4-CONNECTED TRIANGULATIONS ON FEW LINES\textsuperscript{∗†}

Stefan Felsner\textsuperscript{‡}

Abstract. We show that every 4-connected plane triangulation with \(n\) vertices can be drawn such that edges are represented by straight segments and the vertices lie on a set of at most \(\sqrt{2n}\) lines each of them horizontal or vertical. The same holds for plane graphs on \(n\) vertices without separating triangle.

The proof is based on a corresponding result for diagrams of planar lattices which makes use of orthogonal chain and antichain families.

1 Introduction

Given a planar graph \(G\) we denote by \(\pi(G)\) the minimum number \(\ell\) such that \(G\) has a plane straight-line drawing in which the vertices can be covered by a collection of \(\ell\) lines. Clearly \(\pi(G) = 1\) if and only if \(G\) is a forest of paths. The set of graphs with \(\pi(G) = 2\), however, is already surprisingly rich, it contains trees, outerplanar graphs and subgraphs of grids \([1, 9]\).

The parameter \(\pi(G)\) has received some attention in recent years, here is a list of known results:

- It is NP-complete to decide whether \(\pi(G) = 2\) (Biedl et al. [2]).
- For a stacked triangulation \(G\), a.k.a. planar 3-tree or Apollonian network, let \(d_G\) be the stacking depth (e.g. \(K_4\) has stacking depth 1). On this class lower and upper bounds on \(\pi(G)\) are \(d_G + 1\) and \(d_G + 2\) respectively, see Biedl et al. [2] and for the lower bound also Eppstein [8, Thm. 16.13].
- Eppstein [9] constructed a planar, cubic, 3-connected, bipartite graph \(G_\ell\) on \(O(\ell^3)\) vertices with \(\pi(G_\ell) \geq \ell\).

Related parameters have been studied by Chaplick et al. [4, 5].

The main result of this paper is the following theorem.

Theorem 1 If \(G\) is a 4-connected plane triangulation on \(n\) vertices, then \(\pi(G) \leq \sqrt{2n}\).

\textsuperscript{*}An extended abstract of this work appears in Proceedings of the 27th International Symposium on Graph Drawing and Network Visualization (GD 19) \texttt{arXiv:1908.04524v1}

The result is not far from optimal since, using a small number of additional vertices and many additional edges, Eppstein’s graph $G_\ell$ can be transformed into a 4-connected plane triangulation, i.e., in the class we have graphs with $\pi(G) \in \Omega(n^{1/3})$. Figure 1 shows a section of such an extension of $G_\ell$.

![Figure 1: A section of Eppstein’s graph $G_\ell$ (left) and its extension to a 4-connected triangulation (right), extra vertices are shown in blue and additional edges in cyan.](image)

A plane graph on at least 5 vertices and without separating triangles can be extended to a 4-connected triangulation by adding edges and at most one extra vertex, see [3]. Graphs requiring the extra vertex are wheels with an outer cycle of length at least 4 and subgraphs of wheels obtained by removing some cycle edges. These exceptional graphs can be drawn on 3 lines. Plane graphs with at most 4 vertices can be drawn on 2 lines. Therefore, we get:

**Corollary 1** If $G$ is a plane graph on $n$ vertices without separating triangles, then $\pi(G) \leq \sqrt{2n}$.

The proof of Theorem 1 makes use of transversal structures, these are special colorings of the edges of a 4-connected inner triangulation of a 4-gon with colors red and blue.

In Section 2.1 we survey transversal structures. The red subgraph of a transversal structure can be interpreted as the diagram of a planar lattice. Background on posets and lattices is given in Section 2.2. Dimension of posets and the connection with planarity are covered in Section 2.3. In Section 2.4 we survey orthogonal partitions of posets. The theory implies that every poset on $n$ elements can be covered by at most $\sqrt{2n} - 1$ subsets such that each of the subsets is a chain or an antichain.

In Section 3 we prove that the diagram of a planar lattice on $n$ elements has a straight-line drawing with vertices placed on a set of $\sqrt{2n} - 1$ lines. All the lines used for the construction are either horizontal or vertical.

Finally in Section 4 we prove the main result: transversal structures can be drawn on at most $\sqrt{2n} - 1$ lines. In fact, the red subgraph of the transversal structure has such a drawing by the result of the previous section. It is rather easy to add the blue edges to this drawing and thus prove Theorem 1.
2 Preliminaries

2.1 Transversal structures

Let $G$ be an internally 4-connected inner triangulation of a 4-gon, in other words $G$ is a plane graph with quadrangular outer face, triangular inner faces, and no separating triangle. Let $s, a, t, b$ be the outer vertices of $G$ in clockwise order. A transversal structure for $G$ is an orientation and 2-coloring of the inner edges of $G$ such that

1. All edges incident to $s, a, t$ and $b$ are red outgoing, blue outgoing, red incoming, and blue incoming, respectively.

2. The edges incident to an inner vertex $v$ come in clockwise order in four non-empty blocks consisting solely of red outgoing, blue outgoing, red incoming, blue incoming edges, respectively.

Figure 2 illustrates the properties and shows an example. Transversal structures have several applications in graph drawing [18], [13], [14]. In particular it has been shown that every internally 4-connected inner triangulation of a 4-gon admits a transversal structure. Fusy [14] used transversal structures to prove the existence of straight-line drawings with vertices being placed on integer points $(x,y)$ with $0 \leq x \leq W$, $0 \leq y \leq H$, and $H + W \leq n - 1$.

![Figure 2: The two local conditions and an example of a transversal structure.](image)

An orientation of a graph $G$ is said to be acyclic if it has no directed cycle. Given an acyclic orientation of $G$, a vertex having no incoming edge is called a source, and a vertex having no outgoing edge is called a sink. A bipolar orientation is an acyclic orientation with a unique source $s$ and a unique sink $t$, cf. [6]. Bipolar orientations of plane graphs are also required to have $s$ and $t$ incident to the outer face. A bipolar orientation of a plane graph has the property that at each vertex $v$ the outgoing edges form a contiguous block and the incoming edges form a contiguous block. Moreover, each face $f$ of $G$ has two special vertices $s_f$ and $t_f$ such that the boundary of $f$ consists of two non-empty oriented paths from $s_f$ to $t_f$.

Let $G = (V, E)$ be an internally 4-connected inner triangulation of a 4-gon with outer vertices $s, a, t, b$ in clockwise order, and let $E_R$ and $E_B$ respectively be the red and blue oriented edges of a transversal structure on $G$. We define $E_R^+ = E_R \cup \{(s, a), (s, b), (a, t), (b, t)\}$. 
and \( E_B^+ = E_B \cup \{(a,s),(a,t),(s,b),(t,b)\} \), i.e., we think of the outer edges as having both, a red direction and a blue direction. The following has been shown by Kant and He [18] and Fusy [13].

**Proposition 1** The red graph \( G_R = (V,E_R^+) \) and the blue graph \( G_B = (V,E_B^+) \) both come with a bipolar orientation inherits from the transversal structure. \( G_R \) has source \( s \) and sink \( t \), and \( G_B \) has source \( a \) and sink \( b \).

The following two properties are easy consequences of the previous discussion.

(R) The red and the blue graph are both transitively reduced, i.e., if \((v,v')\) is an edge, then there is no directed path \( v,u_1,\ldots,u_k,v' \) with \( k \geq 1 \).

(F) For every blue edge \( e \in E_B \) there is a face \( f \) in the red graph such that \( e \) has one endpoint on each of the two oriented \( s_f \) to \( t_f \) paths on the boundary of \( f \).

### 2.2 Posets

We assume basic familiarity with concepts and terminology for posets, referring the reader to the Trotter’s monograph [21] and survey [22] for additional background material. In this paper we consider a poset \( P = (X,\prec) \) as being equipped with a *strict* partial order.

A *cover relation* of \( P \) is a pair \((x,y)\) with \( x < y \) such that there is no \( z \) with \( x < z < y \), we write \( x \prec y \) to denote a cover relation of the two elements. A *diagram* (a.k.a. Hasse diagram) of a poset is an upward drawing of its transitive reduction. That is, \( X \) is represented by a set of points in the plane and a cover relation \( x \prec y \) is represented by a \( y \)-monotone curve going upwards from \( x \) to \( y \). In general these curves (edges) may cross each other but must not touch any vertices other than their endpoints. A diagram uniquely describes a poset, therefore, we usually show diagrams in our figures. A poset is said to be *planar* if it has a planar diagram.

It is well known that in discussions of graph planarity, we can restrict our attention to straight-line drawings. In fact Schnyder [20] proved that a plane graph on \( n \) vertices admits a plane straight-line drawing with vertices on an \((n-2) \times (n-2)\) grid. Discussions of planarity for posets can also be restricted to straight-line drawings; however, this may come at some cost in visual clarity. Di Battista et al. [7] have shown that an exponentially large grid may be required for upward planar drawings of directed acyclic planar graphs with straight lines. In the next subsection we will see that for certain planar posets the situation is more favorable.

### 2.3 Dimension of planar posets

Let \( P = (X,\prec_P) \) be a poset. A *linear extension* of \( P \) is a total order \( L = (X,\prec_L) \) extending \( P \), i.e., if \( x \prec_P y \), then \( x \prec_L y \). A *realizer* of \( P \) is a collection \( L_1,L_2,\ldots,L_t \) of linear extensions of \( P \) such that \( P = L_1 \cap L_2 \cap \cdots \cap L_t \). The *dimension* of \( P = (X,\prec) \), denoted \( \dim(P) \), is the least positive integer \( t \) such that \( P \) has a realizer of size \( t \). Obviously, a poset \( P \) has dimension 1 if and only if it is a chain (total order). Also, there is an elementary characterization of posets of dimension at most 2 that we shall use.
**Proposition 2** A poset $P = (X, <)$ has dimension as most 2 if and only if its incomparability graph is also a comparability graph.

There are a number of results concerning the dimension of posets with planar order diagrams. Recall that an element is called a zero of a poset $P$ when it is the unique minimal element. Dually, a one is a unique maximal element. A finite poset which is also a lattice, i.e., which has well defined meet and join operations, always has both a zero and a one. Figure 3 shows some posets and lattices.

The following result may be considered part of the folklore of the subject.

**Theorem 2** Let $P$ be a finite lattice. Then $P$ is planar if and only if it has dimension at most 2.

![Figure 3: Three posets with their diagrams: (left) a planar poset of dimension 3, (middle) a non-planar lattice, and (right) a planar lattice.](image)

The complete proof of the theorem can be found in Trotter’s book [21]. For the proof of the reverse direction let $P$ be a lattice of dimension at most 2. Let $L_1$ and $L_2$ be linear orders on $X$ so that $P = L_1 \cap L_2$. For each $x \in X$, and each $i = 1, 2$, let $x_i$ denote the height of $x$ in $L_i$. Then a planar diagram of $P$ is obtained by locating each $x \in X$ at the point in the plane with integer coordinates $(x_1, x_2)$ and joining points $x$ and $y$ with a straight line segment when one of $x$ and $y$ covers the other in $P$. Figure 4 shows an example. A pair of crossing edges in this drawing would violate the lattice property, indeed if $x \prec y$ and $x' \prec y'$ are two covers whose edges cross, then $x \leq y'$ and $x' \leq y$ whence there is no unique least upper bound for $x$ and $x'$.

A planar digraph $D$ with a unique sink and source, both of them on the outer face, and no transitive edges is the digraph of a planar lattice. Hence, the above discussion directly implies the following classical result.

**Proposition 3** A planar digraph $D$ on $n$ vertices with a unique sink and source on the outer face and no transitive edges has an upward drawing on an $(n-1) \times (n-1)$ grid.

To the best of our knowledge the area problem for diagrams of general planar posets is open.

In this paper we will, henceforth, use the terms 2-dimensional poset and planar lattice respectively to refer to a poset $P = (X, <)$ together with a fixed ordered realizer $[L_1, L_2]$. As shown in the proof of Theorem 2, fixing the realizer of a 2-dimensional lattice can be
interpreted as fixing a plane drawing of the diagram. By fixing the realizer of $P$ we also have a well-defined primary conjugate, this is the poset $Q$ on $X$ with realizer $[L_1, L_2]$, where $L_2$ is the reverse of $L_2$. Define the left of relation on $X$ such that $x$ is left of $y$ if and only if $x = y$ or $x \parallel y$, i.e., $x$ and $y$ are incomparable in $P$, and $x < y$ in $Q$. In the drawing of $P$ obtained from $[L_1, L_2]$ element $x$ is left of $y$ if $x$ is in the upper-left quadrant of $y$.

2.4 Orthogonal partitions of posets

Let $P = (X, <)$ be a finite poset. Dilworth’s theorem states that the maximum size of an antichain equals the minimum number of chains partitioning the elements of $P$.

Greene and Kleitman [17] found a nice generalization of Dilworth’s result. A $k$-antichain is defined as a family of $k$ pairwise disjoint antichains.

**Theorem 3** For any partially ordered set $P$ and any positive integer $k$

$$\max \sum_{A \in A} |A| = \min \sum_{C \in C} \min(|C|, k)$$

where the maximum is taken over all $k$-antichains $A$ and the minimum over all chain partitions $C$ of $P$.

Greene [16] stated the dual of this theorem. Let a $\ell$-chain be a family of $\ell$ pairwise disjoint chains.

**Theorem 4** For any partially ordered set $P$ and any positive integer $\ell$

$$\max \sum_{C \in C} |C| = \min \sum_{A \in A} \min(|A|, \ell)$$

where the maximum is taken over all $\ell$-chains $C$ and the minimum over all antichain partitions $A$ of $P$. 

Figure 4: The planar lattice from Fig. 3 with a realizer $L_1, L_2$. 
A further theorem of Greene [16] can be interpreted as a generalization of the Robinson-Schensted correspondence and its interpretation given by Greene [15].

To a partially ordered set $P$ with $n$ elements there is an associated integer partition $\lambda$ of $n$, such that for the Ferrer’s diagram $G(P)$ corresponding to $\lambda$ we get:

**Theorem 5** The number of squares in the $\ell$ longest columns of $G(P)$ equals the maximal number of elements covered by an $\ell$-chain of $P$ and the number of squares in the $k$ longest rows of $G(P)$ equals the maximal number of elements covered by a $k$-antichain of $P$.

Figure 5 shows an example, in this case the Ferrer’s diagram $G(P)$ corresponds to the partition $6+3+3+1+1 = 14$. Several proofs of Greene’s results are known [10], [12], [19]. For a not so recent, but at its time comprehensive survey we recommend West [23].

The approach taken by András Frank [12] is particularly elegant. Following Frank we call a chain family $C$ and an antichain family $A$ of a poset $P = (X, <)$ an orthogonal pair iff

1. $X = \left( \bigcup_{A \in A} A \right) \cup \left( \bigcup_{C \in C} C \right)$, and
2. $|A \cap C| = 1$ for all $A \in A$, $C \in C$.

If $C$ is orthogonal to a $k$-antichain $A$ and $C^+$ is obtained from $C$ by adding the rest of $P$ as singletons, then

$$\sum_{A \in A} |A| = \sum_{C \in C^+} \sum_{A \in A} |A \cap C| = \sum_{C \in C^+} \min(|C|, k).$$

Thus $C^+$ is a $k$ optimal chain partition in the sense of Theorem 3. Similarly an $\ell$ optimal antichain partition in the sense of Theorem 4 can be obtained from an orthogonal pair $A, C$ where $C$ is an $\ell$-chain.

Using the minimum cost flow algorithm of Ford and Fulkerson [11], Frank proved the existence of a sequence of orthogonal chain and antichain families. This sequence is rich enough to allow the derivation of the whole theory. The sequence consists of an orthogonal pair for every point from the boundary of $G(P)$. With the point $(\ell, k)$ from the boundary of $G(P)$ we get an orthogonal pair $A, C$ such that $A$ is a $k$-antichain and $C$ an $\ell$-chain, see Figure 5. Since $G(P)$ is the Ferrer’s diagram of a partition of $n$ we can find a point $(\ell, k)$ on the boundary of $G(P)$ with $\ell + k \leq \sqrt{2n} - 1$. (This is because every Ferrer’s shape of a partition of $m$ which contains no point $(x, y)$ with $x + y \leq s$ on the boundary contains the shape of the partition $(1, 2, \ldots, s + 1)$. From $m \geq \binom{s+2}{2}$ we get $s + 1 < \sqrt{2m}$).

We will use the following corollary of the theory:

**Corollary 2** Let $P = (X, <)$ be a partial order on $n$ elements, then there is an orthogonal pair $A, C$ where $A$ is a $k$-antichain and $C$ an $\ell$-chain and $k + \ell \leq \sqrt{2n} - 1$.

For our application we will need some additional structure on the antichains and chains of an orthogonal pair $A, C$.

The canonical antichain partition of a poset $P = (X, <)$ is constructed by recursively removing all minimal elements from $P$ and make them one of the antichains of the partition.
Figure 5: The Ferrer’s shape of the lattice $L$ from Fig. 4 together with two orthogonal pairs of $L$ corresponding to the boundary points $(3, 3)$ and $(5, 1)$ respectively of $G(L)$; chains of $C$ are blue, antichains of $A$ are red, green, and yellow.

More explicitly $A_1 = \min(X)$ and $A_j = \min(X \setminus \bigcup\{A_i : 1 \leq i < j\})$ for $j > 1$. Note that by definition for each element $y \in A_j$ with $j > 1$ there is some $x \in A_{j-1}$ with $x < y$. Due to this property there is a chain of $h$ elements in $P$ if the canonical antichain partition consists of $h$ non-empty antichains. This in essence is the dual of Dilworth’s theorem, i.e., the statement: the maximal size of a chain equals the minimal number of antichains partitioning the elements of $P$.

**Lemma 1** Let $A, C$ be an orthogonal pair of $P = (X, \prec)$ and let $P_A$ be the order induced by $P$ on the set $X_A = \bigcup\{A : A \in A\}$. If $A'$ is the canonical antichain partition of $P_A$, then $|A| = |A'|$ and $A', C$ is again an orthogonal pair of $P$.

**Proof.** Let $A$ be the family $A_1, \ldots, A_k$. Starting with this family we will change the antichains in the family while maintaining the invariant that the family of antichains together with $C$ forms an orthogonal pair. At the end of the process the family of antichains will be the canonical antichain partition of $P_A$.

The first phase of changes is the uncrossing phase. We iteratively choose two antichains $A_i, A_j$ with $i < j$ from the present family and let $B_i = \{y \in A_i : \text{there is an } x \in A_j \text{ with } x < y\}$ and $B_j = \{x \in A_j : \text{there is a } y \in A_i \text{ with } x < y\}$. Define $A'_i = A_i - B_i + B_j$ and $A'_j = A_j - B_j + B_i$. It is easy to see that $A'_i$ and $A'_j$ are antichains and that the family obtained by replacing $A_i, A_j$ by $A'_i, A'_j$ is orthogonal to $C$. This results in a family of $k$ antichains such that if $i < j$ and $x \in A_i$ and $y \in A_j$ are comparable, then $x < y$.

The second phase is the push-down phase. In this phase we go through $i \in [k - 1]$ and let $B = \{y \in A_{i+1} : \text{there is no } x \in A_i \text{ with } x < y\}$. We then define $A'_{i+1} = A_{i+1} - B$ and $A'_i = A_i + B$. It is again easy to see that $A'_i$ and $A'_{i+1}$ are antichains and that the family obtained by replacing $A_i, A_{i+1}$ by $A'_i, A'_{i+1}$ is orthogonal to $C$. This results in a family of $k$ antichains such that if $y \in A_{i+1}$, then there is an $x \in A_i$ with $x < y$. This implies that $A_j = \min(X_A \setminus \bigcup\{A_i : 1 \leq i < j\})$, hence the family is the canonical antichain partition. □

Let $P = (X, \prec)$ be a 2-dimensional poset with realizer $[L_1, L_2]$ and recall that the primary conjugate has realizer $[L_1, \overline{L_2}]$. The order $Q$ corresponds to a transitive relation on the complement of the comparability graph of $P$, in particular chains of $P$ and antichains of $Q$ are in bijection.
The canonical antichain partition of $Q$ yields the canonical chain partition of $P$. The canonical chain partition $C_1, \ldots, C_w$ of $P$ can be characterized by the property that for each $1 \leq i < j \leq w$ and each element $y \in C_j$ there is some $x \in C_i$ with $x \parallel y$ and in $L_1$ element $x$ comes before $y$. In particular $C_1$ is a maximal chain of $P$.

Let $A, C$ be an orthogonal pair of the 2-dimensional $P = (X, <)$. Applying the proof of Lemma 1 to the orthogonal pair $C, A$ of $Q$ we obtain:

**Lemma 2** Let $A, C$ be an orthogonal pair of $P = (X, <)$ and let $P_C$ be the order induced by $P$ on the set $X_C = \bigcup \{ C : C \in C \}$. If $C'$ is the canonical chain partition of $P_C$, then $|C| = |C'|$ and $C', A$ is again an orthogonal pair of $P$.

In a context where edges of the diagram are of interest, it is convenient to work with maximal chains. The canonical chain partition $C_1, \ldots, C_w$ of a 2-dimensional $P$ induces a canonical chain cover of $P$ which consists of maximal chains. With chain $C_i$ associate a chain $C_i^+$ which is obtained by successively adding to $C_i$ all compatible elements of $C_{i-1}, C_{i-2}, \ldots$ in this order. Alternatively $C_i^+$ can be described by looking at the conjugate $Q^d$ of $P$ with realizer $[L_1, L_2]$ (this is the dual of the primary conjugate $Q$), and defining $C_i^+$ as the first chain in the canonical chain partition of the order induced by $\bigcup \{ C_j : 1 \leq j \leq i \}$, the chain $C_i^+$ corresponds to the antichain of minimal elements of the order induced by $Q^d$ on $\bigcup \{ C_j : 1 \leq j \leq i \})$. The maximality of $C_i^+$ follows from the characterization of the canonical chain partition given above.

### 3 Drawing Planar Lattices on Few Lines

In this section we prove that planar lattices with $n$ elements have a straight-line diagram with all vertices on a set of $\sqrt{2n} - 1$ horizontal and vertical lines. The following proposition covers the case where the lattice has an antichain partition of small size. We assume that a planar lattice is given with a realizer $[L_1, L_2]$ and, hence, with a fixed plane drawing of its diagram.

**Proposition 4** For every planar lattice $L = (X, <)$ with a plane diagram $D_L$ and any order preserving map $h : X \rightarrow \mathbb{R}$ there is a plane straight-line drawing $\Gamma$ of $D_L$ such that each element $x \in X$ is represented by a point with $y$-coordinate $h(x)$. Additionally all elements of the left boundary chain of $D_L$ are aligned vertically in the drawing.

**Proof.** Let $C_1, \ldots, C_w$ be the canonical chain partition and $C_1^+, \ldots, C_w^+$ be the corresponding canonical chain cover. Define $S_i$ as the suborder of $L$ induced by $\bigcup \{ C_j : 1 \leq j \leq i \}$ and note that $S_i$ is a sublattice of $L$ with left boundary chain $C_1 = C_1^+$ and right boundary chain $C_i^+$.

Embed the elements of $C_1$ on a vertical line $g_1$ (e.g. the line $y = 0$) with points as prescribed by $h$. This is a drawing $\Gamma_1$ of $S_1$. Suppose that a drawing $\Gamma_i$ of the diagram $S_i$ is constructed. The right boundary path $\gamma_i$ of $\Gamma_i$ is a polygonal $y$-monotone path. Embed the elements of $C_{i+1}$ on a vertical line $g_{i+1}$ with points as prescribed by $h$. We need a position for $g_{i+1}$ to the right of $\gamma_i$ such that all the diagram edges connecting $C_{i+1}$ to $C_i^+$ can be inserted to obtain a crossing free drawing $\Gamma_{i+1}$ of the diagram of $S_{i+1}$.
Let $E_i$ be the set of diagram edges connecting $C_{i+1}$ to $C_i^+$. For each $e \in E_i$ there are points $p \in \gamma_i$ and $q \in g_{i+1}$ representing the endpoints. Let $K_p$ be an open cone with apex $p$ which intersects $\gamma_i$ only at $p$ and contains a horizontal ray to the right. Let $b_e$ be the minimal horizontal distance of $\gamma_i$ and $g_{i+1}$ such that $q \in K_p$. Let $\beta = \max(b_e : e \in E_i)$. If we place $\gamma_i$ and $g_{i+1}$ at horizontal distance $\beta$, then the edges of $E_i$ can be drawn such that they do not interfere (introduce crossings) with $\gamma_i$. We claim that there is no crossing of edges of $E_i$. Let $e = (p, q)$ and $e' = (p', q')$ be two drawn edges from $E_i$. Since they are edges of a planar diagram, they are cover edges and have endpoints on two chains. We can assume that $h(p) < h(p')$ which implies $h(q) < h(q')$. If the two edges cross, their crossing point is in $K_p \cap K_{p'}$. Let $c$ be the leftmost point of $K_p \cap K_{p'}$ (here we take the closed cones). Note that $h(p) < h(c) < h(p')$. This implies that at the $x$-coordinate of $c$ edge $e'$ is above $e$. At the crossing they change their vertical order, whence, to the right of the crossing $e$ is above $e'$. This implies that $h(q) > h(q')$, a contradiction. Hence we have a planar drawing $\Gamma_{i+1}$ of the diagram of $S_{i+1}$. With induction we obtain the drawing $\Gamma = \Gamma_w$ of $D_L$.

A particularly interesting order preserving map $h : X \to \mathbb{R}$ is the height function. The height $h(x)$ of an element $x$ of $P$ can be defined via the canonical antichain partition $(A_1, \ldots, A_k)$ of $L$, namely $h(x) = i$ if and only if $x \in A_i$. Proposition 4 shows that $\pi(L)$ is upper bounded by the height of $L$, i.e., by the maximum height of an element of $L$.

**Theorem 6** For every planar lattice $L = (X, <)$ with $|X| = n$, there is a plane straight-line drawing of the diagram such that the elements are represented by points on a set of at most $\sqrt{2n} - 1$ lines. Additionally

- each of the lines is either horizontal or vertical,
- each crossing point of a horizontal and a vertical line hosts an element of $X$.

**Proof.** Let $A, C$ be an orthogonal pair of $L$ such that $A$ is a $k$-antichain, $C$ an $\ell$-chain, and $k + \ell \leq \sqrt{2n} - 1$. It follows from Corollary 2 that such a pair exists.

Since $L$ has a fixed ordered realizer $[L_1, L_2]$, we can apply Lemma 1 to $A$ and Lemma 2 to $C$ to get an orthogonal pair $(A_1, \ldots, A_k), (C_1, \ldots, C_{\ell})$ where the antichain family and the chain family are both canonical. Fix an order preserving map $h : X \to \mathbb{R}$ with the property that $h(x) = i$ for all $x \in A_i$. Such a map exists because the antichain family is canonical, i.e., $i < j$ and $x \in A_i, y \in A_j$ implies $x \not\prec y$.

In the following we will construct a drawing $\Gamma$ of the diagram $D_L$ of $L$ such that each element $x \in X$ is represented by a point with $y$-coordinate $h(x)$, and in addition all elements of the chain $C_i$ lie on a common vertical line $g_i$ for $1 \leq i \leq \ell$. By Property 1 of orthogonal pairs, for each $x \in X$ there is an $i$ such that $x \in A_i$ or a $j$ such that $x \in C_j$ or both. Therefore, $\Gamma$ will be a drawing such that the $k$ horizontal lines $y = i$ with $i = 1, \ldots, k$ together with the $\ell$ vertical lines $g_j$ with $j = 1, \ldots, \ell$ cover all the elements of $X$. Property 2 of orthogonal pairs implies the second extra property mentioned in the theorem.

If the number $\ell$ of chains is zero, then $k$ equals the height of $L$ and we get a drawing $\Gamma$ with all the necessary properties from Proposition 4. Now let $\ell > 0$.

The chain family $C_1, \ldots, C_{\ell}$ is the canonical chain partition of the order induced on the set $X_C = \bigcup\{C_i : i = 1 \ldots \ell\}$. Let $C_1^+, \ldots, C_{\ell}^+$ be the corresponding canonical chain
covering of $X_C$. Let $X_i$ for $1 \leq i \leq \ell$ be the set of all elements which are left of some element of $C_i^+$ in $L$, and let $X_{\ell+1} = X$. Since $C_i^+$ is a maximal chain it corresponds to a path from the zero element to the one element in the diagram of the lattice, elements to the left of this path are in $X_i$ which is defined via the more abstract 'left of' relation. Define $S_i$ as the suborder of $L$ induced by $X_i$. Also let $Y_i = X_{i+1} - X_i + C_i^+$ and let $T_i$ be the suborder of $L$ induced by $Y_i$. Note the following properties of these sets and orders:

- $X_i \cap C_j = \emptyset$ for $1 \leq i < j \leq \ell$.
- Each $S_i$ is a planar sublattice of $L$, its right boundary chain is $C_i^+$.
- $T_i$ is a planar sublattice of $L$, its left and right boundary chains are $C_i^+$ and $C_{i+1}^+$, respectively.

A drawing $\Gamma_1$ of $S_1$ with the right boundary chain being aligned vertically is obtained by applying Proposition 4 a reflection with a vertical axis to the diagram $D_L[X_1]$ and reflecting the resulting drawing again with a vertical axis.

We construct the drawing $\Gamma$ of $D_L$ in phases. In phase $i$ we aim for a drawing $\Gamma_{i+1}$ of $S_{i+1}$ extending the given drawing $\Gamma_i$ of $S_i$, i.e., we need to construct a drawing $\Lambda_i$ of $T_i$ such that

1. The left boundary chain of $\Lambda_i$ matches the right boundary chain of $\Gamma_i$.
2. In $\Lambda_i$ all elements of $C_{i+1}$ are on a common vertical line $g_{i+1}$.

The construction of $\Lambda_i$ is done in three stages. First we extend $C_i^+$ to the right by adding 'ears'. Then we extend $C^+_{i+1}$ to the left by adding 'ears'. Finally we show that the left and the right part obtained from the first two stages can be combined to yield the drawing $\Lambda_i$.

To avoid extensive use of indices let $Y = Y_i$, $T = T_i$, $C^+ = C_i^+$, and let $\gamma$ be a copy of the $y$-monotone polygonal right boundary of $\Gamma_i$, i.e., $\gamma$ is a drawing of $C$. We initialize $\Lambda' = \gamma$.

A left ear of $T$ is a face $F$ in the diagram $D_L[Y]$ of $T$ such that the left boundary of $F$ is a subchain of the left boundary chain $C^+$ of $D_L[Y]$. The ear is feasible if the right boundary chain contains no element of $C_{i+1}$. Given a feasible ear we use the method from the proof of Proposition 4 to add $F$ to $\gamma$. We represent the right boundary $z_0 < z_1 < \ldots < z_l$ of $F$ on a vertical line $g$ by points $q_1, \ldots, q_{l-1}$ with $y$-coordinates as prescribed by $h$. The points $q_0$ and $q_l$ representing $z_0$ and $z_l$ respectively are already represented on $\gamma$. Then we place $g$ at some distance $\beta$ to the right of $\gamma$. The value of $\beta$ has to be chosen large enough to ensure that edges $(q_0, q_1)$ and $(q_{l-1}, q_l)$ are drawn such that they do not interfere with $\gamma$. Let $\Lambda'$ be the drawing augmented by the polygonal path $q_0, q_1, \ldots, q_{l-1}, q_l$ and let $C^+$ again refer to the right boundary chain $\gamma$ of $\Lambda'$. Delete all elements of the left boundary of $F$ except $z_0$ and $z_l$ from $Y$ and $T$. This shelling of a left ear from $T$ is iterated until there remains no left feasible ear. Upon stopping we have a drawing $\Lambda'$ which can be glued to the right side of $\Gamma_i$. Let $\gamma'$ be the right boundary chain of $\Lambda'$.

Now let $C = C_{i+1}$. Initialize a new drawing $\Lambda''$ by placing the elements of $C$ on
a vertical line \( g \) at the heights prescribed by \( h \) and connect consecutive ones by an edge whenever the order relation is indeed a cover relation of \( L \). The initial drawing may thus be disconnected and if so this will remain the case throughout this stage. We now consider right ears from \( T \). A right ear of \( T \) corresponding to a face \( F \) is feasible if the left boundary chain of \( F \) contains no element of \( \gamma' \). The left boundary chain of a feasible ear can be drawn as a \( y \)-monotone polygonal chain left of the left boundary \( \gamma'' \) of \( \Lambda'' \). Update \( \gamma'' \) to be the new left boundary of the augmented \( \Lambda'' \) and remove the elements of the ear from \( Y \) and \( T \). The shelling of right ears from \( T \) is iterated until there remains no feasible right ear. Note that \( \gamma'' \) is \( y \)-monotone but it may consist of several components.

In the final stage we have to combine the drawings \( \Lambda' \), \( \Lambda'' \) into a single drawing. This is done by drawing the edges and chains which remain in \( T \) between the two boundary chains as straight segments between \( \gamma' \) and \( \gamma'' \). This will be possible because we can shift \( \gamma' \) and \( \gamma'' \) as far apart horizontally as necessary. Figure 6 gives an example.

![Figure 6: After having added ears (light blue) to the chains \( C_i \) and \( C_{i+1} \) (dark blue) the connecting edges and components are put between them (pink).](source)

First we draw all the edges connecting the two chains. Let \( E \) be the set of edges connecting the left and right boundary chains of \( T \). For each \( e \in E \) the endpoints are represented by points \( p \in \gamma' \) and \( q \in \gamma'' \). Let \( K_p \) be an open cone with apex \( p \) which intersects \( \gamma' \) only at \( p \) and contains a horizontal ray to the right and let \( K_q \) be an open cone with apex \( q \) which intersects \( \gamma'' \) only at \( q \) and contains a horizontal ray to the left.

Let \( b_e \) be the minimal horizontal distance of \( \gamma' \) and \( \gamma'' \) such that \( p \in K_q \) and \( q \in K_p \). Let \( \beta = \max(b_e : e \in E) \). If we place \( \gamma' \) and \( \gamma'' \) at horizontal distance \( \beta \), then the edges of \( E \) can be drawn such that they do not interfere (introduce crossings) with \( \gamma' \) and \( \gamma'' \). We claim that there is no crossing of edges of \( E \). Let \( e = (p,q) \) and \( e' = (p',q') \) be two drawn edges from \( E \). Since they are edges of a planar diagram, they are cover edges and have endpoints on two chains. We can assume that \( h(p) < h(p') \) which implies \( h(q) < h(q') \). If the two edges cross, their crossing point is in \( K_p \cap K_{p'} \). Let \( c \) be the leftmost point of \( K_p \cap K_{p'} \) and note that \( h(p) < h(c) < h(p') \). This implies that at the \( x \)-coordinate of \( c \) edge \( e' \) is above \( e \). The crossing point is also contained in \( K_q \cap K_{q'} \). Let \( b \) be the rightmost point of \( K_q \cap K_{q'} \) and note that \( h(q) < h(b) < h(q') \). This implies that at the \( x \)-coordinate of \( b \) edge \( e' \) is above \( e \). It follows that edge \( e' \) is above \( e \) in the vertical strip defined by \( a \) and \( b \), whence, \( e \) and \( e' \) are not crossing.

Placing \( \Lambda' \) and \( \Lambda'' \) such that \( \beta \) is the distance between their outer chains and drawing
the edges of $E$ yields a drawing $\Lambda$ of a lattice. An important feature of the drawing is that if we move the two subdrawings $\Lambda'$ and $\Lambda''$ further apart the drawing keeps the needed properties, i.e., the height of elements remains unaltered, vertices of a chain which should be vertically aligned remain vertically aligned, and the drawing is crossing-free.

Now assume that $T$ contains elements which are not represented in $\Lambda$. Let $B$ be a connected component of such elements where connectivity is with respect to $D_L$. All the elements of $B$ have to be placed in a face $F_B$ of $\Lambda$. Let $\delta'$ and $\delta''$ be the left and right boundary path of $F_B$.

In the following we repeatedly select a component $B$ and a chain $C$ from $B$ which is to be drawn in the corresponding face $F_B$ of $\Lambda$ such that the minimum and the maximum of $C$ have connecting edges to the two sides of the boundary of $F_B$. Let us consider the case that in $D_L$ the maximum of $C$ has an outgoing edge to an element which is represented by a point $p \in \delta'$ and the minimum of $C$ has an incoming edge from an element represented by $q \in \delta''$. We represent the elements of $C$ as points on the prescribed heights on a line segment $\zeta$ with endpoints $p$ and $q$. It may become necessary to stretch the face horizontally to be able to place $C$. In this case we stretch the whole drawing between $\gamma'$ and $\gamma''$ with a uniform stretch factor. There may be additional edges between elements of $C$ and elements on $\delta'$ and $\delta''$. They can also be drawn without crossing when the distance of $\delta'$ and $\delta''$ exceeds some value $b$.

Stretching the whole drawing between $\gamma'$ and $\gamma''$ allows us to draw the segment $\zeta$ and additional edges inside of $F_B$ because of the following invariant.

- For each face $F$ of the drawing $\Lambda$ and two points $x$ and $y$ from the boundary of $F$ it holds that: if the segment $x,y$ is not in the interior of $F$, then the parts of the boundary obstructing the segment $x,y$ belong to $\gamma'$ or $\gamma''$.

When including a chain $C$ in the drawing $\Lambda$, we place the elements of $C$ at the prescribed heights on a common line segment $\zeta$. This ensures that each new element contributes convex corners in all incident faces. Hence, new elements can not obstruct a visibility within a face. Therefore, obstructing corners correspond to elements of $\gamma'$ or $\gamma''$ and the invariant holds.

The case where the left side of $F$ connects to the minimum and the right side to the maximum of $C$ is symmetric to the previous. Now consider the case where maximum and minimum of the chain $C$ connect to two elements $p$ and $q$ on the same side of $F$. Since $\gamma'$ and $\gamma''$ do not admit ear extensions we know that not both of $p$ and $q$ belong to one of $\gamma'$ and $\gamma''$. If the segment from $p$ to $q$ is obstructed, then the invariant ensures that with sufficient horizontal stretch the segment $\zeta$ connecting $p$ and $q$ will be inside $F$. Hence, chain $C$ can be drawn and $\Lambda$ can be extended.

When there remains no component $B$ containing a chain $C$ which can be included in the drawing using the above strategy, then either all elements of $Y$ are drawn or we have the following: every component $B$ only connects to elements of a line segment $\zeta_B$.

In this situation $B$ is kind of a big ear over $\zeta_B$. We next describe how to draw $B$, but note, that doing this we will not maintain or need the invariant.

By construction all elements of $\zeta_B$ belong to a common chain $C_B$. Consider the union $B + C_B$ and note that this is a planar lattice $L_B$, moreover, $C_B$ is either the left
or the right boundary chain of $L_B$. Assume that $C_B$ is the left boundary chain of $L_B$, the other case is symmetric. Now use Proposition 4 to get a drawing $\Lambda_B$ of $L_B$ aligned vertically. Using an affine transformation we can map $\Lambda_B$ into $\Lambda$ such that the line containing $C_B$ in $\Lambda_B$ is mapped to the line supporting the segment $\zeta_B$. Since the elements of $C_B$ are at their prescribed heights, their representing points in $\Lambda_B$ are mapped to the representing points of $\Lambda$. The affine map also has to compress $\Lambda_B$ horizontally so that it is placed in a narrow strip on the right side of $\zeta_B$. This strip can be chosen narrow enough to make sure that all of $B$ is mapped to the face of $\Lambda$ where it belongs.

The constructed drawing $\Lambda$ is a drawing $\Lambda_i$ of $T_i$. Glueing $\Lambda_i$ to $\Gamma_i$ yields a drawing $\Gamma_{i+1}$ of $S_{i+1}$. Eventually the drawing $\Gamma_\ell$ will be constructed. From there the drawing $\Gamma = \Gamma_{\ell+1}$ is obtained by adding some left ears.

\section{Transversal Structures on Few Lines}

\begin{theorem}
For every internally 4-connected inner triangulation of a 4-gon $G = (V, E)$ with $n$ vertices there is a planar straight line drawing such that the vertices are represented by points on a set of at most $\sqrt{2n} - 1$ lines. Additionally

- each of the lines is either horizontal or vertical,
- each crossing point of a horizontal and a vertical line hosts a vertex.
\end{theorem}

\begin{proof}
Fix a transversal structure of $G$ and consider the red graph $G_R = (V, E^+_R)$. From Proposition 1 and (R) we know that $G_R$ is bipolar and transitively reduced. This implies that there is a planar lattice $L = (V, \prec)$ such that a diagram of $L$ is an upward drawing of $G_R$. The relation $\prec$ is defined as $v \prec v'$ if and only if there is a directed path from $v$ to $v'$ in $G_R$.

We would like to use Theorem 6 to draw $G_R$ on $\sqrt{2n} - 1$ lines and then include the blue edges of the transversal structure in the drawing. This, however, may yield crossings. The good news is that by property (F) every blue edge connects the left and right side of a red face. This suggests that when, in the construction given in the proof of Theorem 6 a red face is closed, we can look at the blue edges and adapt the distance between the sides of the face to include the blue edges crossing free in the drawing.

To see that this is indeed possible we have to go through the cases of the proof. When adding a left feasible ear, i.e., when adding the right boundary of a face $F$, we draw all the blue edges corresponding to the face $F$. If there is an edge $e$ from $p \in \gamma$ to $q \in g$ define $b_e$ as the minimal horizontal distance of $\gamma$ and $g$ such that $q \in K_p$. When placing $g$ at a distance $\beta$ from $\gamma$ which exceeds all the values $b_e$, the blue edges can be drawn crossing free. When adding a right feasible ear the situation is symmetric.

Now let us consider the stage where a left and right drawing $\Lambda'$ and $\Lambda''$ with boundary chains $\gamma'$ and $\gamma''$ have to be combined. When drawing edges connecting the two chains we include all red and all blue edges with one end on $\gamma'$ and one on $\gamma''$ and adapt the distance of the two chains accordingly. Then we continue the combination on the basis of the red edges. Only in the ‘bad’ case where a component $B$ is added to a line segment $\zeta_B$ we have...
to be careful. First, when drawing $L_B$ using Proposition 4 we also include the blue edges in the drawing. This only requires to choose the distances $\beta$ as maxima over larger sets of values $b_e$. Second, when placing the drawing $\Lambda_B$ in a narrow strip on the side of $\zeta_B$ we have to be careful that this does not obstruct a visibility from the left side of the face to the right side. Finally, all the remaining blue edges have to be drawn in the faces between $\gamma'$ and $\gamma''$. Due to the invariant this is possible if we stretch the drawing between the two chains sufficiently. Figure 7 illustrates an intermediate step of such a drawing procedure.

Figure 7: A partially drawn transversal structure. The figure shows a drawing of $\Gamma_4$, these are the vertices left of some element in $C_4^+$ together with the induced edges.

It remains to see how Theorem 1 follows from Theorem 7. Let $G$ be a 4-connected triangulation and let $G'$ be obtained from $G$ by deleting one of the outer edges. Now $G'$ is an internally 4-connected inner triangulation of a 4-gon. Label the outer vertices of $G'$ such that the deleted edge is the edge $s,t$. Slightly stretching Theorem 7 we prescribe $h(s) = -\infty$ and $h(t) = \infty$, this yields a planar straight-line drawing $\Gamma$ of $G'$ such that the vertices except $s$ and $t$ are represented by points on a set of at most $\sqrt{2n} - 1$ lines and the edges connecting to $s$ and $t$ are vertical rays. Moreover with every edge $v,s$ or $v,t$ there is an open cone $K$ containing the vertical ray, such that the point representing $v$ is the apex of $K$ and this is the only vertex contained in $K$. Now let $g$ be a vertical line which is disjoint from $\Gamma$. On $g$ we find a point $p_s$ which is contained in all the upward cones and a point $p_t$ contained in all the downward cones. Taking $p_s$ and $p_t$ as representatives for $s$ and $t$ we can tilt the rays and make them finite edges ending in $p_s$ and $p_t$ respectively, and in addition draw the edge $p_s,p_t$.

We conclude with a remark and two open problems.

- Our results are constructive and can be complemented with algorithms running in polynomial time.
- Is $\pi(G) \in O(\sqrt{n})$ for every planar graph $G$ on $n$ vertices?
- What size of a grid is needed for drawings of 4-connected plane graphs on $O(\sqrt{n})$ lines?
Acknowledgments

Work on this problem began at the 2018 Bertinoro Workshop of Graph Drawing. I thank the organizers of the event for making this possible. Special thanks go to Pavel Valtr, Alex Pilz and Torsten Ueckerdt for helpful discussions.
