Abstract

A 65-year-old Japanese man presented with acute myocardial infarction (AMI) and polycythemia. Biochemical studies of the patient’s hemoglobin (Hb) and the sequencing of his globin genes revealed that the polycythemia was secondary to a high oxygen affinity Hb variant, Hb Fuchu-II. Hb variants with high oxygen affinity can be an additional thrombotic risk factor in older patients and/or those with other risk factors. The patient was diagnosed with hemoglobinopathy after the development of AMI and exemplifies the importance of recognizing such conditions and of taking appropriate prophylactic interventions.

Key words: hemoglobin variant, high oxygen affinity, Hb Fuchu-II, polycythemia, coronary heart disease

Introduction

Approximately 100 hemoglobin (Hb) variants with high oxygen affinity have been identified which may lead to secondary polycythemia (1). While several prospective and cohort studies and a meta-analysis have suggested that increased hematocrit (Ht) and Hb levels are associated with increased risk of cardiovascular events (2) and ischemic heart disease (IHD) (3-5), young patients with polycythemia secondary to Hb variants with high oxygen affinity usually follow a benign clinical course and need no treatment. However, polycythemia secondary to Hb variants is often associated with thrombotic events in older patients and/or those with other risk factors (1).

We herein report the case of a patient presenting with acute myocardial infarction (AMI) and polycythemia in whom the polycythemia was proven to be secondary to a newly characterized high oxygen affinity Hb variant, Hb Fuchu-II, and was considered to have contributed to the development of AMI as an additional cardiovascular risk factor.

Case Report

A 65-year-old Japanese man presented to our emergency department with a chief complaint of chest pain, which had started suddenly one hour before and radiated to the shoulders. He reported that arrhythmia had once been identified in an annual health checkup but that it had not been further evaluated. He had a brother who had previously undergone coronary angiography (CAG). He was a current smoker and smoked 10-15 cigarettes a day.

At presentation, his blood pressure was 96/71 mmHg. His pulse rate was 74 bpm and was regular in rhythm. With the exception of cold extremities, his physical examinations were unremarkable. An electrocardiogram showed ST-segment elevations and hyper acute T waves in leads V1-V5 and a bedside echocardiogram showed abnormal wall motions in the anterior wall and the apex of the heart. A diagnosis of ST-segment elevation myocardial infarction was made and he was admitted to hospital. The patient’s laboratory data showed the following: white blood cell count 6.9x10⁹/L, red blood cell (RBC) count 6.08x10¹²/L, Hb 18.3 g/

dL. Ht 54.8%, and a platelet count of 141×10^9/L. The results of coagulation studies were normal. Blood chemistry tests revealed the following: creatinine kinase (CK) 115 IU/L, CK-MB 23 IU/L, glucose 114 mg/dL, and HbA1c 3.9%. Emergent CAG was performed, which revealed the occlusion of the #6 branch of the left anterior descending artery (Fig. 1) and a bare metal stent was implanted. The CK and CK-MB peaked at 7,295 IU/L and 675 IU/L, respectively.

Emergent CAG was performed at the onset of acute myocardial infarction. Emergent CAG performed on admission reveals an occlusion of the #6 branch of the left anterior descending artery (arrow).

While secondary polycythemia usually occurs as a result of an inappropriately increased level of erythropoietin due to tissue hypoxia of various causes and, less frequently, the inappropriate production of erythropoietin, it may occur secondarily to the increased oxygen affinity of Hb. Thus far, approximately 100 Hb variants with high oxygen affinity have been identified (1). HbA is the major adult Hb and is a tetramer formed by two identical dimers of α1- and β2-globin. HbA1c is located in the C-terminal (1). Hb Fuchu-II is an α2-globin variant Hb that was identified in an asymptomatic Japanese man with polycythemia and which was first reported in 1995 (6). Hb Fuchu-II has an Asn→His substitution at codon 97 of the α-globin, which is located in the α1β1 interface or at the 2 interface (1). Hb Fuchu-II is an Hb with high oxygen affinity. However, the biochemical properties of Hb Fuchu-II have not previously been studied. We studied the oxygen equilibrium curve and the A-V difference of the Hb of the patient and confirmed that Hb Fuchu-II does indeed have a high oxygen affinity and a low

Discussion

While secondary polycythemia usually occurs as a result of an inappropriately increased level of erythropoietin due to tissue hypoxia of various causes and, less frequently, the inappropriate production of erythropoietin, it may occur secondarily to the increased oxygen affinity of Hb. Thus far, approximately 100 Hb variants with high oxygen affinity have been identified (1). HbA is the major adult Hb and is a tetramer formed by two identical dimers of α1β1 and α2β2. The most frequent alterations causing high oxygen affinity Hb variants are located either in the α1β2 interface or at the C-terminal (1). Hb Fuchu-II is an α2-globin variant Hb that was identified in an asymptomatic Japanese man with polycythemia and which was first reported in 1995 (6). Hb Fuchu-II has an Asn→His substitution at codon 97 of the α-globin, which is located in the α1β1 contact region. Theoretically, mutations occurring in this region could be predicted to affect the molecular stabilization and result in an increased oxygen affinity. However, the biochemical properties of Hb Fuchu-II have not previously been studied. We studied the oxygen equilibrium curve and the A-V difference of the Hb of the patient and confirmed that Hb Fuchu-II does indeed have a high oxygen affinity and a low

Figure 2. The oxygen equilibrium curve of the hemoglobin (Hb). The oxygen dissociation curve of the patient’s Hb (red curve) was shifted to the left compared to the control (blue curve) and the p50 was 19.5 Torr, compared to 28.5 Torr in the control.

While secondary polycythemia usually occurs as a result of an inappropriately increased level of erythropoietin due to tissue hypoxia of various causes and, less frequently, the inappropriate production of erythropoietin, it may occur secondarily to the increased oxygen affinity of Hb. Thus far, approximately 100 Hb variants with high oxygen affinity have been identified (1). HbA is the major adult Hb and is a tetramer formed by two identical dimers of α1β1 and α2β2. While secondary polycythemia usually occurs as a result of an inappropriately increased level of erythropoietin due to tissue hypoxia of various causes and, less frequently, the inappropriate production of erythropoietin, it may occur secondarily to the increased oxygen affinity of Hb. Thus far, approximately 100 Hb variants with high oxygen affinity have been identified (1). HbA is the major adult Hb and is a tetramer formed by two identical dimers of α1β1 and α2β2. The most frequent alterations causing high oxygen affinity Hb variants are located either in the α1β2 interface or at the C-terminal (1). Hb Fuchu-II is an α2-globin variant Hb that was identified in an asymptomatic Japanese man with polycythemia and which was first reported in 1995 (6). Hb Fuchu-II has an Asn→His substitution at codon 97 of the α-globin, which is located in the α1β1 contact region. Theoretically, mutations occurring in this region could be predicted to affect the molecular stabilization and result in an increased oxygen affinity. However, the biochemical properties of Hb Fuchu-II have not previously been studied. We studied the oxygen equilibrium curve and the A-V difference of the Hb of the patient and confirmed that Hb Fuchu-II does indeed have a high oxygen affinity and a low
oxygen-carrying capacity. On the other hand, it is expected that the degree of such phenomena depends on the amount of the high-affinity Hb variant. Unfortunately, since Hb Fuchu-II was not separated by isoelectrofocusing, we did not determine the level of Hb Fuchu-II, while the level in the first case was reported to 25%, as determined by cation exchange HPLC (6). The present case unexpectedly had α-α thalassemia (-α7 type) allele, and the Hb Fuchu-II gene was on the other chromosome. Since two α-globin genes reside adjacent to each other on chromosome 16p, the α-globin genotype of the present case was considered to be αα/(αα/αα)[16p], rather than [αα/αα][16p], with a deletion of one of the four α-globin genes. Thus, the content of Hb Fuchu-II in the present case can be predicted to be a little more than 25%, which indicates that an Hb Fuchu-II level of more than 25% is sufficient to cause polycythemia.

The elevation of Ht increases blood viscosity at low shear rates and displaces platelets toward the vessel wall at high shear-rates, facilitating shear-induced platelet activation, and, thus increasing both venous and arterial thrombotic risks (7). It is reported that an Ht level of above 45% is associated with a higher rate of cardiovascular death and major thrombosis in patients with polycythemia vera (8). Likewise, although cohort or prospective studies do not always report consistent statistically significant results, possibly due to the study design (9, 10), patients with polycythemia due to other etiologies are at an increased risk of IHD (3-5). Therefore, we believe that polycythemia secondary to Hb Fuchu-II contributed to the development of AMI in the present patient who had other preexisting cardiovascular risk factors, namely smoking and aging, and also to the formation of left ventricular thrombus. While young patients with polycythemia secondary to high oxygen affinity variant Hb usually follow a benign clinical course, it is associated with thrombotic events in older patients and/or those with other risk factors (1). Therefore, it is possible that his cardiovascular risk was further raised by the increased Ht level caused by secondary polycythemia. In addition, although we could not confirm the long-term variation of the Ht level in the present case, secondary polycythemia may emerge or progress later in life in patients with certain high oxygen affinity Hb variants and such patients may be at a higher risk of thrombotic complications as they age (11).
