherm model is:

\[ \ln q_e = \ln K_F + \frac{1}{n} \ln C_e \]

where \( K_F \) is a constant relating the biosorption capacity and 1/n is related to the adsorption intensity of adsorbent.

Biosorption kinetics. The experimental biosorption kinetic data were modeled using the pseudo-first-order, and pseudo-second-order models. The linear pseudo-first-order model [19] can be represented by the following equation:

\[ \log \left( q_e - q_t \right) = \log \frac{q_m}{K_1} - \frac{K_1}{2.303} t \]

where, \( q_t \) (mg g−1) and \( q_m \) (mg g−1) are the amounts of adsorbed metal on the sorbent at the equilibrium time and at any time t, respectively, and \( K_1 \) (min−1) is the rate constant of the pseudo-first-order adsorption process. The linear pseudo-second-order model [20] can be represented by the following equation:

\[ \frac{t}{q_t} = \frac{1}{K_2 q_m^2} + \frac{t}{q_m} \]

where \( K_2 \) (g mg−1 min−1) is the equilibrium rate constant of pseudo-second-order.

Intracellular biosynthesis of copper NPs by R. mucilaginosa
Only dead biomass of R. mucilaginosa was used for the analysis of copper NPs production since it exhibited high adsorption capacity of the copper metal ion than live biomass. The biosynthesis of copper NPs by dead biomass of R. mucilaginosa was investigated using the equilibrium data and a solution containing 100 mg L−1 copper (II). After reaction with the copper ions, sections of R. mucilaginosa cells were analyzed by transmission electron microscopy (TEM) (JEOL-1010) to determining the size, shape and location of copper NPs on the biosorbent. Analysis of small fragments of the biological material before and after the formation of copper NPs, were performed on pin stubs then coated with gold.
under vacuum, and examined by SEM (JEOL 6460 LV) equipped with an energy dispersive spectrometer (EDS) to identify the composition of elements of the sample. The XPS analysis was carried out at a pressure of less than $5 \times 10^{-7}$ Pa using a commercial spectrometer (UNI-SPECS UHV System). The Mg Kα line was used ($h\nu = 1253.6$ eV) and the analyzer pass energy was set to 10 eV. The inelastic background of the C 1s, O 1s, N 1s and Cu 2p$_{3/2}$ electron core-level spectra was subtracted using Shirley’s method. The composition (at.%) of the near surface region was determined with an accuracy of ±10% from the ratio of the relative peak areas corrected by Scofield’s sensitivity factors of the corresponding elements. The binding energy scale of the

**Figure 1. Sorption studies.** Influence of the physico-chemical factors on the live and dead biomass of *R. mucilaginosa*. (A) Effect of the amount of biosorbent. (B) Effect of pH. (C) Effect of temperature. (D) Effect of contact time. (E) Effect of agitation rate. (F) Effect of initial copper concentration. doi:10.1371/journal.pone.0087968.g001
spectra was corrected using the C 1s hydrocarbon component of the fixed value of 285.0 eV. The spectra were fitted without placing constraints using multiple Voigt profiles. The width at half maximum (FWHM) varied between 1.2 and 2.1 eV and the accuracy of the peak positions was ±0.1 eV.

Results and Discussion

The sensitivity towards at copper of the *R. mucilaginosa* when subjected to minimum inhibitory concentration at different metal concentrations (50–3000 mg L$^{-1}$) showed that this yeast can survive within high level concentrations until 2000 mg L$^{-1}$. The yeast uses several mechanisms to balance intracellular metal concentrations and counter metal toxicity. The resistance mechanism includes sequestration of heavy metals by metallothioneins.

through their high cysteine content and adsorption of heavy metal cations by the cellular walls [21–22].

Effects of the physico-chemical factors on biosorption

This study showed that copper removal by R. mucilaginosa biomass was significantly influenced by the effects and interactions with the physico-chemical factors. As can be seen in Figure 1, the percentage of copper removal was higher for dead biomass than live biomass for all parameters tested (p<0.0001 in all cases). Figure 1A shows that the dead biomass was more efficient in the removal of copper compared with the live biomass (p<0.0001 in the five levels of amount of biosorbent), indicating that dead biomass possess a higher affinity for copper than live biomass. The use of dead biomass for Cu (II) removal has the advantages that it is not toxic and, does not require growth media and nutrients for its maintenance [23]. Therefore the R. mucilaginosa may become a potential biosorbent in removing heavy metals from polluted water. The effectiveness of biomass concentration in percentage sorption of the metals was also observed to Rhodotorula glutinis [24]. In this study copper biosorption was maximum around pH 5.0, for the two types of biomass (Figure 1B, p<0.0001 in both cases), would be expected to interact more strongly with negatively charged binding sites on the biosorbent. At higher pH levels (pH 5), more ligands with negative charges would be exposed, with the subsequent increase in attraction sites to positively charged metal ion [25]. Some researchers have also investigated the effect of pH on the biosorption of toxic metals and found similar results [26,27,28,29]. The maximum removal of copper was observed at 30°C for the two types of biomass (Figure 1C, p<0.0001 in both cases). The influence of temperature on the sorption of metals has also been reported for the yeast Pehia stipitis [28] and Rhodotorula sp. Y11 [29], for the bacterium Morganella psychrotolerans [30] and for the plant Cymbopogon flexuosus [31] and others. The decrease in adsorption with increasing temperature may be due to the weakening of adsorptive forces between active sites of the adsorbents and the adsorbate species [32]. In Figure 1D, the graph shows sigmoidal kinetics for the types of biomass (p<0.0001 in both cases), which is characteristic of an enzyme-catalyzed reaction. The kinetics of copper NPs formation by dead biomass showed that more than 90% of the particles were formed within 60 min of reaction. The importance of contact time of the metal with the biomass has also been reported for Rhodotorula sp. Y11 [33]. The optimum copper removal was observed at an agitation speed of 150 rpm for both types of biomass (Figure 1E,
p<0.0001 in both cases). At high agitation speeds, vortex phenomena occur and the suspension is no longer homogenous, a fact impairing metal removal [34]. The percentage of copper adsorption decreased with increasing metal concentration (50–500 mg L\(^{-1}\)) for both types of biomass, as shown in Figure 1F (\(p<0.0001\) in both cases). The same has been observed for fungi at concentration of Zn ranging from 100–400 mg L\(^{-1}\) [35], and for copper removal by *Rhodotorula mucilaginosa* RCL-11 and *Candida* sp. RCL-3 [36].

**Biosorption isotherms and adsorption kinetics models**

Langmuir and Freundlich adsorption isotherms, were used to describe the adsorption data for a range of copper (II) concentrations (25–600 mg L\(^{-1}\)). The Langmuir model better described the Cu (II) biosorption isotherms than the Freundlich model. The Langmuir isotherm for Cu (II) biosorption obtained for the two types of *R. mucilaginosa* biomass is shown in Figure 2A and Figure 2B. The isotherm constants, maximum loading capacity estimated by the Langmuir and Freundlich models, and regression coefficients are shown in Table 1. The maximum adsorption rate of Cu (II) by *R. mucilaginosa* (26.2 mg g\(^{-1}\)) observed in this study was higher than the adsorption rates reported for other known biosorbents, such as *Pleurotus pulmonaris*, *Schizophyllum commune*, *Penicillium spp.*, *Rhizopus arizus*, *Trichoderma viride*, *Pichia stipitis*, *Pycnoporus sanguineus*, with adsorption rates of 6.2, 1.52, 15.08, 19.0, 19.6, 15.85 and 2.76 mg g\(^{-1}\) respectively [37,38,39,40,28,41]. Comparison with biosorbents of bacterial origin showed that the Cu (II) adsorption rate of *R. mucilaginosa* is comparable to that of *Bacillus subtilis* IAM 1026 (20.8 mg g\(^{-1}\)) [42], but higher than the rates reported for the algae *Cladophora spp* and *Fucus vesiculosus* (14.28 and 23.4 mg g\(^{-1}\)) [43–44].

Onto both types of biomasses of *R. mucilaginosa* the kinetics of copper biosorption were analysed using pseudo-first-order and pseudo-second-order models. All the constants and regression coefficients are shown in Table 2. In the present study, biosorption by *R. mucilaginosa* was best described using a pseudo-second-order kinetic model as shown in Figure 2C and Figure 2D. This adsorption kinetics is typical for the adsorption of divalent metals onto biosorbents [45].

**Synthesis of copper nanoparticles from dead biomass of *R. mucilaginosa***

The researching of biosynthetic methods to the metals NPs formation is important in order to determine even more reliable and reproducible methods for its synthesis and have drawn attention as a simple and viable alternative to chemical procedures and physical methods. The information of the location of copper NPs in the yeast cell is important for elucidating the mechanism of their formation and was obtained through TEM analysis of thin sections of dead biomass (Figure 3). The results clearly showed the high concentration of intracellular copper NPs in the yeast cell, uniformly distributed (monodispersed) without significant agglomeration and was absent in control, the ultrastructural change such as shrinking of cytoplasmatic material was observed in control and in the biomass impregnated with copper due to autoclaving process. However, it was not observed the disruption of the cell wall likely due to the autoclaving method, whose principle consists in causing the death of the microorganisms by denaturation of some proteins [46]. It is important to note, that the cell wall of most yeasts, consists of about 85%–90% polysaccharides and 10%–15% protein and the polysaccharide component consists of a mixture of water-soluble mannan, alkali-soluble glucan, alkali insoluble glucan and small amounts of chitin [47], being these components of polysaccharides responsible for the high mechanical resistance of the cell wall [48] (Figure 3A and Figure 3B).

The two most important features that control the chemical, physical, optical and electronic properties of nanoscale materials are the size and shape of these particles [49–50]. As observed in Figure 3B, the majority of the particles are spherical in shape and with size of an average diameter of 10.5 nm. To confirm the presence of copper NPs in the dead biomass of yeast it was performed a spot profile SEM-EDS measurement. SEM micrographs recorded before and after biosorption of Cu (II) by yeast

---

**Figure 5. EDS spectra of dead biomass of *R. mucilaginosa*. (A) before exposure to copper solution and (B) after exposure to the metal confirming the presence of copper.**

doi:10.1371/journal.pone.0087968.g005
Figure 6. XPS spectra. C 1s, N 1s, O 1s and Cu 2p core level binding energies after biosynthesis of copper NPs.
doi:10.1371/journal.pone.0087968.g006
biomass was showed in Figure 4A and Figure 4B respectively. It was observed a surface modification by an increasing of the irregularity, after binding of copper NPs with the yeast biomass. The EDS spectrum recorded in the examined region of the yeast cells confirmed the presence of copper. (Figure 3A and Figure 3B). The signals for C, N, O and P may be originate from biomolecules that are bound to the surface of copper NPs.

Unfortunately the intracellular mechanism formation of copper NPs by the dead biomass of yeast R. mucilaginosa is not fully understood at the moment. The ions copper possibly could diffuse through the cell wall and are reduced by enzymes present on the cytoplasmic membrane and within the cytoplasm. This enzyme-based pathway, also was proposed to silver nanoparticles synthesis [51]. The XPS spectra Figure 6 shows C 1s, N 1s, O 1s and Cu 2p core level after biosynthesis of copper NPs by dead biomass of R. mucilaginosa. As can be seen in the high resolution spectra of carbon (C 1s), the components of higher binding energy were deconvoluted within four elements. The main component at 284.8 eV is attributed to the hydrocarbon chains of the cellular phase; the peak at 286.7 eV to the \( \alpha \)-carbon, the peak at 288.0 eV to the carboxyl groups, and finally the peak at 292.2 eV to the carboxylic groups from the peptides/proteins bound to copper NPs [52]. The deconvoluted spectra of oxygen (O 1s), showed peaks at 531.2 eV, 532.4 eV and 533.5 eV related to the peaks found in the C 1s spectra. The spectra of nitrogen (N 1s) have two components, the main 400.1 eV and a lower at 402.3 eV. In the O 1s and N 1s spectra the major binding energies at 532.4 eV and 400.1 eV respectively were observed confirming the presence of proteins involving copper NPs, which suggests the possibility of these agents acting as capping agents [52]. The Cu 2p core level showed a sharp peak arise at 932.9 eV and it corresponds to the Cu 2p3/2 level characteristic of Cu(0) [53,54,55]. The presence of CuO (Cu (II)) phase can be excluded considering the lacking of the signal at 953.7 eV, as well as the presence of Cu2O, that can be ruled out by the fact of no Cu 2p satellite peak appears with Cu2O [56–57]. There are several reports in literature of yeast mediating the synthesis of nanoparticles of metal ions except to copper such as, peptide-bound CdS quantum crystallites by Candida glabrata [58], Schizochytrium limacinum [59] also produced CdS nanoparticles [59], PbS nanocrystals by Torulopsis sp. [60], gold nanoparticles by Pichia jadinii (Candida utilis) [61–62], the tropical marine yeast

\[ Yarrowia lipolytica \text{ NCIM 3589 also synthesized gold nanoparticles} \] [63], \( \text{Sb}_2\text{O}_3 \) nanoparticles by \( \text{Saccharomyces cerevisiae} \) [64] and silver nanoparticles by yeast MKY3 [65]. Honary et al. [66] reported the production of copper nanoparticles by filamentous fungi, but the authors only used live biomass. The bioprocess proposed here, using dead biomass has the advantages, that it is not toxic, and does not require growth media and nutrients for its maintenance. The intracellular production of copper NPs by dead biomass of R. mucilaginosa was probably the result of a reduction process inside the cell mediated by proteins and enzymes present in the cytoplasm. However the type of proteins interacting with copper NPs remains to be determined and this knowledge would open new perspectives for a more efficient green synthesis of copper NPs.

Conclusions

In summary, we described for the first time a biological economic template, and non-toxic using dead biomass of the red yeast R. mucilaginosa, that may be considered an efficient bioprocess to the synthesis of metallic copper NPs, and probable system for the adsorption of copper ions from wastewater. The dead biomass had a dual role, acting as a reducing agents and stabilizer during the formation of copper NPs, as well as in the uptake of copper ions during the bioremediation process. This natural method affords an amenable process to large scale commercial production. In future studies, we intend to characterize the role of biomacromolecules in the biosorption and bioreduction processes during the synthesis of copper NPs.
