ABSTRACT

Galaxies and their dark matter halos populate a complicated filamentary network around large, nearly empty regions known as cosmic voids. Cosmic voids are usually identified in spectroscopic galaxy surveys, where 3D information about the large-scale structure of the Universe is available. Although an increasing amount of photometric data is being produced, its potential for void studies is limited since photometric redshifts induce line-of-sight position errors of ~ 50 Mpc/h or more that can render many voids undetectable. In this paper we present a new void finder designed for photometric surveys, validate it using simulations, and apply it to the high-quality photo-z redMaGiC galaxy sample of the Dark Energy Survey Science Verification (DES-SV) data. The algorithm works by projecting galaxies into 2D slices and finding voids in the smoothed 2D galaxy density field of the slice. Fixing the line-of-sight size of the slices to be at least twice the photo-z scatter, the number of voids found in these projected slices of simulated spectroscopic and photometric galaxy catalogs is within 20% for all transverse void sizes, and indistinguishable for the largest voids of radius ~ 70 Mpc/h and larger. The positions, radii, and projected galaxy profiles of photometric voids also accurately match the spectroscopic void sample. Applying the algorithm to the DES-SV data in the redshift range 0.2 < z < 0.8, we identify 87 voids with comoving radii spanning the range 18-120 Mpc/h, and carry out a stacked weak lensing measurement. With a significance of 4.4σ, the lensing measurement confirms the voids are truly underdense in the matter field and hence not a product of Poisson noise, tracer density effects or systematics in the data. It also demonstrates, for the first time in real data, the viability of void lensing studies in photometric surveys.

Key words: large-scale structure of Universe – cosmology: observations – gravitational lensing: weak

1 INTRODUCTION

Cosmic voids are low-density regions in space surrounded by a network of dark matter halos and the galaxies that populate them. Given their intrinsic low-density environment, voids are only weakly affected by complicated non-linear gravitational effects which have a strong impact in crowded environments such as galaxy clusters. This simplicity makes it possible to constrain cosmological parameters with voids [Betancort-Rijo et al. 2009; Lavaux & Wandelt 2010; Sutter et al. 2014b; Kitaura et al. 2015; Hamaus et al. 2016; Mao et al. 2016; Sahlen, Zubeldia & Silk 2016]. Furthermore, the unique low-density environments of voids make possible probes of the nature of dark energy, alternate theories of gravity [Lee & Park 2009].
A number of different void finding algorithms exist in the literature: Voronoi tessellation and watershed methods (Platen, Van De Weygaert & Jones 2007; Neyrinck, 2008; Lavaux & Wandell 2012; Sutter et al. 2012; Nadathur et al. 2015), growth of spherical underdensities (Hoyle & Vogeley 2002; Colberg et al. 2009; Padilla, Ceccarelli & Lambas 2005; Ceccarelli et al. 2006; Li 2011), hybrid methods (Jennings, Li & Hu 2013), 2D projections (Clampitt & Jain 2013), dynamical criteria (Elyiv et al. 2013), and Delaunay Triangulation (Zhao et al. 2015), among other methods (Colberg et al. 2008). Most void finders currently applied to data use galaxies with spectroscopic redshifts to define voids. However, when using far less precise photometric redshifts (photo-$z$), the void-finding process needs to be revisited to overcome the smearing in the line-of-sight position of tracer galaxies.

Spectroscopic surveys like 2dF (Colless et al. 2001), VVDS (Le Fèvre et al. 2003), WiggleZ (Drinkwater et al. 2010) or BOSS (Dawson et al. 2013) provide 3D information of the galaxy distribution, but they are expensive in terms of time, and may suffer from selection effects, incompleteness and limited depth. In contrast, photometric surveys such as SDSS (York et al. 2000), PanSTARRS (Kaiser, Tonry & Luppino 2005), WiggleZ (Drinkwater et al. 2010), KiDS (de Jong et al. 2013) or LSST (Tyson et al. 2003) are more efficient and nearly unaffected by selection bias, more complete and deeper, but do not provide complete 3D information of the galaxy distribution due to their limited resolution in the galaxy line-of-sight positions, obtained by measuring the photo-$z$ of each galaxy from the fluxes measured through a set of broadband filters.

A few void catalogs exist that use photometric redshift tracers (Granett, Neyrinck & Szapudi 2008). Many voids about the size of the photo-$z$ error or smaller will not be found at all; in other cases, spurious, or Poisson, voids will appear in the sample due to photo-$z$ scatter. For the larger voids in the sample, those with sizes much larger than the photo-$z$ error, the photo-$z$ scatter should not affect the void sample substantially. However, these huge voids are very few due to the rapidly falling size distribution of cosmic voids in the universe. In any case, it should also be possible to find voids smaller than the photo-$z$ scatter, since the latter acts to smooth out the density field, but retains the topology of the large-scale structure to some extent. Therefore, by designing a void finding algorithm specifically for photometric redshift surveys, the purity and completeness of the resulting void sample can be improved.

Qualitatively, our void finding method can be understood with an analogy to galaxy clustering measurements. In that case, the ideal scenario is to measure the 3D correlation function of galaxies when spectroscopic redshifts are available. However, for photometric survey data sets, one usually avoids computing the 3D correlation function of galaxies because of the photo-$z$ dispersion affecting the line-of-sight component. The standard approach is therefore to split galaxies into tomographic photometric redshift bins, and compute the 2D angular correlation function in the projection of each of these line-of-sight bins. The photometric redshift errors make the actual size of the redshift bins to be effectively comparable or larger than the photo-$z$ scatter (see for instance Crocce et al. 2011). Then, in order to minimize the noise in the measurement, the optimal approach is to set the width of the redshift bins to be comparable or larger than the photo-$z$ scatter. Finally, one measures the angular clustering in each of these redshift bins, and hence the evolution of clustering with redshift. In this work we present a void finder that follows the same approach: finding voids in the angular projection of the galaxy distribution in redshift slices that are broader than the photo-$z$ dispersion, and then combining the slices to get the most of the line-of-sight information in the data.

Before applying the algorithm to the DES Science Verification (DES-SV) data set, we use simulations with mock spectroscopic and realistic photometric redshifts to validate the method, running the void finder in both cases and studying the differences among the void catalogs coming from the corresponding projected slices. Once the DES-SV void catalog is defined, we measure the weak gravitational lensing signal around voids and confirm the voids are also empty in the dark matter.

The plan of the paper is as follows. In Sec. 2 we describe the Dark Energy Survey Science Verification data used in this paper, together with the simulations used to test the validity of the finder. Section 3 presents the 2D angular void finder algorithm and some simulation tests comparing the algorithm output when using spectroscopic and photometric redshifts for the tracer galaxies. Then, in Sec. 4 we apply the algorithm to DES-SV data and discuss the choice of redshift slices and the way we deal with survey edge effects. Finally, in Sec. 5 we use the final DES-SV void catalog to measure the weak gravitational lensing around voids and we discuss our results and conclusions in Sec. 6.

## 2 DATA AND SIMULATIONS

The Dark Energy Survey (DES, Flaugher 2005; Flaugher et al. 2015, Dark Energy Survey Collaboration et al. 2016) is a photometric redshift survey that will cover about one eighth of the sky (5000 sq. deg.) to a depth of $i_{AB} < 24$, imaging about 300 million galaxies in 5 broadband filters ($grizY$) up to redshift $z = 1.4$. The DES camera (DECam, Flaugher et al. 2015) includes sixty-two 2048x4096 science CCDs, four 2048x2048 guider CCDs, and eight 2048x2048 focus and alignment chips, for a total of 570 megapixels. In this paper we use 139 sq. deg. of data from the Science Verification (SV) period of observations (Diehl et al. 2014), which provided science-quality data at close to the nominal depth of the survey.

In a photometric redshift survey, such as DES, the photo-$z$‘s of tracer galaxies will impact the identification of voids with sizes comparable to the photo-$z$ scatter $\sigma_z$, in a way that renders some voids smeared and undetected. For DES main galaxies, this is a problem since $\sigma_z \approx 0.1$ (Sánchez et al. 2014), corresponding to $\sim 220$ Mpc$/h$ at $z = 0.6$, and typical voids have a comoving size of about 10-100 Mpc$/h$. However, we do not need to use all DES galaxies as void tracers. Instead, we can restrict ourselves to the Luminous Red Galaxies (LRGs) in the sample, which are still good tracers of the large-scale structure and have much better photo-$z$ resolution.

### 2.1 Void tracer galaxies: the redMaGiC catalog

The DES-SV redMaGiC catalog (Rozo et al. 2015) presents excellent photo-$z$ performance: redMaGiC photometric redshifts are nearly unbiased, with median bias $(z_{\text{spec}} - z_{\text{phot}}) \approx 0.5\%$, a scatter $\sigma_z/(1+z) \approx 1.70\%$, and a $1.4\%$ 5$\sigma$ redshift outlier rate. That scatter corresponds to a redshift resolution of $\sim 50$ Mpc$/h$ at $z = 0.6$, a substantial improvement over DES main galaxies. Next we summarize the redMaGiC selection...
algorithm, but we refer the reader to [Rozo et al. 2015] for further details.

The red-sequence Matched-filter Galaxy Catalog (redMaGiC, [Rozo et al. 2015]) is a catalog of photometrically selected luminous red galaxies (LRGs). We use the terms redMaGiC galaxies and LRG interchangeably. Specifically, redMaGiC uses the redMaPPer-calibrated model for the color of red-sequence galaxies as a function of magnitude and redshift [Rykoff et al. 2014]. This model is used to find the best fit photometric redshifts for all galaxies under the assumption that they are red-sequence members, and the \( \chi^2 \) goodness-of-fit of the model is then computed. For each redshift slice, all galaxies fainter than some minimum luminosity threshold \( L_{\text{min}} \) are rejected. In addition, redMaGiC applies a cut \( \chi^2 < \chi_{\text{max}} \), where the cut \( \chi_{\text{max}} \) as a function of redshift is chosen to ensure that the resulting galaxy sample has a constant space density \( \bar{n} \). In this work, we set \( \bar{n} = 10^{-3} h^3 \text{Mpc}^{-3} \) with CDM cosmological parameters \( \Omega_\Lambda = 0.7, h_0 = 100 \), and redMaGiC galaxies are selected in the redshift range \( 0.2 < z < 0.8 \). We expect the redMaGiC galaxy selection to be only marginally sensitive to the cosmological parameters assumed (see [Rozo et al. 2015] for details). The luminosity cut is \( L \geq L_\ast(z)/2 \), where the value of \( L_\ast(z) \) at \( z = 0.1 \) is set to match the redMaPPer definition for SDSS [Rykoff et al. 2014], and the redshift evolution for \( L_\ast(z) \) is that predicted using a simple passive evolution starburst model at \( z = 3 \) [Bruzual & Charlot 2003].

We use the redMaGiC sample because of the exquisite photometric redshift performance of the redMaGiC galaxy catalog. Also, because void properties depend on the tracer sample used, the constant comoving density of redMaGiC tracers helps in assuring the resulting voids have similar properties. For example, the dark matter profile [Sutter et al. 2014a] and void bias [Chan, Hamaus & Desjacques 2014] [Clampitt, Jain & Sánchez 2016] [Pollina et al. 2016] have been shown to depend on the tracer density or tracer bias used to define voids.

Aside from the data catalog presented above, in this work we also use ACDM simulations that mimic the properties of the DES-SV redMaGiC data set. The mock galaxy catalog is the Buzzard-v1.0 from the Blind Cosmology Challenge (BCC) simulation suite, produced for DES (Wechsler et al., in preparation). These catalogs have previously been used for several DES studies (see e.g. [Chang et al. 2015] [Leistedt et al. 2015] [Becker et al. 2015] [Clampitt et al. 2016] [Kwan et al. 2016]). The underlying N-body simulation is based on three cosmological boxes, a 1050 Mpc/h box with 1400\(^3\) particles, a 2600 Mpc/h box with 2048\(^3\) particles and a 4000 Mpc/h box with 2048\(^3\) particles, which are combined along the line of sight producing a light cone reaching DES full depth. These boxes were run with LGadget-2 [Springel 2005] and used 2LPTic initial conditions [Croce, Pueblas & Scoccimarro 2006] with linear power spectra generated with CAMB [Lewis & Bridle 2002]. ROCKSTAR [Behroozi, Wechsler & Wu 2013] was utilized to find halos in the N-body volumes. The ADDGALS algorithm [Wechsler 2004] [Busha et al. 2013] [Wechsler et al, in preparation] is used to populate the dark matter simulations with galaxies as a function of luminosity and color. ADDGALS uses the relationship between local dark matter density and galaxy luminosity, to populate galaxies directly onto particles in the low-resolution simulations. This relationship is tuned to reproduce the galaxy–halo connection in a higher resolution tuning simulation, in which galaxies are assigned using subhalo abundance matching (e.g. [Conroy, Wechsler & Kravtsov 2006] [Reddick et al. 2013]), in this case matching galaxy luminosity to peak circular velocity. Finally, each galaxy is assigned a color by using the color-density relationship measured in the SDSS [Aihara et al. 2011] and evolved to match higher redshift observations. The redMaGiC algorithm has been run on the simulation in a similar way as it is run on the DES data. This produces a simulated sample with the same galaxy selection and photometric redshift performance as the DES-SV redMaGiC catalog but gives us access to the true redshifts of the galaxies in the sample, a fact that we will use to test the void finder presented in this work.

### 2.2 Lensing source catalog

The catalog of galaxy shapes used in the lensing measurement of this work is the ngmix\(^\ast\) catalog presented in [Jarvis et al. 2015]. ngmix is a shear pipeline which produces model fitting shape measurements, and that was applied to a large subset of DES-SV galaxies, meeting the requirements of an extensive set of null and systematics tests in [Jarvis et al. 2015]. The photometric redshifts of the galaxies in the ngmix shear catalog were studied in detail in [Bonnett et al. 2015], using 4 different photo-z codes. In this work we use the SkyNet photo-z method, which demonstrated excellent performance in that comparison.

### 3 PHOTO-Z VOID FINDER ALGORITHM

In this Section we present a new void finder designed specifically to work on photometric surveys. We explain the algorithm and test its performance on simulations, providing validation for the results shown later in the paper.

#### 3.1 Void finder algorithm

The void finder works by projecting galaxies in redshift slices and finding underdensities in the 2D angular distribution of galaxies in the given slices. If the line-of-sight width of the projected slice is sufficiently large, at least about twice the photo-z resolution, then most galaxies will still be assigned to the correct slice. Since the finder works by projecting all galaxies within a given slice onto a 2D surface, the line-of-sight position within the slice does not affect the results.

The void finder of [Clampitt & Jain 2015] also begins by treating each slice in isolation, but has the disadvantage that voids are required to be completely empty of galaxies near the center. Thus, photo-z scatter, which moves a single galaxy between slices, can inappropriately break up a single large void into several smaller voids, or even result in no void being detected at all. To overcome this problem, we smooth the 2D projected galaxy density field in each slice and then voids are found from minima of the smoothed density field. This means a few galaxies moving between different slices will not greatly affect the resulting set of voids, as will be demonstrated in Sec. 3.2.

In detail, the void finding algorithm involves the following steps:

(i) We select the galaxies from a redshift slice of thickness \( 2s_v \) (we define \( s_v \) to be half the slice thickness) and we project them into a HEALpix map [Gorski et al. 2005], with a resolution of \( N_{\text{side}} = 512 \) representing an angular resolution

\* https://github.com/esheldon/ngmix
of 0.1 deg. and a physical resolution of 1.5 Mpc/h at \( z = 0.3 \) (3 Mpc/h at \( z = 0.6 \)).

(ii) We compute the mean density in the map corresponding to the given redshift slice, \( \bar{n}_{2d} \), and convert the galaxy map to a density contrast map as \( \delta = n_{2d}/\bar{n}_{2d} - 1 \), where \( n_{2d} \) is the galaxy map.

(iii) Then we smooth the density contrast map with a Gaussian filter of comoving scale \( \sigma_s = 10 \) Mpc/h.

(iv) We take this smoothed contrast map and consider only the most underdense pixels (with \( \delta < \delta_m = -0.3 \)) as potential void centers. We define the most underdense pixel in the map as the first void center.

(v) Next we start defining circular shells of increasing radius around that center, stopping when the mean density within the slice (\( \delta = 0 \)) is reached. That is, starting with a shell of radius \( R_i^{\delta} \), we measure the average galaxy density in the shell \( \delta(R_i^{\delta}) \), and if the density is negative we check the next larger shell \( \delta(R_{i+1}^{\delta}) \), and so on, until the mean density within shells is 1 Mpc/h in radius. For some shell \( R_j^{\delta} \) the density contrast reaches zero, \( \delta(R_j^{\delta}) \geq 0 \), and at that point the void radius is defined as \( R_v = R_j^{\delta} \) (see Fig. 1 for a graphical explanation).

(vi) Then all pixels contained in this void are removed from the list of potential void centers, preventing any of these pixels to become the center of any other void. From the remaining pixels that satisfy \( \delta < \delta_m = -0.3 \), we define the next most underdense pixel as the second void center. The process is repeated until all pixels with \( \delta < \delta_m = -0.3 \) have been assigned to a void.

Beyond the dependency on the line-of-sight size of the projected slice in which the finder is executed, studied in more detail later in this section, the void catalog produced by this algorithm depends on two parameters: the smoothing scale, \( \sigma_s \), and the maximum density contrast of a pixel to become a void center, \( \delta_m \). The smoothing scale (\( \sigma_s = 10 \) Mpc/h) is chosen to be about half the radius of the smallest voids we can access in our data sample (because of photo-z smearing), and increasing it would erase the structure leading to some of these smallest voids, leaving the large voids intact. On the other hand, the most significant voids found by the algorithm, the deepest ones, are independent of the choice \( \delta_m = -0.3 \) since their void center pixel is more underdense than that. By changing the value of \( \delta_m \) we are only affecting the shallower voids of the sample. The impact of the \( \delta_m \) choice is studied in Appendix A. Also, voids found by this algorithm can overlap or even enclose one another, but just in the case where a subvoid is deeper than the bigger void enclosing it.

The process detailed above will produce a list of voids for a given redshift slice. Before describing how various slices are combined to obtain the full void catalog, we first study the performance of the single slice results in simulations.

### 3.2 Performance on simulations

In order to validate the performance of the algorithm we use the simulations, where we have both spectroscopic and photometric redshifts to find voids, and we compare the voids found in spec-\( z \) and photo-\( z \) space. In particular, we run the void finding algorithm twice on each redshift slice: first using spectroscopic redshifts for selecting the galaxies that go into the slice and then using photometric redshifts that mimic the ones we have in real DES data.

Once we have the spec-\( z \) and photo-\( z \) defined void catalogs, we measure the projected galaxy density profiles of the voids in them in radial annuli using the true redshifts. Figure 2 shows the resulting density profiles for both cases in different slice comoving thicknesses. As expected, the void finder performs poorly if the size of the projected slice is smaller or similar to the photo-\( z \) dispersion \( \sigma_z \approx 50 \) Mpc/h. Therefore, the accuracy of the finder is a function of the thickness of the projected slice: for slice width \( \sim 2 \) times the size of the typical photometric redshift scatter, the difference between the average density profiles of voids found in spec-\( z \) and photo-\( z \) is not significant, being smaller than the standard deviation of the stacked void profiles.

Figure 2 shows that voids found by the algorithm in photo-\( z \) space can indeed have very similar density profiles as voids found in spec-\( z \) space. However, it is also important to know the relative number of voids found in the two cases. Photometric redshifts produce a smearing in the line-of-sight position of tracers that can actually erase some of the structure, especially on scales comparable to the size of the photo-\( z \) scatter or smaller. That will have the consequence of some small voids not being detected in the photo-\( z \) case. The voids of size larger than the photo-\( z \) scatter should be detected in both cases. Figure 3 shows the distribution of void radii in simulations for spec-\( z \) and photo-\( z \) samples. As expected, we find less voids in the photo-\( z \) case, with the difference being more important for small voids and becoming negligible for the voids substantially larger than the photo-\( z \) dispersion (\( \sigma_z \approx 50 \) Mpc/h).

In addition to the comparison of the galaxy density profiles of voids, which is the most important test of the algorithm, Fig. 4 shows a visual comparison between the positions and radius of spec-\( z \) and photo-\( z \) defined voids in a random 100 Mpc/h-thick slice of our simulations. The correlation between the two sets of voids is very clear, in both positions and radii. In some cases, especially for the biggest voids, the match...
between spec-z and photo-z voids is almost perfect. This is remarkable given the magnitude of the scatter in the line-of-sight direction being added by photometric redshifts.

Figure 2. (left panel): Comparison of 2D spectroscopic galaxy density profiles of voids found in the simulations using galaxy spectroscopic redshifts (solid line) or photometric redshifts (dotted, red). The shaded regions show the corresponding error bars computed as the standard deviation among all the stacked voids. The projected 2D slice width is 25 Mpc/h (comoving distance), a scale corresponding to ∼ 1/2 the photometric redshift scatter. For this thin slice, the galaxy density profile is damped significantly by photo-z scatter, making the galaxy profile of photo-z defined voids more shallow. (center panel): The same, but for a thicker slice of width 50 Mpc/h, comparable to the photo-z scatter. (right panel): The same, but for a projected slice of width 100 Mpc/h, twice the size of the typical photo-z scatter. In this case there is a good match between the profiles of spec-z and photo-z selected voids. For such a thick slice, the fraction of galaxies that are placed in the incorrect slice due to photometric redshift scatter is smaller, allowing accurate void identification from the smoothed galaxy field.

Figure 3. (upper panel): Void radius distribution for voids found in spec-z and photo-z simulated galaxy samples, for a slice thickness of $2s_v = 100$ Mpc/h. (lower panel): Relative difference between the distributions (with respect to the spectroscopic redshift case). Some voids with sizes smaller than the photo-z scatter ($\sigma_z \approx 50$ Mpc/h) are smeared out due to photo-z scatter and not detected, resulting in a smaller number of voids relative to the spectroscopic case. For large voids this effect is not important and the two distributions agree within errors.

Figure 4. Comparison between voids found in spec-z (centers: solid black points; radius: solid circles) and photo-z (centers: open red squares; radius: red dashed circles) in the simulations for a slice of thickness $2s_v = 100$ Mpc/h. The background gray-scaled field is the smoothed galaxy field ($\sigma = 10$ Mpc/h) used by the void-finder. The correlation between spec-z and photo-z defined voids is clear: in many cases the void position and radius match almost exactly.

4 DES-SV VOID CATALOG

In the previous Section we have presented a void finder that works by projecting galaxies into redshift slices (see Sec. 3.1 for a detailed description and parameters used in the algorithm). We have shown (Sec. 3.2) that as long as the thickness of the projected slice is large enough compared to the photo-z scatter, using photometric redshifts for the position of void tracers...
works nearly as well as using spectroscopic redshifts. Nevertheless, the algorithm will find some voids that are not likely to correspond to voids in the dark matter density field. Such false voids may be due to a number of effects: (i) at the survey edge or masked areas we have no information on galaxy positions, and (ii) duplicate voids may appear if slices overlap in redshift. In this Section we apply the algorithm to real DES-SV data, and present the way we deal with voids near the survey edge (Sec. 4.1) and the strategy we follow to get the most of the line-of-sight information in the data (Sec. 4.2). The properties of the final DES-SV void catalog are presented in Sec. 4.3.

### 4.1 Voids near the survey edge

The assignment of each void’s radius does not distinguish between voids that are fully contained within the survey and those that extend beyond it. The void radius may stretch beyond the edge of the survey, into areas which may or may not correspond to voids in the galaxy distribution. To remove such voids which extend far beyond the survey edge, we use the method of Clampitt & Jain (2015). A random point catalog drawn using the survey mask is generated, and for each void we calculate the density of random points inside $R_v$. The distribution of random points density inside voids is shown in Fig. 5, and it presents a Gaussian-like shape at high densities (peaked around 9500 points/deg$^2$ with $\sigma \approx 2000$ points/deg$^2$), corresponding to voids centered in the survey mask, and a low density tail reaching almost zero density, which corresponds to edge voids. Due to the small size of the DES-SV patch used in this work, with an area of 139 sq. deg., and the size of some of the voids detected (a void with $R_v \sim 80$ Mpc/$h$ would span more than 10 deg. in diameter at $z = 0.3$), we place a conservative cut and discard voids with random point density less than 9000 points/deg$^2$, which constitute 33% of the total number of voids.

### 4.2 Line of sight slicing strategy

To obtain more information about the line-of-sight position of each void we oversample the volume with a number of different slice centers. In particular, first we slice the line-of-sight range of the survey, $0.2 < z < 0.8$, in equal slices of comoving thickness $2\Delta z = 100$ Mpc/$h$ taking the upper redshift limit, $z = 0.8$, as the upper limit of the furthest slice. Then we apply a shift to this slicing of 20 Mpc/$h$ towards low redshift, and we repeat the process four times so that we have a slice of thickness 100 Mpc/$h$ centered every 20 Mpc/$h$ in the line-of-sight range in the data (see Fig. 6 for a graphical representation).

Since the volume has been oversampled with a number of different slice centers, sometimes the same physical void will be found in multiple slices, creating elongated void structures in the line of sight (left panel in Fig. 7). Each of these structures may actually correspond to one physical underdensity, or at least their void candidate members will have a consistent lensing profile since they are essentially at the same redshift and have very similar sizes. In order to remove the duplicate voids, and also to pick up the right void center in the line-of-sight direction, we need to group these void structures together. The groups are found by joining voids in neighboring (and hence overlapping) slices that have a small angular separation between them. In particular, two voids with radii $R_v$ and $R_v'$ and found in neighboring slices will become part of the same group if the angular distance between their centers is smaller than half the mean angular radii of the two voids: $R_v/2 = (R_v + R_v')/4$. The groups are shown in the central panel in Fig. 7 and the right panel shows the final void catalog, without obvious elongated structures in the line of sight.

![Figure 5. Distribution of random point density inside DES-SV voids, where the random points are distributed uniformly through the DES-SV area. The distribution shows roughly a Gaussian shape at high densities corresponding to voids inside the survey mask, and a low density tail corresponding to edge voids. We remove all voids with random point density less than 9000 points/deg$^2$ (shaded region), most of them near the survey edge. This cut removes 33% of the total number of voids.

![Figure 6. Graphical representation of the line-of-sight (LOS) slicing performed in this paper. The black vertical arrow represents the redshift range, $0.2 < z < 0.8$, and the red horizontal bars represent the boundaries of the redshift slices in which the void finder is run. As the diagram shows, we oversample the line of sight with slices of thickness 100 Mpc/$h$ every 20 Mpc/$h$. In Fig. 7 we show the way voids in adjacent slices are combined to form the final catalog.](https://example.com/figure6.png)
This resulting void catalog is not very sensitive to the choice of $R_e/2$: Increasing this minimum separation from $0.5R_e$ to $0.6R_v$ $(0.8R_e)$ results in removing 6% (10%) of the voids in the final catalog.

Once we have the void groups corresponding to those line-of-sight structures, we compute the 3D position of each group (RA, Dec and redshift) as the median position of the different void members of the group. The relative scatter in this determination inside each group (taken as the standard deviation of each quantity with respect to its mean value) is very small (less than 0.4% for RA and Dec and around 2% in redshift). The void radius is also computed as the median void radius of the different void members in each group, with a relative scatter around 14%. The final void candidates, after removal of duplications of potential physical underdensities due to the oversampled slicing, are shown in the right panel of Fig. 7. The effect of the LOS slicing strategy in the void lensing measurement is tested in Appendix B where we show it helps reduce the noise but it does not affect the main outcomes from the measurement.

### 4.3 Final void catalog

Applying the void finding algorithm described in Sect. 3 using slices of 100 Mpc/h thickness, to the DES-SV redMaGiC catalog, and after making the cuts presented in Sections 4.1 and 4.2 we find a total of 87 voids in the 139 sq. deg. of survey area. These voids are identified in the redshift range $0.2 < z < 0.8$, and they have comoving sizes ranging from $R_v = 18$ Mpc/h to $R_v = 120$ Mpc/h, with a mean void radius of $R_e = 37$ Mpc/h. Figure 8 shows the full void radius distribution for the sample. The mean angular radius of voids in the sky is 1.5 degrees while their mean redshift is $\bar{z} = 0.57$.

Figure 9 shows the 2D galaxy density profiles of voids found in DES-SV data and simulations, using galaxy photometric redshifts. The shaded regions show the corresponding error bars computed as the standard deviation among all the stacked voids.
5 VOID LENSING

Using the void catalog defined in the previous section we now focus on the lensing measurement around voids. This represents a key result, since a significant lensing signal around voids proves them to be underdense in the matter field, this way demonstrating the void catalog is primarily composed of real underdensities rather than spurious detections, tracer density effects or any systematics in the data.

In this section we present the details of the lensing measurement and covariance, the results for the tangential and cross components of that measurement and their significance, and the fit of the tangential component to a void model widely used in the literature.

5.1 Measurement

Assuming an axisymmetric density profile, the stacked excess surface mass density $\Delta \Sigma$ is related to the tangential shear $\gamma_t$ of source galaxies by

$$\Delta \Sigma(R/R_v) = \Sigma_{\text{crit}} \gamma_t(R/R_v),$$

where the proportionality factor describing the lensing strength is

$$\Sigma_{\text{crit}}(z_L, z_s) = \frac{c^2}{4\pi G} \frac{D_L(z_s)(1 + z_L)^2}{D_A(z_L)D_A(z_L, z_s)},$$

with $\Sigma_{\text{crit}}^{-1}(z_L, z_s) = 0$ for $z_s < z_L$, where $z_L$ and $z_s$ are the lens and source galaxy redshifts, respectively. Note both the use of comoving units and that we need to assume a certain cosmology (flat $\Lambda$CDM with $\Omega_m = 0.3$) when calculating the angular diameter distances $D_A$ in $\Sigma_{\text{crit}}$. Our lensing projected surface density estimator is therefore given by

$$\Delta \Sigma_k(R/R_v; z_L) = \sum_j \left[ w_j \gamma_{jk}(R/R_v) \Sigma_{\text{crit}}(z_L, z_s) \right]$$

where $k$ denotes the two possible components of the shear (tangential and cross), the summation $\sum_j$ runs over all the source galaxies in the radial bin $R/R_v$, around every void position, and the optimal weight for the $j$-th galaxy is given by Sheldon et al. (2004):

$$w_j = \frac{\Sigma_{\text{crit}}^{-1}(z_L, z_s)^2}{\sigma_{\text{shape}}^2 + \sigma_{m,j}^2}.$$  

Here $\sigma_{\text{shape}}$ is the intrinsic shape noise for each source galaxy, and $\sigma_{m,j}$ is the shape measurement error. In Sec. 5.2 we relate the differential surface density $\Delta \Sigma$ to the 3D void profile $\rho_v$. Note that since the projected void radius $R_v$ ranges from 20 to more than 100 Mpc/$h$, we stack the measured shear profiles in units of the void radius, $R/R_v$. Stacking the profiles in physical distance would smooth out the stacked void density profiles and hence some of the signal would be lost.

5.2 Covariance

In order to estimate the covariance for the $\Delta \Sigma(R)$ measurements in this work we combine two different approaches: we rely on the jackknife (JK) method to estimate the signal variance while we estimate the off-diagonal shape of the covariance from the lensing shape noise of the measurement (Melchior et al. 2014). The main reason for that combination is the limitation in the JK technique due to the small number of voids ($\sim 100$) in our catalog, yielding very noisy off-diagonal correlations. However, we can obtain smooth shape-noise-only covariances by applying any number of random rotations to the ellipticities of source galaxies. Next we explain the precise combination of the two approaches.

Due to the small number of voids in the DES-SV catalog, we perform a void-by-void jackknife; we carry out the measurement multiple times with each void omitted in turn to make as many jackknife realizations as voids we have in the sample ($N$). Then, the variance of the measurement (Norberg et al. 2009) is given by

$$\sigma_{\text{JK}}^2(\Delta \Sigma_i) = \frac{(N - 1)}{N} \sum_{k=1}^{N} \left[ (\Delta \Sigma_i)_{\text{JK}-k} - \Delta \Sigma_i \right]^2$$

where the mean value is

$$\Delta \Sigma_i = \frac{1}{N} \sum_{k=1}^{N} (\Delta \Sigma_i)_{\text{JK}-k},$$

and $(\Delta \Sigma_i)_{\text{JK}-k}$ denotes the measurement from the $k$-th JK realization and the $i$-th spatial bin.

The shape noise (SN) covariance of the measurement is estimated by randomly rotating the orientation of each source galaxy ellipticity many times ($N_{\text{SN}} = 300$ in this analysis) and repeating the $\Delta \Sigma$ lensing measurement each time. Then the covariance is estimated as:

![Figure 10](image-url)
\[ \text{Cov}_{\text{SN}}[\Delta \Sigma_i, \Delta \Sigma_j] = \frac{1}{N_{\text{SN}}} \times \sum_{k=1}^{N_{\text{SN}}} \left[ (\Delta \Sigma_i)^{\text{SN}-k} - \overline{\Delta \Sigma_i} \right] \left[ (\Delta \Sigma_j)^{\text{SN}-k} - \overline{\Delta \Sigma_j} \right] \]

where the mean value is

\[ \overline{\Delta \Sigma_i} = \frac{1}{N} \sum_{k=1}^{N} (\Delta \Sigma_i)^{\text{SN}-k} , \]

and \((\Delta \Sigma_i)^{\text{SN}-k}\) denotes the measurement from the \(k\)-th shape noise (SN) realization and the \(i\)-th spatial bin.

Figure 10 shows a comparison of the measurement variance estimated from jackknife and shape noise, following the techniques described above. The errors coming from the two approaches agree well on the smallest scales, as expected since the intrinsic noise limitation of the JK technique. Hence, in order to have a smooth covariance matrix with variance accurately estimated from JK, we follow the approach of fixing the shape of the covariance as given by the shape noise calculation, and renormalize it to the JK estimates of the variance:

\[ \text{Cov}[\Delta \Sigma_i, \Delta \Sigma_j] = \text{Corr}_{\text{SN}}[\Delta \Sigma_i, \Delta \Sigma_j] \sigma_{\text{JK}}(\Delta \Sigma_i) \sigma_{\text{JK}}(\Delta \Sigma_j) \]

where \(\text{Corr}_{\text{SN}}[\Delta \Sigma_i, \Delta \Sigma_j]\) is the shape noise correlation matrix (or reduced covariance) given by:

\[ \text{Corr}_{\text{SN}}[\Delta \Sigma_i, \Delta \Sigma_j] = \frac{\text{Cov}_{\text{SN}}[\Delta \Sigma_i, \Delta \Sigma_j]}{\sigma_{\text{SN}}(\Delta \Sigma_i) \sigma_{\text{SN}}(\Delta \Sigma_j)} \]

The approach of renormalizing a smooth covariance to a JK estimated variance has been used before in the literature, for example by Crocce et al. (2016).

5.3 Null tests: Cross-component and randomized voids

The cross-component of the measurement described in Sect. 5.1 is not produced by gravitational lensing and therefore is expected to vanish at first order. Similarly, the tangential component of the same measurement around randomized voids, which follow the size and redshift distribution of true voids but are randomly distributed in the survey area (Appendix C), is also expected to vanish. Figure 11 shows the cross-component of the stacked lensing measurement for true voids and the tangential component for randomized voids.

With \(\text{dof} = N_{\text{bin}}\) as the number of \(R/R_v\) bins in the measurement and no model parameters, the null hypothesis \(\chi^2\) can be computed as

\[ \chi_{\text{null}}^2 = \sum_{i,j} (\Delta \Sigma_i \text{Cov}_{i,j}^{-1} \Delta \Sigma_j) \]

where \(i, j\) correspond to radial bins in \(\Delta \Sigma\) and \(\text{Cov}\) is the covariance matrix.

The cross-component of the measurement yields a \(\chi^2_{\text{null}}/\text{dof} = 8.2/16\), and the tangential measurement around randomized voids, which are 10 times more numerous than true voids and whose production is described in greater detail in Appendix C, yields a \(\chi^2_{\text{null}}/\text{dof} = 18.7/16\), both showing consistency with the null hypothesis.
5.4 Tangential shear profile

Figure 12 shows the measurement of the tangential component of the stacked lensing signal around voids. Assuming a non-central \( \chi^2 \) distribution we can compute the signal-to-noise (\( S/N \)) of the measurement as

\[
(S/N)^2 = \chi_{\text{null}}^2 - \text{dof} = \sum_{i,j} \Delta \Sigma_i \text{Cov}^{-1}_{ij} \Delta \Sigma_j - N_{\text{bin}} \tag{12}
\]

The evaluation of this expression yields \( \chi^2/\text{dof} = 35.5/16 \) and hence \( S/N = 4.4 \). The significance of the signal is complemented with the null tests in the previous subsection being consistent with the null hypothesis. Furthermore, we test the robustness of the signal to changes in the LOS slicing strategy in Appendix B and to changes in the value of \( \delta_{m} \) in Appendix A.

5.5 Model fits

We use the 3D void profile of Hamaus, Sutter & Wandelt (2014) (henceforth HSW14)

\[
\rho_v(r) = \frac{\delta_c}{\bar{\rho}} \frac{1}{1 + (r/R_v)^\alpha}, \tag{13}
\]

and fit two parameters: the central underdensity \( \delta_c \) and the scale radius \( R_v \). Note that \( r \) here denotes the 3D (in contrast to projected) radius. We do not fit the inner and outer slopes \( \alpha \) and \( \beta \) using the lensing data, but fix their values to the simulation fits of HSW14. That work showed that \( \alpha \) and \( \beta \) are not independent parameters but determined by the ratio \( r_s/R_v \), which yields \( \alpha = 2.1 \) and \( \beta = 9.1 \) for the best fit \( r_s \) shown in Fig. 13. Following Krause et al. (2013) the lensing observable \( \Delta \Sigma(R/R_v) \) is related to the 3D density by

\[
\Delta \Sigma(R/R_v) = \Sigma(<R/R_v) - \Sigma(R/R_v), \tag{14}
\]

where the projected surface density is given by

\[
\Sigma(R/R_v) = \int dr_{\text{los}} \rho_v \left( \sqrt{r_{\text{los}}^2 + R^2} - \bar{\rho} \right), \tag{15}
\]

and \( \bar{\rho} \) is the cosmological mean mass density.

The resulting parameter constraints are shown in Fig. 13. The reduced \( \chi^2/\text{dof} = 13.2/14 \) implies a good fit to the theory model. Even though the uncertainties are important, the best-fit \( \delta_c = -0.60 \) is in agreement with the density profile shown in Fig. 9, which is at the same time in agreement with the profile measured in simulations. In order to determine the data measurement using simulations, we have measured the lensing signal in the simulations using the same number of voids as in the data. The resulting measurement can be found in Fig. 12 and it shows consistency with the best-fit model to the data with \( \chi^2/\text{dof} = 10.1/14 \).

Additionally, the best-fit \( \delta_c \) and the trend in Fig. 13 are in agreement with findings in HSW14. However, note the important differences between our work and HSW14: we use photometric galaxies instead of N-body dark matter particles. More importantly, we are using a different void finder. Thus it should not be surprising that our mean void radius (\( R_v \)), scale radius (\( r_s \)), and mean void underdensity (\( \delta_c \)) do not match all the relations obeyed by theirs. For example, their void sample with \( r_s/R_v \approx 1.05 \) (matching our best-fit value) is slightly smaller (\( R_v \approx 29 \text{ Mpc}/h \)) and more empty (\( \delta_c \approx -0.7 \)) than ours.

Finally, we can use the constraints on \( \delta_c \) being negative as an alternative estimate of the significance in the lensing detection, which is consistent with the estimation in eq. 12:

![Figure 13. Constraints on void central underdensity \( \delta_c \) and scale radius \( r_s \) from the DES-SV data void lensing measurements in Fig. 12. Best-fit values are \( r_s = 1.05 R_v \) and \( \delta_c = -0.60 \), and the \( \chi^2/\text{dof} \) for the fit is 13.2/14. There is good agreement between the void edge determined from galaxies, \( R_v \), and the void edge determined from lensing, \( r_s \).](image)

5.6 Comparison to previous measurements

Other measurements of weak gravitational lensing around voids or underdensities have been performed in recent years. Melchior et al. (2014) used the SDSS void catalog of Sutter et al. (2012) to carry out the first detection of lensing around voids, although at low \( S/N \). Clampitt & Jain (2015) used a similar data sample, optimized the void finding strategy for lensing purposes and were able to achieve a higher \( S/N \approx 7 \) in the lensing measurement. The void finder in this work is similar to that of Clampitt & Jain (2015), even though we did not attempt to optimise the lensing detection but to minimise the photo-z related impact in the void finding procedure. Our comparable lensing \( S/N \) is encouraging given the use of photometric redshifts and a smaller dataset – this highlights the viability of photometric void finders as well as the quality of the DES data.

Gruen et al. (2016) changed the approach and, instead of looking at individual cosmic voids, measured the lensing signal around troughs in the DES-SV galaxy distribution, defined as underdensities in the projection of lens galaxies over a wide range in redshift. That produced a high \( S/N \) lensing measurement around those structures, and they successfully modelled that to probe the connection between galaxies and matter. In that respect, trough lensing does not constrain void profiles.
or abundances but it is sensitive to the galaxy bias and even cosmology.

6 DISCUSSION

We have presented a new void finder designed for photometric surveys and applied it to early Dark Energy Survey data and simulations. Fixing the line-of-sight size of the slice to be at least twice the photo-z scatter, we find the number of voids found in simulated spectroscopic and photometric galaxy catalogs to be within 20% for all transverse void sizes, and indistinguishable for voids with projected size larger than 70 Mpc/h. For such large voids, most have a one-to-one match with nearly the same assigned center and radius.

This result – that the largest voids are the ones most faithfully preserved in a photometric redshift survey – has implications for the expected spatial and dynamic properties of our voids. Ceccarelli et al. (2013) classified voids into those with and without surrounding overdense shells: large voids without shells tend to expand, while smaller voids surrounded by overdense shells are in the process of being crushed by the surrounding shell. This is a useful division for understanding void dynamics, as predicted analytically by Sheth & van de Weygaert (2004) and later studied in simulations (Paz et al. 2013; Ceccarelli et al. 2013; Hamaus, Sutter & Wandelt 2014) and data (Ruiz et al. 2015). Furthermore, this classification has been useful for predicting large-scale bulk flows of voids in both simulations (Lambas et al. 2016) and data (Ceccarelli et al. 2015). These works found that large voids are on average receding from each other, while small voids in overdense shells are approaching each other.

Most importantly, we have applied the algorithm to the DES-SV data and found a total of 87 voids over the redshift range 0.2 ≤ z ≤ 0.8. Our ∼ 4σ detection of the weak gravitational lensing signal of these voids shows they are truly underdense in the matter field and hence not simply a product of Poisson noise, tracer density effects or any systematics in the data. Assuming a model profile (Hamaus, Sutter & Wandelt 2014), we find a best-fit central density of δc ≈ −0.6 and scale radius r_s ≈ R_v. Since r_s is the void edge determined from lensing, and R_v is the edge determined from the galaxy distribution, the best-fit lensing model shows consistency between the mass and galaxy distributions of voids. Note however that the contours are broad and still allow for the possibility of r_s ≲ R_v.

Further applications of the same void finder will be explored in future DES data samples. Of particular interest is the study of the CMB cold imprint of voids (Kovács et al. in prep), related to the properties and presence of Dark Energy through the integrated Sachs-Wolfe effect (Granett, Neyrinck & Szapudi 2008; Cai et al. 2010; Cai, Padilla & Li 2014; Hotchkiss et al. 2014).

The advances in this work towards finding voids in photometric surveys are also exciting in light of recent advances in void cosmology. Clampitt, Jain & Sánchez (2016) studied void-void and void-galaxy clustering and derived void bias using the spectroscopic SDSS luminous red galaxy (LRG) sample. Hamaus et al. (2016) applied the Alcock-Paczynski test to void clustering statistics to put ∼ 10% constraints on Ω_m using voids identified using CMASS galaxies as tracers, a result that was anticipated in simulations by the same group (Hamaus et al. 2014a, 2015). Kitaura et al. (2015) reported greater than 3σ evidence of the presence of baryonic acoustic oscillations (BAO) in void correlations, again using CMASS galaxies. This impressive measurement was made possible by the new void finder presented in Zhao et al. (2015) and detailed studies with mock CMASS samples presented in Liang et al. (2015). While the CMASS sample from BOSS covers a very large area, it lacks a suitable background source sample for direct lensing measurements of void density profiles. Upcoming photometric surveys, which will have many background sources available, will make the combination of void clustering and lensing over large volumes a reality.

In addition to constraining standard cosmological parameters, voids have been used to investigate alternative dark matter scenarios like warm dark matter (Yang et al. 2015), or the effects of neutrinos on void lensing (Massara et al. 2015). Especially numerous are the studies on void abundance (Li 2011; Clampitt, Cai & Li 2013; Cai, Padilla & Li 2015; Zivick et al. 2015; Lam et al. 2015; Pollina et al. 2016) and lensing (Cai, Padilla & Li 2014; Barreira et al. 2015) as promising probes of alternatives to General Relativity (GR). In particular, Barreira et al. (2015) used simulations of Galileon gravity to show that the lensing signal of voids can be double that in GR. Comparing to the SDSS void lensing results of Clampitt & Jain (2015), they showed that the size of the difference is comparable to current observational errors. Furthermore, another recent development by Cantum, Cai & Frenk (2015) has shown that the signal-to-noise for void lensing can be increased by describing the void profile relative to the boundary rather than the center. Such advances, combined with the increasing quality and volume of data from ongoing surveys, will bring modified gravity constraints using voids within reach. The algorithm in this work ensures that the statistical power of these new photometric datasets can be brought to bear on void measurements.

ACKNOWLEDGMENTS

This paper has gone through internal review by the DES collaboration. It has been assigned DES paper id DES-2016-0168 and FermiLab preprint number PUB-16-173-AE.

Figure 14. Stacked void lensing signal in DES-SV data for three choices of δm: −0.33, −0.30 (fiducial), −0.27. The black line shows the best-fit model to the fiducial measurement. The comparison shows good agreement between the three sets of measurements.

APPENDIX

A Choice of δm

The void finder presented in Sect. 3 of this paper produces a void catalog which depends on the chosen value for the maximum density contrast (δm) of a pixel to become a void center (see Sect. 3.1). The most significant, and hence deepest voids found by the algorithm are independent of the choice of δm, but the total number of voids in the catalog will vary with that choice. With the fiducial value being δm = −0.30, in this appendix we vary that value by 10% high and low, and test the impact of these changes in the void lensing signal in the data.

The fiducial void catalog with δm = −0.30 contains 78 voids and the goodness of the best-fit model to its lensing signal (see Sect. 5.5) is 13.2/14. The catalog with δm = −0.33 contains 73 voids and the goodness of the lensing fiducial best-fit model is 12.9/14. The catalog with δm = −0.27 contains 107 voids and the goodness of the lensing fiducial best-fit model is 11.9/14. The good agreement between the lensing signal in the three cases is also shown in Fig. 14.

B Lensing on individual slicings

In Sect. 4.2 we presented a way of combining different slicings of the line of sight (LOS), oversampling it with slices of 100 Mpc/h thickness every 20 Mpc/h, in order to get more information in that direction. Voids found in neighboring slices are
joined if their centers are close enough, and the resulting group of voids is considered an individual physical underdensity.

In this appendix we test the impact of that procedure on the void lensing results presented in this paper (Sect. 5). For that purpose, we perform the lensing measurement on the set of voids found in each individual slicing, corresponding to the five columns in the graphical representation of Fig. 6. Note that in the case of individual slicings there is no overlap between the slices in which voids are found. The corresponding five lensing measurements, together with their mean and standard deviation, are shown in Fig. 15, where they are compared to the lensing measurement of the final void catalog from Sect. 5. The comparison shows how the combined slicing approach is not affecting the lensing results in this way in any other way than reducing the noise in the measurement.

C Randomized void catalog

The randomized void catalog in this paper is produced such that it mimics the properties of the true void catalog in redshift and radius. We start from a set of random points inside the data mask; they will constitute the centers of the randomized voids. We assign a redshift to each random point drawn for the true redshift distribution of voids and, to each randomized void, we assign an angular radius from the true distribution of angular radii for voids of similar redshift (in a window of $\Delta z = 0.1$), this way preserving the redshift - angular radius relation. Finally, from the angular radius and the redshift we compute the comoving radius of the randomized voids.

After this process we have a randomized void catalog with the same properties as the true one. Then, we also apply the process described in Sect. 4.1 to get rid of voids near the survey edges. At the end, the randomized void catalog has 10 times as many objects as the true one. Figure 15 shows the agreement between the distributions of the true and randomized voids in redshift and comoving and angular radius.
