On Rational Maps with Two Critical Points

J. Milnor

Abstract. This is a preliminary investigation of the geometry and dynamics of rational maps with only two critical points.

Contents:
0. Introduction
1. Conjugacy invariants and the moduli space $\mathcal{M}$
2. Fixed points and the curves $\text{Per}_1(\lambda)$
3. Shift locus or connectedness locus
4. The parabolic shift locus $\mathcal{S}_{\text{par}} \cong \mathbb{C} \setminus \mathbb{D}$
5. Real maps
6. The extended moduli space $\hat{\mathcal{M}} = \mathcal{M} \cup L_\infty$
7. The extended hyperbolic shift locus $\hat{\mathcal{S}}_{\text{hyp}} \subset \hat{\mathcal{M}}$
8. The curves $\overline{\text{Per}}_p(\lambda) \subset \hat{\mathcal{M}}$

Appendix A: No Herman rings

Appendix D: Entire and meromorphic maps

References

§0. Introduction. We consider rational maps $f : \hat{\mathbb{C}} \to \hat{\mathbb{C}}$ of degree $n \geq 2$ which are bicritical, in the sense that they have only two critical points. Note that every rational map of degree two is bicritical. (See [M2], [R2], [R3], [Si], [Sti] for discussion of this case.) For $n > 2$, bicriticality is a very strong restriction. In fact bicritical maps seem to behave much more like quadratic rational maps than like general rational maps of degree $n$.

It is shown that the moduli space $\mathcal{M} = \mathcal{M}_n$, consisting of all holomorphic conjugacy classes of bicritical maps of degree $n$, is biholomorphic to $\mathbb{C}^2$. Furthermore, the Julia set of a bicritical map is either connected, or totally disconnected and isomorphic to the one sided shift on $n$ symbols. In the latter case this Julia set can be either hyperbolic or parabolic. Correspondingly the moduli space splits as the disjoint union

$$\mathcal{M} = \mathcal{C} \cup \mathcal{S}_{\text{hyp}} \cup \mathcal{S}_{\text{par}}$$

of the connectedness locus, the hyperbolic shift locus, and the parabolic shift locus. Here $\mathcal{S}_{\text{hyp}}$ is a connected open subset of $\mathcal{M}$ with free cyclic fundamental group, while $\mathcal{S}_{\text{par}}$ is a codimension one subset, conformally isomorphic to $\mathbb{C} \setminus \mathbb{D}$.

Remark 0.1. There is another interesting trichotomy obtained by considering the multipliers $\lambda_1, \ldots, \lambda_{n+1}$ at the various fixed points (see §2). If we assume that $|\lambda_j| \neq 1$ for all of these multipliers, then there are three possibilities as follows. If two of the fixed points are attracting, then we are in the principal hyperbolic component, and the Julia set is a quasicircle. If there is just one attracting fixed point, then we are in the polynomial-like case, and can reduce to the polynomial case by a quasiconformal surgery. (If $N$ is a compact neighborhood of the attracting point which contains exactly one critical value, with $f(N)$
compactly contained in $N$, then $f$ carries $\hat{\mathbb{C}} \setminus f^{-1}(N)$ onto $\hat{\mathbb{C}} \setminus N$ by a map which is polynomial-like in the sense of [DH2].) Note that the hyperbolic shift locus is included here. Finally, it may happen that all $n+1$ fixed points are strictly repelling. This essentially non-polynomial-like case is the most interesting, since this is where we must look for any new or exotic behavior. (Compare 3.2.)

In order to understand limiting behavior as the rational map becomes degenerate, it is convenient to introduce a partial compactification of moduli space by adding a line $L_{\infty} \cong \mathbb{C}$ of “points at infinity”. The resulting extended moduli space $\hat{\mathcal{M}} = \mathcal{M} \cup L_{\infty}$ fibers as a complex line bundle

$$\mathbb{C} \hookrightarrow \hat{\mathcal{M}} \xrightarrow{X} \hat{\mathbb{C}}$$

over the Riemann sphere, with Chern number equal to $n-1$. Here $X : \mathcal{M} \to \mathbb{C}$ is a certain conjugacy class invariant which can be described up to sign as a cross-ratio (see 1.7), and $X(L_{\infty}) = \infty$. The connectedness locus $\mathcal{C} \subset \mathcal{M}$ has compact closure within $\hat{\mathcal{M}}$.

For each $\lambda \in \mathbb{C} \setminus \{0\}$ the curve $\text{Per}_1(\lambda)$ consisting of conjugacy classes of maps with a fixed point of multiplier $\lambda$ forms a holomorphic section of the line bundle $\hat{\mathcal{M}} \to \hat{\mathbb{C}}$. Any two such sections have exactly $n-1$ intersections, counted with multiplicity. On the other hand, for $\lambda = 0$ the locus $\text{Per}_1(0)$ is not a section, but rather coincides with a fiber

$$L_0 = \{ (f) \in \hat{\mathcal{M}} : X(f) = 0 \}.$$

This fiber can be identified with the set of conjugacy classes of unicritical polynomial maps $z \mapsto z^n + \text{constant}$.

The moduli space $\mathcal{M} = \mathcal{M}_n \cong \mathbb{C}^2$ contains a real subspace $\mathcal{M}_{\mathbb{R}} \cong \mathbb{R}^2$. This consists not only of conjugacy classes of maps with real coefficients but also, when the degree $n$ is odd, of a more exotic region consisting of conjugacy classes of maps $f$ which commute with the antipodal map $z \mapsto -1/\bar{z}$ of the Riemann sphere. Such $f$ give rise to dynamical systems on the nonorientable surface which is obtained by identifying $z$ with $-1/\bar{z}$. Similarly the extended moduli space $\hat{\mathcal{M}} \supset \mathcal{M}$ contains a real subset $\hat{\mathcal{M}}_{\mathbb{R}}$ which fibers as a real line bundle

$$\mathbb{R} \hookrightarrow \hat{\mathcal{M}}_{\mathbb{R}} \xrightarrow{X} \mathbb{R} \cup \{\infty\}$$

over the circle $\mathbb{R} \cup \{\infty\}$. Topologically, $\hat{\mathcal{M}}_{\mathbb{R}}$ is either a cylinder or Möbius band according as $n$ is odd or even.

**Erratum.** The preliminary version “On bicritical rational maps” of this note contained a wrong computation of the degree of $\text{Per}_p(\lambda)$, and also an incorrect proof in Appendix A.

**Acknowledgements.** I am indebted to A. Epstein for suggesting the problem, to D. Schleicher and M. Shishikura for valuable assistance, particularly in the proof of 4.2, and to A. Douady for suggestions leading to Appendices A and D. Furthermore, I am indebted to the Gabriella and Paul Rosenbaum Foundation and to the National Science Foundation (Grant DMS-9505833) for their support of mathematical activity at the Institute for Mathematical Sciences at Stony Brook.
§1. Conjugacy Invariants and the Moduli Space \( \mathcal{M} \)

Let \( \text{Bicrit}_n \) be the space of all bicritical maps of degree \( n \geq 2 \). (It is not hard to check that \( \text{Bicrit}_n \) is a smooth 5-dimensional complex manifold.) By definition, two rational maps \( f \) and \( g \) are (holomorphically) conjugate if there exists a Möbius automorphism \( \phi \) of the Riemann sphere so that \( g = \phi \circ f \circ \phi^{-1} \). We are interested in the moduli space \( \mathcal{M} = \mathcal{M}_n \) consisting of all conjugacy classes \((f)\) of degree \( n \) bicritical maps. The first two sections will provide a rather formal algebraic description of this space.

First consider the marked moduli space \( \mathcal{M}' \), consisting of conjugacy classes of \( f \) with numbered critical points \( c_1, c_2 \). Here, by definition, the conjugacy class of \((f, c_1, c_2)\) consists of all \((\phi \circ f \circ \phi^{-1}, \phi(c_1), \phi(c_2))\), where \( \phi \) ranges over Möbius automorphisms of the Riemann sphere \( \hat{\mathbb{C}} \). In order to construct a complete set of invariants for such an \((f, c_1, c_2)\), we proceed as follows.

**Lemma 1.1.** If we put the critical points \( c_1 \) at infinity and \( c_2 \) at zero, then \( f \) must have the form

\[
    f(z) = \frac{az^n + b}{cz^n + d}, \quad \text{with derivative} \quad f'(z) = \frac{n z^{n-1}(ad - bc)}{(cz^n + d)^2}. \tag{1}
\]

(There should be no confusion between the coefficient \( c \) and the critical points \( c_j \).) Here the determinant \( ad - bc \) must be non-zero. Note that this transformation depends only on the ratios \( a : b : c : d \).

**Proof of 1.1.** Write \( f(z) \) as the quotient \( p(z)/q(z) \) and look at the equation \( f(z) = v \) or \( p(z) - vq(z) = 0 \). Suppose, to fix our ideas, that the two critical values \( v_1 = f(0) \) and \( v_2 = f(\infty) \) are finite. Then the polynomial \( p(z) - v_2q(z) \) has no finite roots, and hence must be constant. Similarly, \( p(z) - v_1q(z) \) has no non-zero roots, hence must have the form \( kz^m \). Solving the resulting linear equations for \( p(z) \) and \( q(z) \), the conclusion follows easily. The case where \( v_1 \) or \( v_2 \) is infinite can be handled by a similar argument. \( \square \)

**Remark.** The Julia set of a bicritical map of degree \( n \) always has an \( n \)-fold rotational symmetry about its critical points. If we use the normal form (1), then this symmetry is expressed by the equation \( f(\omega z) = f(z) \) and hence \( J = \omega J \), whenever \( \omega^n = 1 \).

**Theorem 1.2.** A complete set of conjugacy invariants for a map \( f \) in the normal form (1), with marked critical points at zero and infinity, is given by the expressions

\[
    X = \frac{bc}{ad - bc}, \quad Y_1 = \frac{a^{n+1}b^{n-1}}{(ad - bc)^n}, \quad Y_2 = \frac{c^{n-1}d^{n+1}}{(ad - bc)^n}. \tag{2}
\]

These are subject to the relation

\[
    Y_1 Y_2 = X^{n-1}(X + 1)^{n+1}, \tag{3}
\]

but to no other relations. Hence the moduli space \( \mathcal{M}' \) consisting of all such marked conjugacy classes is homeomorphic to the affine algebraic variety consisting of all \((X, Y_1, Y_2) \in \mathbb{C}^3\) satisfying equation (3).
As an example, the polynomial function \( f(z) = z^n + b \) corresponds to the matrix
\[
\begin{bmatrix}
a & b \\
c & d
\end{bmatrix} = \begin{bmatrix} 1 & b \\ 0 & 1 \end{bmatrix}
\] with invariants \( X = Y_2 = 0, \ Y_1 = b^{n-1} \).

Compare Figures 1a and 2 for pictures of the \( Y_1 \)-coordinate plane and the \( b \)-coordinate plane for degree \( n = 4 \), in this locus \( X = Y_2 = 0 \) of polynomial maps.

**Proof of 1.2.** Multiplying the four coefficients in (1) by a common factor, we can normalize so that \( ad - bc = 1 \). The coefficients are then uniquely determined up to a common change of sign. Note that the expressions (2) are all invariant under this transformation, since numerator and denominator are homogeneous of the same degree. With this normalization, we can write (2) in the simpler form
\[
X + 1 = ad, \quad X = bc, \quad Y_1 = a^{n+1}b^{n-1}, \quad Y_2 = c^{n-1}d^{n+1} \quad (2')
\]

Such a normal form with critical points at zero and infinity is not unique, since we are still free to conjugate by a Möbius automorphism which fixes both zero and infinity. If we write such an automorphism as \( \phi(z) = z/t^2 \), then we must replace \( f \) by \( \phi \circ f \circ \phi^{-1}(z) = f(t^2z)/t^2 \).

A brief computation shows that the four coefficients, normalized so that the determinant remains +1, are then transformed by the rule
\[
(a, b, c, d) \mapsto (t^{n-1}a, \ b/t^{n+1}, \ t^{n+1}c, \ d/t^{n-1}) \quad (4)
\]

It is clear that the three expressions (2') are invariant under this transformation (4), and also under a simultaneous change of sign for \( a, b, c, d \), and that they satisfy the required relation (3).

Conversely, given \( (X, Y_1, Y_2) \) satisfying (3), we must show that there is one and only one corresponding choice of \( \pm(a, b, c, d) \), up to the transformation (4).

**Case 1.** Suppose that \( Y_2 \neq 0 \), hence \( c \neq 0 \) and \( d \neq 0 \). Then using (4) we can make a linear change of variables so that \( d = 1 \). It follows from (2') that
\[
a = X + 1, \quad b = X/c, \quad c^{n-1} = Y_2.
\]

Thus we obtain a normal form which is uniquely determined by \( X \) and \( Y_2 \), up to a choice of \((n - 1)\)-st root for \( Y_2 \). With this choice of \( a, b, c, d \), note that the relation \( Y_1 = a^{n+1}b^{n-1} \) follows from (3). But applying (4) again with \( t \) equal to any \((2n - 2)\)-nd root of unity, since \( t^{n-1} = \pm 1 \), we see that
\[
(a, b, c, d) \mapsto \pm(a, b/t^2, t^2c, d),
\]

where \( t^2 \) can be an arbitrary \((n - 1)\)-st root of unity. Therefore, the conjugacy class does not depend on a particular choice of \((n - 1)\)-st root \( c \).

**Case 2.** If \( Y_1 \neq 0 \) the argument is similar.

**Case 3.** If \( Y_1 = Y_2 = 0 \), then \( X \) must be either 0 or \(-1\) by equation (3). If \( X = Y_1 = Y_2 = 0 \), then making use of the hypothesis that \( ad - bc = 1 \) we see that \( b = c = 0 \) and that \( f \) is conjugate to
\[
z \mapsto z^n.
\]

On the other hand, if \( X + 1 = Y_1 = Y_2 = 0 \), then it follows similarly that \( a = d = 0 \) and
that \( f \) is conjugate to the map

\[ z \mapsto z^n. \]

(Remark: These two exceptional points in moduli space will often require special attention.) This completes the proof. \( \square \)

Now consider the quotient space of \( M' \) under the involution

\[ (f, c_1, c_2) \leftrightarrow (f, c_2, c_1) \]

which interchanges the two critical points.

**Corollary 1.3.** This quotient space \( M \), consisting of all holomorphic conjugacy classes of degree \( n \) bicritical maps, is biholomorphic to \( \mathbb{C}^2 \), with coordinates \( X \) and \( Y = Y_1 + Y_2 \).

We will use the notation \( L_{X_0} \) for the complex line consisting of all \( (f) \in M \) with \( X(f) = X_0 \).

**Proof of 1.3.** If \( f \) is given by (1), then a holomorphically conjugate map with critical points interchanged is given by

\[ \frac{1}{f(1/z)} = \frac{dz^n + c}{bz^n + a}. \]

Thus \( (a, b, c, d) \leftrightarrow (d, c, b, a) \) and \( Y_1 \leftrightarrow Y_2 \), with \( X \) fixed. We must form the quotient of \( M' \) under this involution. Since the product \( Y_1Y_2 \) can be expressed as a smooth function of \( X \), it is easy to check that the two quantities \( X \) and \( Y = Y_1 + Y_2 \) form a complete and independent set of invariants for the quotient variety \( M \). \( \square \)

**Remark.** Note that the algebraic variety (3) has a singular point at \( X = -1, Y_1 = Y_2 = 0 \), and (if \( n \geq 3 \)) another singular point at \( X = Y_1 = Y_2 = 0 \). However, by passing to the quotient variety in which we unmark the critical points, these two singular points miraculously disappear.

**Corollary 1.4.** The symmetry locus \( \Sigma \subset M \), consisting of all conjugacy classes of \( f \) which commute with some Möbius automorphism, is the variety defined by the equation

\[ Y^2 = 4X^{n-1}(X + 1)^{n+1}. \]

**Proof.** First suppose that there exists a non-trivial automorphism which fixes the two critical points. Then it must also fix the critical values, hence the set of critical points must coincide with the set of critical values. There are only two possibilities: Either \( f \) fixes both critical points hence \((f)\) is the conjugacy class of \( z \mapsto z^n \) with \( X = Y = 0 \), or else \( f \) interchanges the two critical points, hence \((f)\) is the class of \( z \mapsto 1/z^n \) with \( X + 1 = Y_1 = Y_2 = 0 \). (In these two exceptional cases, the group of automorphisms fixing the critical points is cyclic of order \( n - 1 \) or \( n + 1 \) respectively, and the full group of automorphisms is dihedral of order \( 2(n - 1) \) or \( 2(n + 1) \) respectively.)

If we exclude these two cases, then a non-trivial automorphism \( \iota \) commuting with \( f \) must be an involution which interchanges the two critical points, and must be unique. It is easy to see that such an involution exists if and only if \( Y_1 = Y_2 = Y/2 \). Since the two exceptional cases also satisfy this equation, the conclusion then follows from (3). \( \square \)
Remark 1.5. When \( n \) is odd, this symmetry locus is a reducible variety, splitting as \( \Sigma_+ \cup \Sigma_- \) where \( \Sigma_{\pm} \) is defined by
\[
Y = \pm 2X^{(n-1)/2}(X + 1)^{(n+1)/2}.
\]
In fact a class \((f) \in \mathcal{M}\) can be symmetric in two essentially different ways when \( n \) is odd. Let \( \iota \) be the (usually unique) involution which commutes with \( f \). Then the two fixed points of \( \iota \) are also fixed by \( f \) when \((f) \in \Sigma_+\), but are interchanged by \( f \) when \((f) \in \Sigma_-\). This can be proved by using the normal form (1), taking \( \iota(z) \) to be \( 1/z \), so that
\[
f(z) = \pm \frac{az^n + b}{bz^n + a}.
\]
(Note that the two exceptional conjugacy classes, where the involution \( \iota \) is not uniquely determined, constitute the intersection \( \Sigma_+ \cap \Sigma_- \).) For \((f) \in \Sigma_+\), computation shows that the two invariant fixed points have multipliers \( \lambda_1 \) and \( \lambda_2 \) with sum \( \lambda_1 + \lambda_2 = 2n(2X + 1) \) and with product \( \lambda_1\lambda_2 = n^2 \). On the other hand, for \((f) \in \Sigma_-\) the two fixed points of \( \iota \) constitute a period two orbit for \( f \) with multiplier \( n^2 \). It follows that \( \Sigma_- \) is contained as one irreducible component in the curve \( \text{Per}_2(n^2) \) of \( \S 8 \).

Evidently, the two halves of the symmetry locus represent quite different dynamic behavior. For example if \((f) \in \Sigma_-\) then there are either two non-repelling fixed points or none. In either case, it follows that the Julia set is connected. On the other hand, if we use the normal form (5\(_\pm\)) then a brief computation shows that the multiplier at the fixed point \( 1 = f(1) = \iota(1) \) equals \( n(a - b)/(a + b) \). Whenever this fixed point is attracting, it follows by symmetry that both critical points must lie in its immediate basin. Using Theorem B.5 in the Appendix, it follows that the Julia set is totally disconnected.

For \( n \) even, the symmetry locus is irreducible, conformally isomorphic to a punctured plane. In fact each \((f) \in \Sigma\) has a unique fixed point which is invariant under the involution. The multiplier \( \lambda \) at this fixed point can take any non-zero value, and computation shows that \( X = (\lambda/n + n/\lambda - 2)/4 \) is then uniquely determined. (The correspondence \( \lambda \mapsto X \) is two-to-one, since a generic fiber \( L_X \) intersects \( \Sigma \) in two different points.)

Remark 1.6. The following observation is due to Adam Epstein. Again let \( \iota \) be the (usually unique) involution commuting with \( f \). Then there is a natural involution of the symmetry locus given by \((f) \mapsto (f^*)\), where \( f^* = f \circ \iota = \iota \circ f \) has the same Julia set as \( f \). The map \( f^* \) has invariants \( X^* = -1 - X \) and \( Y^* = (-1)^nY/X/(1 + X) \). When \( n \) is odd, note that this involution maps each irreducible component \( \Sigma_\pm \) to itself. Using the normal form (5\(_\pm\)), this involution interchanges the coefficients \( a \) and \( b \).

An interesting involution of the entire moduli space \( \mathcal{M} \) is given by the correspondence \((f) \mapsto (J \circ f)\), where \( J = J_f \) is the unique involution of the Riemann sphere which fixes the two critical values. If \( f \) is given by (1), then
\[
J \circ f(z) = \frac{az^n - b}{cz^n - d},
\]
with \( X(J \circ f) = X(f) \) and \( Y_i(J \circ f) = -Y_i(f) \). Thus this involution maps the symmetry locus to itself, interchanging \( \Sigma_+ \) and \( \Sigma_- \) in the odd degree case.

The correspondence \((f) \mapsto X(f)\) is rather natural, and can be defined in several different ways. For example we will see in \( \S 2 \) that \( X(f) \) is linearly related to the sum of the multipliers
2. FIXED POINTS

at the various fixed points of \( f \). As another example, note the following cross-ratio formula. (Compare Appendix C.)

**Lemma 1.7.** If \( f \) is a rational map with critical points \( c_1, c_2 \) and with critical values \( v_j = f(c_j) \), then the invariant \( X = X(f) \) is equal to the negative of the cross-ratio

\[
\frac{(c_1 - v_1)(c_2 - v_2)}{(c_1 - c_2)(v_1 - v_2)}.
\]

**Proof.** This cross-ratio is clearly well defined and invariant under conjugation. (Note that the denominator never vanishes.) Putting the critical points at \( c_1 = \infty \) and \( c_2 = 0 \), the left hand factors cancel and the cross-ratio reduces to

\[
\frac{0 - v_2}{v_1 - v_2} = \frac{-b/d}{a/c - b/d} = \frac{-bc}{ad - bc},
\]

as required. \( \square \)

For further cross-ratio formulas, see Appendix C.

**Corollary 1.8.** Denote the modulus of an annulus \( A \subset \hat{\mathbb{C}} \) by \( \text{mod}(A) \), and let \( \text{mod}(f) \geq 0 \) be the largest possible modulus of an annulus in \( \hat{\mathbb{C}} \) which separates the critical values of \( f \) from the critical points of \( f \) (taking \( \text{mod}(f) = 0 \) when there is no such annulus). Given a sequence of conjugacy classes \( (f_i) \in \mathcal{M} \), the invariants \( |X(f_i)| \) tend to infinity if and only if the invariants \( \text{mod}(f_i) \) tend to infinity.

**Proof.** In fact we will show that

\[
\frac{\log(r)}{2\pi} \leq \text{mod}(f) \leq \text{mod}(\hat{\mathbb{C}} \setminus ([-1,0] \cup [r, +\infty])),
\]

where \( r = |X| \), and where both the upper and the lower bound tend to infinity as \( r \to \infty \). After a Möbius automorphism, we may assume that the critical points are located at \( 0, -1 \) and the corresponding critical values at \( X, \infty \). Now the lower bound is obtained by using the round annulus \( \{z \mid 1 < |z| < r\} \), while the upper bound follows from [A, Ch. III]. \( \square \)

The space \( \mathbb{C}^2 \) is an extremely flabby object, with a very large group of holomorphic automorphisms. In §6 we will impose a much more rigid structure on the moduli space \( \mathcal{M} \cong \mathbb{C}^2 \) by partially compactifying it. The invariant \( X \) will play a key role in this partial compactification, since it will serve as the projection map of a canonical fibration, with typical fiber \( L_{X_0} = \{(f) \mid X(f) = X_0\} \).

\section{2. Fixed Points and the curves \( \text{Per}_1(\lambda) \)}

Recall that the **multiplier** of a rational map \( f \) at a finite fixed point \( z = f(z) \) is defined to be the first derivative \( \lambda = f'(z) \). (In the case of a fixed point at infinity the multiplier is equal to the limit of \( 1/f'(z) \) as \( z \to \infty \).) We first prove the following.

**Lemma 2.1.** Let \( f \) be a bicritical map of degree \( n \) with invariants \( X \) and \( Y \).

If \( f \) has a fixed point of multiplier \( \lambda \), then the product \( \lambda^n Y \) can be expressed as a polynomial function of degree \( 2n \) in the variables \( X \) and \( \lambda \).
Definition. Let $\text{Per}_1(\lambda) \subset M$ be the set of all conjugacy classes of bicritical maps which admit a fixed point of multiplier $\lambda$.

Corollary 2.2. For $\lambda \neq 0$, the curve $\text{Per}_1(\lambda)$ can be described as the graph of a polynomial function $Y = \text{polynomial}_\lambda(X)$. In particular, for $\lambda \neq 0$, each fiber $L_{X_0} = \{(f) ; X(F) = X_0\}$ contains one and only one conjugacy class $(f)$ of maps which have a fixed point of multiplier $\lambda$.

Proof of 2.1 and 2.2. We will use the normal form (1). First suppose that $\lambda \neq 0$. Then the fixed point of multiplier $\lambda$ must be distinct from the two critical points 0 and $\infty$. After a linear change of coordinates, we may assume that this fixed point is $z = 1$. Thus $1 = f(1) = (a + b)/(c + d)$. Multiplying the coefficients by a common factor, we may assume that $a + b = c + d = 2$. If we define parameters $\mu$ and $\xi$ by the equations

$$
a = 1 + \mu + \xi, \quad b = 1 - \mu - \xi, \\
c = 1 - \mu + \xi, \quad d = 1 + \mu - \xi,
$$

then a straightforward computation shows that

$$
ad - bc = 4\mu, \quad \lambda = f'(1) = \frac{n(ad - bc)}{(c + d)^2} = n\mu, \quad X = \frac{(1 - \mu)^2 - \xi^2}{4\mu},
$$

and that

$$
Y = \frac{(1 + \mu + \xi)^{n+1}(1 - \mu - \xi)^n - 1 + (1 - \mu + \xi)^n(1 + \mu - \xi)^{n+1}}{(4\mu)^n}.
$$

Thus $\mu^nY$ is equal to a polynomial of degree $2n$ in the variables $\mu$ and $\xi$. Note that this expression for $Y$ is unchanged if we replace $\xi$ by $-\xi$. (The involution $\xi \leftrightarrow -\xi$ corresponds to the conjugation $f(z) \leftrightarrow 1/f(1/z)$.) Hence $\mu^nY$ can be expressed as a polynomial function of $\mu$ and $\xi^2$. Substituting $\xi^2 = (1 - \mu)^2 - 4\mu X$ and $\mu = \lambda/n$, we obtain the required polynomial expression for $\lambda^nY$, of degree $n$ in $\lambda$ and $X$. This proves 2.2.

To prove 2.1, we must also check that this same polynomial relation remains valid when $f$ has a fixed point (necessarily 0 or $\infty$) of multiplier $\lambda = 0$. In that case, the product $\lambda^nY$ is certainly zero, and $X = 0$ so that $\xi = \pm 1$, and the numerator of the expression for $Y$ is identically zero, as required.□

We can describe the form of these polynomial relations more precisely as follows. We will continue to work with the quotient $\mu = \lambda/n$.

Theorem 2.3. For each $n$ there exist polynomials

$$P_0(X), P_1(X), P_2(X), \ldots, P_{n+1}(X)$$

with integer coefficients, where each $P_k(X)$ has degree $\leq k$, so that

$$\mu Y = P_{n+1}(X) - \mu P_n(X) + \mu^2 P_{n-1}(X) - \cdots + (-\mu)^n P_1(X) + (-\mu)^{n+1} P_0(X).$$

(As explicit examples, we have

$$\mu Y = X - \mu X(2X - 1) + \mu^2(4X + 1) - \mu^3 \quad \text{for} \quad n = 2,$$
\[ \mu Y = X^2 - 2\mu X^2(X - 1) + \mu^2(9X^2 + 4X + 1) - 2\mu^3(3X + 1) + \mu^4 \quad \text{for} \quad n = 3. \]

**Proof of 2.3.** From the proof of 2.1, it follows easily that we can define polynomials \( P_j(X) \) by the formula

\[ \mu Y = \sum_{i+j=n+1} (-\mu)^i P_j(X), \quad (7) \]

where \( 0 \leq j \leq 2n \) or equivalently \( n + 1 \geq i \geq 1 - n \), and where each \( P_j(X) \) has degree \( \leq j \). What is new in 2.3 is the statement that the \( P_j \) have integer coefficients, and that \( P_j = 0 \) for \( j > n + 1 \). To prove this, we will derive the same formula (7) in a different way. Again we use the normal form (1) with a fixed point of multiplier \( \lambda \neq 0 \) at \( z = 1 \), but now we normalize so that \( ad - bc = 1 \), and set \( u = a + b = c + d \). Then computation shows that \( \mu = \lambda/n = 1/u^2 \). Furthermore

\[ 1 = ad - bc = (u-b)(u-c) - bc = u^2 - (b+c)u, \]

or in other words

\[ b + c = u - 1/u. \]

Since \( bc = X \), it follows that \( b \) and \( c \) are the two roots of the equation

\[ b^2 - (u - 1/u)b + X = 0. \]

Thus

\[ 2b = u - 1/u \pm \sqrt{(u - 1/u)^2 - 4X}. \]

For \( |u| \) large, each of the two solutions \( b \) and \( c \) can be expressed as a Laurent series in \( u \) with coefficients depending on \( X \). One of these two solutions has the form

\[ b = \frac{X}{u} + \frac{X(1+X)}{u^3} + \frac{X(1+X)(1+2X)}{u^5} + \cdots, \]

tending to zero as \( u \to \infty \), where the successive coefficients are polynomials in \( X \) with integer coefficients which can be computed by a straightforward induction. The other solution is then given by \( c = u - 1/u - b = u - (1 + X)/u - \cdots \), and is asymptotic to \( u \). From these we can compute

\[ Y = (u-b)^{n+1}b^{n-1} + (u-c)^{n+1}c^{n-1} \]

as a Laurent series in \( u \). This series begins as

\[ Y = u^2X^{n-1} - X^{n-1}(2X + 1 - n) + (n^2X^{n-1} + \cdots + 1)/u^2 + O(1/u^4) \]

\[ = X^{n-1}/\mu - X^{n-1}(2X + 1 - n) + (n^2X^{n-1} + \cdots + 1)\mu + O(\mu^2), \]

or in other words as

\[ \mu Y = X^{n-1} - X^{n-1}(2X + 1 - n)\mu + (n^2X^{n-1} + \cdots + 1)\mu^2 + O(\mu^3) \]

as \( \mu \to 0 \). Thus there are no terms in \( \mu^i \) with \( i < 0 \). This proves that formula (7) reduces to the required form. \( \square \)

Here is some more precise information about the polynomials \( P_k(X) \). It will be convenient to introduce the abbreviation

\[ \beta(m, k) = \binom{m-k}{k} + \binom{m-k-1}{k-1}. \]
for the sum of two binomial coefficients.

**Lemma 2.4.** Each $P_k(X)$ with $0 \leq k \leq n$ is a polynomial of degree $k$, however $P_{n+1}(X)$ is a polynomial of degree $n-1$. We have

$$
P_0(X) = 1,
\quad P_1(X) = 2nX + (n-1),
\quad \ldots
$$

$$
P_{n-1}(X) = n^2X^{n-1} + \sum_{j=0}^{n-2} \binom{n+1}{j} X^j,
\quad P_n(X) = 2X^n + (1-n)X^{n-1},
\quad P_{n+1}(X) = X^{n-1}.
$$

The constant term $P_k(0)$ in these polynomials is equal to the binomial coefficient $\binom{n-1}{k}$, while the coefficient of the degree $k$ term is equal to the sum $\beta(2n, k)$.

**Proof Outline.** The explicit formulas for $P_k(X)$ with $k \geq n-1$ can be derived from the computation (8). For the remaining information, we again use the normal form (1) with $ad - bc = 1$ and with $u = a + b = c + d$. Let $s_k = b^k + c^k$, where $s_1 = b + c = u - 1/u$. Starting from the Newton formula

$$
s_{k+1} = (b+c)s_k - (bc)s_{k-1} = (u-u^{-1})s_k - Xs_{k-1},
$$

it follows inductively that we can express each $s_k$ as a polynomial function of $u - u^{-1}$ and $X$. The precise formula is

$$
s_k = \sum_{0 \leq j \leq k/2} \beta(k, j) (-X)^j (u-u^{-1})^{k-2j}.
$$

(Note that this computation is independent of the degree $n$.) Equivalently, recalling that $\mu = 1/u^2$, we can write

$$
\frac{s_k}{u^k} = \sum_{0 \leq j \leq k/2} \beta(k, j) (-\mu X)^j (1-\mu)^{k-2j},
$$

(9)

Now we can compute

$$
Y = a^{n+1}b^{n-1} + c^{n-1}d^{n+1}
\quad = (u-b)^{n+1}b^{n-1} + c^{n-1}(u-c)^{n+1}
\quad = u^{n+1}s_{n-1} - \left( \frac{n+1}{1} \right) u^n s_n + \left( \frac{n+1}{2} \right) u^{n-1} s_{n+1} - \cdots + \pm s_{2n},
$$

or equivalently

$$\mu^n Y = \frac{s_{n-1}}{u^{n-1}} - \left( \frac{n+1}{1} \right) \frac{s_n}{u^n} + \left( \frac{n+1}{2} \right) \frac{s_{n+1}}{u^{n+1}} - \cdots + \pm \frac{s_{2n}}{u^{2n}}.\quad (10)$$

Substituting (9) into (10), we obtain a fairly explicit formula for $\mu^n Y$. Further details will be left to the reader. □

As an application, we can give a more precise form of 2.2.

**Corollary 2.5.** Each $\text{Per}_1(\lambda) \subset \mathcal{M}$ with $\lambda \neq 0$ can be described a smooth
curve of the form
\[ Y = -2X^n + (n(\lambda + \lambda^{-1} + 1) - 1)X^{n-1} + \cdots + \lambda(n - \lambda)^{n-1}/n^n. \]

If \( \lambda \neq \lambda' \) with \( \lambda\lambda' \neq 0, 1 \), then it follows easily that the two curves \( \text{Per}_1(\lambda) \) and \( \text{Per}_1(\lambda') \) have exactly \( n-1 \) points of intersection, counted with multiplicity.

**Proof.** The first statement is proved by plugging the explicit values from 2.4 into the equation 2.3. It follows that each intersection \( \text{Per}_1(\lambda) \cap \text{Per}_1(\lambda') \) with \( \lambda \neq \lambda' \) is described by a polynomial equation of the form
\[ n\left(\lambda + \frac{1}{\lambda} - \lambda' + \frac{1}{\lambda'}\right)X^{n-1} + (\text{lower terms}) = 0. \]

In the generic case where \( \lambda\lambda' \neq 0, 1 \), this equation has degree \( n-1 \), and the assertion follows. \( \square \)

(On the other hand, if \( \lambda\lambda' = 1 \) then the leading coefficient of this polynomial equation is zero. In this case, we must count one or more “intersections at infinity”, in order to get the right number. (See §6.) A more significant exception occurs when \( \lambda' = 0 \). In fact, to make the count come out right, we should identify \( \text{Per}_1(0) \) with the curve \( X^{n-1} = 0 \), or in other words with the locus \( L_0 \) counted \( n-1 \) times. (Compare §8.) In fact, as \( \lambda' \to 0 \) with \( Y \) bounded, the locus \( \text{Per}_1(\lambda') \) degenerates towards an \( (n-1)\)-sheeted covering of the locus \( X = 0 \) towards the curve \( X^{n-1} = 0 \) of multiplicity \( n-1 \).

**Definition.** Every rational map \( f \) of degree \( n \) has \( n+1 \) fixed points counted with multiplicity. Let \( \lambda_1, \ldots, \lambda_{n+1} \) be the multipliers at these fixed points, and let
\[ \sigma_k = \sum_{1 \leq i_1 < \cdots < i_k \leq n+1} \lambda_{i_1} \cdots \lambda_{i_k} \]
be the \( k \)-th elementary symmetric function of these multipliers. It is convenient to set \( \sigma_0 = 1 \). Note that the quotient \( \sigma_k/n^k \) can be described as the \( k \)-th elementary symmetric function of the quotients \( \mu_i = \lambda_i/n \).

**Theorem 2.6.** These elementary symmetric functions can be computed by the formula
\[ \sigma_k/n^k = P_k(X) \quad \text{for} \quad 0 \leq k \leq n+1, \ n \neq 0, \quad \text{but} \]
\[ \sigma_n/n^n = P_n(X) + Y. \]  

**Proof.** Each of the \( n+1 \) multipliers \( \lambda = \lambda_k \) trivially satisfies the polynomial equation
\[ \lambda^{n+1} - \sigma_1\lambda^n + \sigma_2\lambda^{n-1} - \cdots - \sigma_n = \prod_{k=1}^{n+1} (\lambda - \lambda_k) = 0. \]

Hence the quotient \( \mu = \lambda/n \) satisfies
\[ \mu^{n+1} - \sigma_1\mu^n + \sigma_2\mu^{n-1}/n - \cdots - \sigma_{n+1}/n^{n+1} = 0. \]

On the other hand, from 2.3 we see that
\[ \mu^{n+1} - P_1(X)\mu^n + P_2(X)\mu^{n-1} - \cdots = (P_n(X) + Y)\mu \pm P_{n+1}(X) = 0. \]

The difference of these two polynomial equations is a polynomial of degree \( n \) in \( \mu \) which vanishes at all \( n+1 \) of the \( \mu_i \). If the \( \mu_i \) are pairwise distinct (or in other words if the
multipliers $\lambda_i = n\mu_i$ are pairwise distinct), then it follows immediately that corresponding coefficients are equal, which proves the identities (11). These identities follow in the general case by continuity or by analytic continuation, since for generic $(f) \in \mathcal{M}$ the $n+1$ multipliers are indeed distinct. To prove this, we need only construct a single example where the multipliers are distinct. For example if $f(z) = z^n + b$ then the multipliers are distinct provided that we exclude $n$ very special values of the parameter $b$. First we must guarantee that $(f) \notin \text{Per}_1(1)$, in order to be sure that the $n+1$ fixed points are distinct. But if $(f) \in \text{Per}_1(1)$, then the fixed point equation $b = z - z^n$ together with the multiplier equation $n z^{n-1} = 1$ imply that the invariant $Y = b^{n-1}$ is equal to $(n-1)^{n-1}/n^n$. Finally, we must choose $b \neq 0$ to guarantee that two distinct fixed points, say $z \neq \omega z$, cannot have the same multiplier $\lambda = nz^{-1} = n(\omega z)^{-1}$. But this would imply that $\omega^{n-1} = 1$, and the fixed point equation $z - z^n = b$ would then yield $(\omega z) - (\omega z)^n = \omega b \neq b$, provided that $b \neq 0$. Also, no finite fixed point has multiplier zero provided that $b \neq 0$. Thus generically the multipliers are distinct, which completes the proof. □

Remark 2.7. As an immediate corollary of 2.4 and 2.6: We could equally well use the two invariants $\sigma_1$ and $\sigma_n$ as coordinates for the moduli space $\mathcal{M} \cong \mathbb{C}^2$, in place of the invariants $X$ and $Y$ of §1. (In practice, in §6, it will be convenient to use $X$ and $\sigma_n$ as coordinates.)

Remark 2.8. It seems surprising that every one of the elementary symmetric functions $\sigma_k$ with $k \neq n$ can be expressed as a function of $X$ alone. Only $\sigma_n$ depends also on the coordinate $Y$. As an example to illustrate this statement, consider the family of unicritical polynomials

$$f(z) = z^n + b,$$

with invariants $X = 0$ and $Y = b^{n-1}$. For the special case $b = 0$, there are two fixed points of multiplier zero and $n-1$ fixed points of multiplier $n$, hence

$$\sigma_k/n^k = \binom{n-1}{k},$$

for every $k$. It follows from 2.6 that this same formula holds for any value of the parameter $b$, provided that $k \neq n$. On the other hand for $k = n$, since this binomial coefficient is zero, it follows that

$$\sigma_n/n^n = Y = b^{n-1}.$$

For example in the quadratic case $f(z) = z^2 + b$, it follows that the multipliers at the finite fixed points satisfy $\lambda_1 + \lambda_2 = 2$ and $\lambda_1\lambda_2 = 4b$.

Remark 2.9. The holomorphic fixed point formula asserts that

$$\sum_{1}^{n+1} \frac{1}{1-\lambda_j} = 1$$

provided that $\lambda_j \neq 1$ for all $j$. (See for example [M1].) This gives rise to a linear relation between the $\sigma_k$, or equivalently between the $P_k$, which takes the form

$$\sum_{0}^{n+1} (-1)^k (n-k) \sigma_k = \sum_{0}^{n+1} (-n)^k (n-k) P_k(X) = 0 .$$

It follows by continuity that this relation still holds also when some of the $\lambda_j$ equal 1. Note that the invariant $Y$ is not involved, since the coefficient of $\sigma_n$ in this formula is zero.
Remark 2.10. It is sometimes convenient to consider the moduli space for bicritical maps with one marked fixed point. In this case, a complete set of invariants is provided by $X$ and $Y$ together with the multiplier $\lambda = n \mu$ at this marked point. These are subject only to the relation $\mu Y = X^{n-1} - \mu P_n(X) + \mu^2 P_{n-1}(X) + \cdots + (-\mu)^n$. We can understand the topology of the resulting variety better by introducing a new coordinate $Y_\mu = Y + P^2_n(X) - \mu P^2_{n-1}(X) + \cdots + (-\mu)^n$ in place of $Y$. Then $X, Y_\mu$ and $\mu$ are subject only to the relation $\mu Y_\mu = X^{n-1}$. For $n \geq 3$ this variety has a singular point at $X = Y = Y_\mu = \mu = 0$.

§3. Shift Locus or Connectedness Locus

By definition, a conjugacy class $(f)$ of degree $n$ rational maps belongs to the connectedness locus $C$ if the Julia set $J_f$ is connected; and belongs to the shift locus $S$ if $J_f$ is totally disconnected with $f|_{J_f}$ topologically conjugate to the one sided shift on $n$ symbols. This section will prove that every conjugacy class of maps with only two critical points must belong to one or the other:

**Theorem 3.1.** Every $(f) \in M$ belongs either to the connectedness locus or to the shift locus.

**Note:** If $(f)$ belongs to the shift locus, then evidently both critical points belong to the Fatou set $\hat{C} \setminus J_f$, which is connected but far from simply connected. There are two possibilities. If $f$ has an attracting fixed point, and hence is hyperbolic on its Julia set, then we will say that $(f)$ belongs to the hyperbolic shift locus $S_{hyp}$. Otherwise, $f$ must have a parabolic fixed point, and we will say that $(f)$ belongs to the parabolic shift locus $S_{par}$. Thus the moduli space partitions as a disjoint union

$$M = C \cup S_{hyp} \cup S_{par}.$$  

We will explore this partition of $M$ further in Sections 4 and 7.

**Remark 3.2.** In contrast with the polynomial case, we will see that the connectedness locus is neither closed nor bounded in $M$ (although it has compact closure in the extended moduli space $\hat{M}$). In analogy with the polynomial case, one might be tempted to conjecture that the interior of the connectedness locus consists only of hyperbolic maps. In fact this conjecture is true if we restrict attention to the open subset consisting of $(f)$ with at least one attracting fixed point. (Compare 0.1.) However, the connectedness locus also contains an “essentially non-polynomial-like” region $C_{NP}$ consisting of maps for which all $n+1$ fixed points are strictly repelling. This region is certainly contained in the interior of the connectedness locus, and yet contains many non-hyperbolic maps. (Compare [R1].) Here is one example. If

$$f(z) = \kappa + (1 - \kappa)/z^n \quad \text{with} \quad \kappa^n = 1, \quad \kappa \neq 1,$$

then the critical points are 0 and $\infty$ with $0 \mapsto \infty \mapsto \kappa \mapsto 1$, so that both critical orbits eventually land at the repelling fixed point 1. It follows that the Julia set is the entire Riemann sphere, and that all periodic orbits are strictly repelling. (This map lies in the locus $X = -1$, where one critical point maps directly to the other. Compare [BB].) It is conjectured that the region $C_{NP}$ is a topological 4-cell. When $n = 2$, this can be proved as follows. Let $I_j = 1/(1 - \lambda_j)$ be the holomorphic fixed point index at the $j$-th fixed point.
Then this region in moduli space can be identified with the star shaped region consisting of unordered triples of complex numbers \( I_j \) with \( 0 < \text{Re}(I_j) < 1/2 \) and \( I_1 + I_2 + I_3 = +1 \). On the other hand, for \( n > 2 \), I don’t know even whether \( \mathcal{C}_{\text{NP}} \) is simply connected. Evidently an understanding of the topology and dynamics associated with this region \( \mathcal{C}_{\text{NP}} \) would be fundamental in reaching an understanding of bicritical maps.

The first ingredient in the proof of 3.1 is the following result which is due to Shishikura.

**Theorem A.1.** A rational map with two critical points cannot have any Herman rings.

In fact a proof of this statement can be extracted from his paper [Sh] although it is not explicitly stated there. See Appendix A for a proof without using quasiconformal surgery.

The second key ingredient is the following special case of a theorem of Przytycki and Makienko.

**Theorem B.5.** If a map \( f \) with two critical points has the property that both critical values lie in a common Fatou component, then \((f) \) belongs to the shift locus.

In fact, more generally, it is shown in [Pr] and in [Ma] that any rational map with all critical values in a single Fatou component, when restricted to its Julia set, is isomorphic to the one sided shift. However, since their argument is rather complicated, and since we need only the bicritical case, a proof of B.5 is included in Appendix B.

**Remark 3.3.** Here is an alternative statement: Suppose that both critical orbits are eventually absorbed by an invariant Fatou component, \( \Omega = f(\Omega) \). Then \((f) \) belongs to the shift locus. In fact such a Fatou component must contain at least one of the two critical points, and hence must be fully invariant, \( \Omega = f^{-1}(\Omega) \). Hence it contains both critical values, and 3.1 applies. (By way of contrast, a map with three critical points may well have connected Julia set, even though all critical orbits are eventually absorbed by an invariant Fatou component. For example the map \( f(z) = 2 + 2z^3/(27(2 - z)) \) has critical points \( 0, 3, \infty \) with orbit \( 3 \mapsto 0 \mapsto 2 \mapsto \infty \) ending on a superattractive fixed point. The immediate basin of infinity contains no other critical point, since no critical orbit converges non-trivially to infinity, hence this basin is simply connected. It follows, as in the proof of 3.1, that every Fatou component is simply connected.)

The proof of 3.1 will also make use of the following elementary observation.

**Lemma 3.4.** Let \( P \subset \hat{\mathbb{C}} \) be a region bounded by a simple closed curve which passes through neither critical value. Then the pre-image of \( P \) under \( f \) can be described as follows.

**Case 0.** If \( P \) contains no critical value, then \( f^{-1}(P) \) consists of \( n \) disjoint simply-connected regions bounded by \( n \) disjoint simple closed curves.

**Case 1.** If \( P \) contains just one critical value, then \( f^{-1}(P) \) is a single simply connected region bounded by a simple closed curve, and maps onto \( P \) by a ramified \( n \)-fold covering.

**Case 2.** If \( P \) contains both critical values, then \( f^{-1}(P) \) is a multiply connected region with \( n \) boundary curves, and maps onto \( P \) by a ramified \( n \)-fold covering.
4. PARABOLIC SHIFT LOCUS

The proof is straightforward. (Note that Cases 0 and 2 correspond to the “inside” and “outside” of the same simple closed curve. In the case of just one critical point in \( P \), the set \( f^{-1}(P) \) must be connected since \( f \) is locally \( n \)-to-one near a critical point, and the branched covering \( f^{-1}(P) \to P \) is unique up to isomorphism, since the fundamental group of \( P \setminus \) (critical value) is free cyclic, so that there is only one \( n \)-fold covering of this set up to isomorphism.) □

Proof of 3.1. Suppose that \((f)\) is not in the shift locus, and hence that no Fatou component contains more than one critical value. If \( L \) is a loop in an arbitrary Fatou component, then using Sullivan’s Non-Wandering Theorem we see that some forward image \( f^{\circ k}(L) \) lies in a simply connected region \( U \) which is either:

1. a linearizing neighborhood of some geometrically attracting periodic point,
2. a Böttcher neighborhood of some superattracting periodic point,
3. an attracting petal for a parabolic point, or
4. a Siegel disk.

Here we are using the fact that there are no Herman rings (Theorem A.1). Using 3.4, it follows by induction on \( k \) that each component of \( f^{-k}(U) \) is simply connected. This proves that every Fatou component is simply connected, and hence that the Julia set is connected. □

§4. The Parabolic Shift Locus \( S_{\text{par}} \cong \mathbb{C} \setminus \bar{D} \)

Recall from §3 that the moduli space \( \mathcal{M} \) splits as a disjoint union

\[ \mathcal{M} = \mathcal{C} \cup S_{\text{hyp}} \cup S_{\text{par}} . \]

Evidently \( S_{\text{hyp}} \) is an open subset of moduli space, disjoint from the curve \( \text{Per}_1(1) \cong \mathbb{C} \), while \( S_{\text{par}} \) is a relatively open subset of this curve \( \text{Per}_1(1) \).

We will first prove the following.

Lemma 4.1. The parabolic shift locus is contained in the common topological boundary \( \partial S_{\text{hyp}} = \partial \mathcal{C} \). Hence the closure \( \overline{\mathcal{C}} \subset \mathcal{M} \) is equal to \( \mathcal{C} \cup \text{Per}_1(1) \), with complement \( S_{\text{hyp}} \).

Proof. For every \((f)\) in the parabolic shift locus, we must show that \( f \) can be approximated arbitrarily closely by a map with connected Julia set, and also by a hyperbolic map with totally disconnected Julia set. Let \( \{f_t\} \) be a holomorphic one-parameter family of maps with \( f_0 = f \). We will assume that each \( f_t \) has two critical points, and that this family is not contained in \( \text{Per}_1(1) \). Then for \( |t| \) small but non-zero, the parabolic fixed point for \( f_0 \) splits into two nearby fixed points, with multipliers say \( \lambda_1 \) and \( \lambda_2 \). As \( t \) traverses a loop around \( t = 0 \), these two fixed points may be interchanged. However, if we set \( t = u^2 \), then both \( \lambda_1 \) and \( \lambda_2 \) can certainly be expressed as single valued holomorphic functions of \( u \), with \( \lambda_1(0) = \lambda_2(0) = 1 \). Since these functions are non-constant, we can choose \( u \) close to zero so that \( \lambda_1(u) \) takes any required value close to \( 1 \).

First let us choose \( u \) so that \( \lambda_1(u) = e^{2\pi i/q} \), with \( q > 1 \). Then the corresponding fixed point is parabolic, with at least two attracting petals. Hence the associated Fatou set is not connected, and \((f_u^2)\) must belong to the connectedness locus \( \mathcal{C} \).

Now let us choose \( u \) so that \( \lambda_1(u) \) is real, with \( \lambda_1 < 1 \), so that the corresponding fixed point is strictly attracting. For \( u \) sufficiently close to zero, we will show that \((f_u^2)\) belongs
to the hyperbolic shift locus. Choose a simple arc $A$ joining the two critical points with the Fatou set for $f_0$. Then for large $k$ the image $f_0^{0k}(A)$ lies close to the parabolic point, and within a sector of small angular size about the attracting direction for this parabolic point. An easy perturbation argument then shows that the same description holds for $f_{u^2}$, provided that $\lambda_1(u) < 1$ with $u$ close to zero. (See for example [M3, §4].) Thus both critical values lie in a common Fatou component, and it follows that $(f_{u^2}) \in S_{\text{hyp}}$. □

**Figure 1.** Pictures of $\mathcal{C} \cap \text{Per}_1(\lambda)$ for $\lambda = 0, .01, 0.5, \text{ and } \lambda = 1$ respectively, for the degree $n = 4$. The configuration deforms continuously for $0 < \lambda < 1$, and conjecturally as $\lambda \to 1$ also. However, there is a qualitative difference between the first and second pictures due to the fact that as $\lambda \to 0$ the curve $\text{Per}_1(\lambda)$ converges not towards $\text{Per}_1(0)$ but rather towards an $(n-1)$-fold branched covering of $\text{Per}_1(0)$ as shown in Figure 2. Thus Figure 1b is a somewhat squashed version of Figure 2. The surrounding curves in the 5a, 5b, 5c represent equal rates of convergence towards the attracting fixed point for the more slowly converging critical point. (For the corresponding curves in Figure 1d, see 4.3 below.)

**Theorem 4.2.** The intersection $\mathcal{C} \cap \text{Per}_1(1)$ is a compact, connected full subset of the curve $\text{Per}_1(1) \cong \mathbb{C}$. Equivalently, the parabolic shift locus $S_{\text{par}} = \text{Per}_1(1) \smallsetminus (\mathcal{C} \cap \text{Per}_1(1))$ is always non-vacuous, conformally isomorphic to a punctured disk.

(Compare Figure 1d, as well as [M2, Figure 4].)

I will outline two proofs of 4.2, one suggested by conversations with Schleicher, and one suggested by Shishikura. The first begins as follows.

**Proof of compactness.** It will be convenient to use the normal form (1), choosing the matrix of coefficients to have the form

$$
\begin{bmatrix}
 a & b \\
 c & d
\end{bmatrix} = \begin{bmatrix}
 n + 1 + \alpha & n - 1 - \alpha \\
 n - 1 + \alpha & n + 1 - \alpha
\end{bmatrix},
$$

(12)

where $\alpha \in \mathbb{C}$ is a parameter. Then it is easy to check that the associated rational function $f$ satisfies $f(1) = f'(1) = 1$, and that the invariant $X = X(f)$ of §1 is given by $X = ((n - 1)^2 - \alpha^2)/4n$, so that $|X| \to \infty$ as $|\alpha| \to \infty$.

**Remark.** The special case $\alpha = 0$ corresponds to the unique conjugacy class $(f)$ such that $f$ has a fixed point of multiplier $+1$ with two attracting petals. Using this normal form (12), the corresponding Julia set is the unit circle.
Figure 2. The "Multibrot set" for degree $n = 4$, that is the connectedness locus in the $b$-parameter plane for the family of unicritical polynomial maps $z \mapsto z^4 + b$. (See for example [LS2].) Note the $(n-1)$-fold rotational symmetry. The corresponding figure in the $b^3$-plane is shown in Figure 1a.

Assuming that $\alpha \neq 0$, let us set

$$z = 1 + \frac{2}{\alpha w}, \quad w = \frac{2}{\alpha(z-1)}.$$ 

Then a straightforward computation shows that the map $z \mapsto f(z)$ corresponds to

$$w \mapsto F(w) = \frac{2}{\alpha f(1 + 2/\alpha w)} - \alpha = w + O\left(\frac{1}{\alpha w}\right), \quad (13)$$

where the error estimate holds uniformly provided that both $|\alpha|$ and $|\alpha w|$ are sufficiently large. In particular, it follows that the region $\{z : \text{Re}(w) > 1/2\}$ maps holomorphically into itself, and hence is contained in the Fatou set of $f$, provided that $|\alpha|$ is sufficiently large. On the other hand, it is not hard to check that

$$f(0) = \frac{b}{d} = 1 + \frac{2}{\alpha w_1}, \quad f(\infty) = \frac{a}{c} = 1 + \frac{2}{\alpha w_2}$$

where

$$w_1 = 1 - \frac{n+1}{\alpha} \quad \text{and} \quad w_2 = 1 + \frac{n-1}{\alpha}. \quad (14)$$

Thus, for $|\alpha|$ sufficiently large, both critical values belong to the half-plane $\text{Re}(w) > 1/2$, and hence belong to the same Fatou component, so that $(f)$ belongs to the parabolic shift locus. Therefore the closed set $\mathcal{C} \cap \text{Per}_1(1)$ is bounded and hence compact, as asserted.

**Remark 4.3.** We can construct a holomorphic function $\Phi : S_{\text{par}} \to \mathbb{C}$ as follows. For any $(f) \in S_{\text{par}}$, let $P \subset \hat{\mathbb{C}} \setminus J_f$ be an attracting petal for the parabolic fixed point, and let $\phi$ be a Fatou coordinate, mapping $P$ biholomorphically into $\mathbb{C}$, and satisfying

$$\phi(f(z)) = \phi(z) + 1.$$ 

Then $\phi$ extends canonically to a holomorphic map which carries the entire parabolic basin onto $\mathbb{C}$, satisfying this same functional equation. In particular, if $c_1$ and $c_2$ are the critical points, then the difference $\phi(c_1) - \phi(c_2)$ is a well defined complex number, independent of the choice of petal and Fatou coordinate. In order to make this construction independent of
the numbering of the critical points, we set
\[ \Phi(f) = (\phi(c_1) - \phi(c_2))^2. \]
then it is not difficult to check that
\[ \Phi : S_{\text{par}} \to \mathbb{C} \]
is well defined and holomorphic. (Compare the construction of Fatou coordinates as given in [Ste].) The curves \(|\Phi| = \text{constant}\) are shown in Figure 1d, and in a much larger region of \(\text{Per}_1(1)\) in Figure 3. The asymptotic formula
\[
\Phi(f) \simeq \left(\frac{2n}{\alpha}\right)^2 \simeq -\frac{n}{X(f)},
\]
as \(|X(f)| \to \infty\) can be verified as follows. The inequality
\[
\frac{dF(w)}{dw} = 1 + O\left(\frac{1}{\alpha w^2}\right)
\]
follows from (13) together with the Schwarz Lemma. Hence
\[
\frac{F(w_2) - F(w_1)}{w_2 - w_1} = 1 + O\left(\frac{1}{\alpha w^2}\right)
\]
provided that \(w_2/w_1\) is reasonably close to 1. Setting
\[
\phi(c_2) - \phi(c_1) = \lim (F^{\circ m}(w_2) - F^{\circ m}(w_1))
\]
as in [Ste], it follows that
\[
\phi(c_2) - \phi(c_1) = (w_2 - w_1)(1 + O(1/\alpha)).
\]
But \(w_2 - w_1 = 2n/\alpha\) by (14); and (15) follows.

\[\text{Figure 3. Another picture of } \mathcal{C} \cap \text{Per}_1(1) \text{ in the degree 4 case, showing a much larger region in order to illustrate behavior near infinity.}\]

The proof of 4.2 continues as follows. In order to show that \(\mathcal{C} \cap \text{Per}_1(1)\) is connected, we study the limit, in the Hausdorff topology, of the intersection \(\mathcal{C} \cap \text{Per}_1(\lambda)\) as \(\lambda\) tends to 1 through real values \(\lambda < 1\). First note that
\[
\limsup_{\lambda \nearrow 1} \mathcal{C} \cap \text{Per}_1(\lambda) \subset \mathcal{C} \cap \text{Per}_1(1).
\]
(16)
Suppose that \((f)\) can be approximated arbitrarily closely by elements of \(\mathcal{C} \cap \text{Per}_1(\lambda)\) with \(\lambda \nearrow 1\). If \((f)\) did not belong to \(\mathcal{C} \cap \text{Per}_1(1)\), then it would have to belong to the parabolic shift locus. From the proof of 4.1, it would follow that any approximating map in \(\text{Per}_1(\lambda)\) with \(\lambda < 1\) must belong to the hyperbolic shift locus, contradicting our assumption.

On the other hand, we will show that
\[
\liminf_{\lambda \nearrow 1} \partial(\mathcal{C} \cap \text{Per}_1(\lambda)) \supset \partial(\mathcal{C} \cap \text{Per}_1(1)).
\] (17)

We again use the normal form (12) with marked critical points \(0\) and \(\infty\), and with parabolic fixed point \(z = 1\), writing \(f = f_\alpha\), where \(\alpha\) is the parameter. Consider a boundary point \(f_{\alpha_0}\) of \(\mathcal{C} \cap \text{Per}_1(1)\). We will show that \(f_{\alpha_0}\) can be approximated arbitrarily closely by maps \(f_\alpha\) such that one critical orbit of \(f_\alpha\) lands on a repelling periodic orbit. To fix our ideas, suppose that the critical point \(\infty\) lies in the parabolic basin for \(f_{\alpha_0}\), and consider the sequence of maps \(\alpha \mapsto f_\alpha \circ k_{\alpha}(0)\) for \(k = 1, 2, 3, \ldots\), where \(\alpha\) ranges over some neighborhood of \(\alpha_0\).

**Case 1.** Suppose that the \(f_\alpha \circ k_{\alpha}(0)\) do not form a normal family throughout any neighborhood of \(\alpha_0\). Choose a repelling periodic orbit for \(f_{\alpha_0}\) with period \(\geq 3\). This orbit varies holomorphically with the parameter \(\alpha\), throughout some neighborhood of \(\alpha_0\). By non-normality, we can choose \(\alpha\) arbitrarily close to \(\alpha_0\) so that the orbit of \(0\) under \(f_\alpha\) eventually lands on this periodic orbit. Now perturbing slightly, we can preserve this critical orbit relation but replace the multiplier at the fixed point \(z = 1\) by some number \(\lambda < 1\). The resulting map must belong to \(\mathcal{C} \cap \text{Per}_1(\lambda)\), as required.

**Case 2.** Now suppose that the \(f_\alpha \circ k_{\alpha}(0)\) do form a normal family throughout some neighborhood of \(\alpha_0\). The hypothesis that every neighborhood of \(f_{\alpha_0}\) intersects the parabolic shift locus then guarantees that this family of maps must converge uniformly near \(\alpha_0\) to the constant map \(\alpha \mapsto 1\) as \(k \to \infty\). In particular, \(f_{\alpha_0} \circ k_{\alpha}(0)\) must converge to \(1\). If \(0\) lies in the same parabolic basin as \(\infty\), then it follows that \(f_{\alpha_0}\) lies in the shift locus, contradicting our hypothesis. The only other possibilities are that either:

(a) \(\alpha_0 = 0\), so that \(f_{\alpha_0}\) has two distinct parabolic basins and \(z = 1\) is a fixed point of higher multiplicity, or

(b) some forward image \(f_{\alpha_0} \circ k_{\alpha}(0)\) is precisely equal to the parabolic fixed point \(z = 1\).

In case (a), under a slight perturbation within \(\text{Per}_1(1)\) this fixed point splits into one fixed point of multiplier +1. together with a second fixed point which can have any multiplier close to +1. In particular, if we perturb so that this second fixed point is attracting, then we must be within the connectedness locus. Therefore \(f_{\alpha_0}\) is not an isolated point of \(\mathcal{C} \cap \text{Per}_1(1)\). Hence it is not an isolated boundary point, and, after a slight perturbation, we can obtain a contradiction by the argument above.

In case (b), there is only one parabolic basin. Suppose that \(f_{\alpha_0}\) were an isolated point of \(\mathcal{C} \cap \text{Per}_1(1)\). Let \(\alpha\) range over a small circle centered at \(\alpha_0\), and assume that the corresponding maps \(f_\alpha\) all belong to the (parabolic) shift locus. Then the corresponding images \(f_{\alpha_0} \circ k_{\alpha}(0)\) must loop around the parabolic fixed point \(z = 1\) one or more times, without ever hitting the Julia set \(J(f_\alpha)\). By Mañé-Sad-Sullivan or Lyubich, this Julia set must vary continuously as we go around around the loop. Choose a repelling periodic point of period \(\geq 2\) which is close enough to \(z = 1\) so that it remains inside this loop in the \(z\)-plane, for
all parameter values in the circle. A priori, we might worry that this periodic point comes back to a different periodic point as we go around the circle. However this cannot happen since we can deform the circle in $\text{Per}_1(1)$ into a circle in $\text{Per}_1(1 - \epsilon)$ which deforming the Julia set homeomorphically. The corresponding disk in $\text{Per}_1(1 - \epsilon)$ bounds a disk in the hyperbolic shift locus, so the monodromy must be trivial. Now shrink the parameter loop down to the point $z = 1$. A winding number argument shows that at some point during this shrinking, the image $f_{\alpha}^k(0)$ must exactly hit the corresponding repelling point, and hence belong to the Julia set. This contradicts the hypothesis that $f_{\alpha_0}$ was isolated in $\mathcal{C} \cap \text{Per}_1(1)$. But if this point is not isolated, then we see as above that it is indeed possible to approximate $f_{\alpha_0}$ by a map with 0 eventually mapping to a repelling periodic point.

Now as we vary $\lambda = 1$ to a value slightly less than 1, the point in moduli space satisfying this critical orbit relation, say $f^{\epsilon k}(0) = f^{\epsilon l}(0)$ deforms continuously, and necessarily belongs to the connectedness locus. This proves (17).

**Remark.** In fact it is conjectured that $\mathcal{C} \cap \text{Per}_1(1)$ is equal to the Hausdorff limit of $\mathcal{C} \cap \text{Per}_1(\lambda)$ as $\lambda \searrow 1$. However, our arguments will leave open the possibility of a “parabolic que"r component” in $\mathcal{C} \cap \text{Per}_1(1)$, whose points can be approximated arbitrarily close by points in the hyperbolic shift locus.

**Proof that $\mathcal{C} \cap \text{Per}_1(1)$ is connected.** For $|\lambda| < 1$, it is known that $\mathcal{C} \cap \text{Per}_1(\lambda)$ is compact, connected and full, with connected boundary. (Compare [GK], [M2].) If $\mathcal{C}\cap\text{Per}_1(1)$ were not connected, then we could choose boundary points in two different components. By (17), these could be approximated by points in the boundary of say $\mathcal{C} \cap \text{Per}_1(1 - \epsilon)$. Since this is true for arbitrarily small $\epsilon$, it would follow from (16) that these points must actually belong to the same component. Thus $\mathcal{C} \cap \text{Per}_1(1)$ is connected.

In order to prove that $\mathcal{C} \cap \text{Per}_1(1)$ is full, or equivalently that the parabolic shift locus is connected, we will need a sharper form of the construction used to prove B.5.

**Lemma 4.4.** If $(f) \in \mathcal{S}_{\text{par}}$ has no critical orbit relation, then there exists an attracting petal for $f$ which contains both critical values.

Here by an attracting petal we mean a simply-connected open set $P$ which eventually captures all orbits in the parabolic basin, and such that $f$ maps the closure $\overline{P}$ homeomorphically, with $f(\overline{P}) \subset P \cup \{\hat{z}\}$ where $\hat{z}$ is the parabolic fixed point. By a critical orbit relation, we mean some relation of the form $f^{\epsilon k}(c_1) = f^{\epsilon l}(c_2)$.

Let us start with some petal $P_0$ , with smooth boundary containing no points of the critical orbits. We may assume that $P_0$ contains no critical value. Inductively construct $P_0 \subset P_1 \subset P_2 \subset \ldots$ where $P_{k+1}$ is the connected component of $f^{-1}(P_k)$ which contains $P_k$. Define the two integers $0 \leq k_1 \leq k_2$ , by setting $k_j$ equal to the smallest integer such that $P_{k_j}$ contains $j$ distinct critical values. Then $P_{k_1}$ is itself a petal, but $P_{k_1+1}$ is not, since it contains a critical point (using 3.4). The proof of 4.4 will be by induction on the difference $k_2 - k_1$. To start the induction, if $k_1 = k_2$ , then $P_{k_1}$ is the required petal, and we are done.

Suppose then that $k_1 < k_2$ . Let $v_1$ be the critical value which is contained in $P_{k_1}$ . By 3.4 we know that $P_{k_1+1}$ is a simply connected open set which contains the corresponding critical point $c_1$ and is a branched $n$-fold covering of $P_{k_1}$ . Let $x = f^{\epsilon(k_2-k_1)}(c_2)$ be the unique point in $P_{k_1+1} \setminus P_{k_1}$ which belongs to the second critical orbit. Choose some path $\gamma$ within $\overline{P}_{k_1} \setminus P_{k_1-1}$ which joins the critical value $v_1$ to the boundary of $P_{k_1}$ , and
which avoids the point \( f(x) = f^{\circ(k_2-k_1)}(v_2) \). Then the preimage of \( \gamma \) under \( f \) is a union \( \gamma_1 \cup \cdots \gamma_n \) of \( n \) paths, each joining the critical point \( c_1 \) to the boundary of \( P_{k_1+1} \). These \( n \) paths cut the open set \( P_{k_1+1} \) into \( n \) regions, each of which maps diffeomorphically onto \( P_{k_1} \setminus \gamma \). Exactly one of these \( n \) regions contains the point \( x \), and exactly one of these \( n \) regions contains \( P_{k_1} \).

**Assertion:** It is possible to choose the path \( \gamma \) so that \( x \) and \( P_{k_1} \) belong to the same connected component of \( P_{k_1+1} \setminus (\gamma_1 \cup \cdots \gamma_n) \).

As an example, in Figure 4 this requirement fails as the figure is drawn. However, if we modify the path \( \gamma \) in a neighborhood of \( v_1 \) so as to loop any number of times around an arc joining \( v_1 \) to \( f(x) \) before terminating on \( \partial P_{k_1} \). By choosing the number of loops appropriately, we can easily guarantee that \( x \) lies in the required component of \( P_{k_1+1} \setminus (\gamma_1 \cup \cdots \gamma_n) \). Details will be left to the reader.

The proof of 4.4 now proceeds as follows. Construct a new attracting petal \( P_0' \) which contains no critical value by removing a thin neighborhood of \( \gamma \) from \( P_{k_1} \). Then the preferred component \( P_1' \) of \( f^{-1}(P_0') \) will consist of the component of

\[
P_{k_1+1} \setminus (\text{neighborhood of } (\gamma_1 \cup \cdots \gamma_n))
\]

which contains \( P_{k_1} \). By the construction, both \( v_1 \) and \( x = f^{\circ(k_2-k_1)}(c_2) \) belong to this set \( P_1' \). Therefore, the new difference \( k_2' - k_1' \) will be equal to \( k_2 - k_1 - 1 \). The conclusion of 4.4 now follows by induction. □

**Proof of 4.2 (conclusion).** We must show that the parabolic shift locus is connected. The proof will make use of a standard quasiconformal surgery argument, as suggested to me by D. Schleicher. After a small perturbation of \( f \), we may assume that there are no critical
orbit relations. Choose a petal $P$ as in 4.4, and choose an embedded disk $\Delta \subset P \setminus \overline{f(P)}$ which contains both critical values in its interior. Now choose a diffeomorphism from $\Delta$ to itself which is the identity near the boundary and which moves the critical value $v_2$ arbitrarily close to $v_1$. Pulling the standard conformal structure back under this diffeomorphism, we obtain a new conformal structure on $P \setminus \overline{f(P)}$. Now push this new structure forward under the various iterates of $f$, and also pull it backwards under the various iterates of $f^{-1}$. Since the Shishikura Condition is satisfied: *every orbit intersects $\Delta$ at most once*, it follows that we obtain a well defined measurable conformal structure, invariant under $f$. By the measurable Riemann Mapping Theorem, there is a quasiconformal mapping $\Phi$ which conjugates this new structure to the standard conformal structure. Now $g = \Phi \circ f \circ \Phi^{-1}$ is a new rational map, topologically conjugate to $f$. By the construction, the two critical values of $g$ are close together in an embedded disk $\Phi(\Delta)$ which contains no critical point. By 1.8, it follows that the invariant $|A(g)|$ is arbitrarily close to infinity. Thus $g$ belongs to the unbounded component of the parabolic shift locus. Since $f$ and $g$ clearly belong to the same connected component of $S_{\text{par}}$, this shows that $S_{\text{par}}$ is connected. □

![Figure 5](image.png)

**Figure 5.** The regions $P_0 \subset P_1 \subset \cdots$ for the quadratic case $n = 2$. (Note: In the region outside of $P_4$, all of the iterated preimages of $\partial P_0$ have been drawn in, so that this figure looks more complicated near the basin boundary.)

**Alternative Proof of 4.2.** I am grateful to Shishikura for suggesting a quite different argument, based on an explicit model for the parabolic shift locus which can be outlined as
follows. Start with the map
\[ f(z) = z^n + b \quad \text{with} \quad b = (n - 1)/n^{n/(n-1)}, \]
which has a parabolic fixed point at \( z = (1/n)^{1/(n-1)} \). The corresponding parabolic basin \( \mathcal{B} \) is connected and simply-connected, and contains a single critical point \( 0 \mapsto b \). Let \( \mathcal{P}_0 \subset \mathcal{B} \) be the largest attracting petal such that the Fatou coordinate map carries \( \mathcal{P}_0 \) diffeomorphically onto a right half-plane. Thus the critical point \( 0 \) belongs to the boundary of \( \mathcal{P}_0 \), and the critical value \( b \) belongs to the boundary of the smaller petal \( \mathcal{P}_{-1} = f(\mathcal{P}_0) \). Our model space
\[ \mathcal{S}_{\text{par}} = (\mathcal{B} \setminus (\mathcal{P}_{-1} \cup \{b\}))/\alpha, \]
conformally isomorphic to a punctured disk, is obtained by removing the subset \( \mathcal{P}_{-1} \cup \{b\} \) from the basin \( \mathcal{B} \), and then gluing the two halves of \( \partial \mathcal{P}_{-1} \setminus \{b\} \) onto each other under the correspondence \( \alpha : z \mapsto \overline{z} \). To each point \( v \) in this model space, we construct a multiply connected parabolic basin \( \mathcal{B}'_v \) with two critical points as follows. The original basin \( \mathcal{B} \) can be described as the union of open subsets
\[ \mathcal{P}_0 \subset \mathcal{P}_1 \subset \mathcal{P}_2 \subset \cdots, \]
where each \( \mathcal{P}_k \) is the interior of a region bounded by a Jordan curve, and where \( f \) maps each \( \mathcal{P}_{k+1} = f^{-1}(\mathcal{P}_k) \) onto \( \mathcal{P}_k \) by an \( n \)-fold cyclic covering, branched only over \( b \). Let \( k_0 \) be the smallest index such that \( v \in \mathcal{P}_{k_0} \). Construct a new family
\[ \mathcal{P}'_0 \subset \mathcal{P}'_1 \subset \mathcal{P}'_2 \subset \cdots \]
as follows. Let \( \mathcal{P}'_k = \mathcal{P}_k \) for \( k \leq k_0 \), but let \( \mathcal{P}'_{k+1} \) be the \( n \)-fold cyclic covering of \( \mathcal{P}'_k \), branched over both \( b \) and \( v \) for \( k \geq k_0 \). The covering should extend over the boundary, so that each boundary curve of \( \mathcal{P}'_k \) for \( k \geq k_0 \) is covered by \( n \) distinct boundary curves for \( \mathcal{P}'_{k+1} \). Then the inclusion \( \mathcal{P}'_{k-1} \hookrightarrow \mathcal{P}'_k \) lifts inductively to an inclusion \( \mathcal{P}'_k \hookrightarrow \mathcal{P}'_{k+1} \). Let \( \mathcal{B}'_v \) be the union of the \( \mathcal{P}'_k \). Note that there is a canonical parabolic map \( f_v \) from this Riemann surface \( \mathcal{B}'_v \) to itself, carrying each \( \mathcal{P}'_{k+1} \) onto \( \mathcal{P}'_k \) by an \( n \)-fold branched covering.

In the special case where \( v \in \partial \mathcal{P}_{-1} \setminus \{b\} \), the two critical values \( b \) and \( v \) are on the boundary of the same petal \( \mathcal{P}_{-1} \), and there is a canonical isomorphism \( \mathcal{B}'_v \cong \mathcal{B}'_v \) which carries \( v \) to \( b \) and \( b \) to \( \overline{v} \). Hence we identify \( \mathcal{B}'_v \) with \( \mathcal{B}'_v \) in this special case.

Conversely, suppose that we start with a point \( (g) \) in the parabolic shift locus. Let \( \mathcal{Q}_0 \) be the largest petal for \( g \) such that the Fatou coordinate maps \( \mathcal{Q}_0 \) isomorphically onto a right half-plane. Then \( \partial \mathcal{Q}_0 \) contains at least one critical point \( c_0 \), and there is a unique conformal isomorphism \( \phi_0 : \mathcal{P}_0 \rightarrow \mathcal{Q}_0 \) which conjugates \( f \) to \( g \) and (extended over the boundary) carries \( 0 \) to \( c_0 \). Now let \( \mathcal{Q}_k = g^{-k}\mathcal{Q}_0 \), and let \( k_0 \geq 0 \) be the smallest index such that \( \mathcal{Q}_{k_0} \) contains both critical values of \( g \). Then \( \phi_0 \) extends uniquely to a conformal isomorphism \( \phi_{k_0} : \mathcal{P}_{k_0} \rightarrow \mathcal{Q}_{k_0} \), still conjugating \( f \) to \( g \). Let \( v \) be the unique point of \( \mathcal{P}_{k_0} \) which maps to the second critical value under \( \phi_{k_0} \). In this way we obtain a holomorphic map \( (g) \mapsto v \) from the parabolic shift locus \( \mathcal{S}_{\text{par}} \) to the model space \( \mathcal{S}'_{\text{par}} \). (Furthermore, it is not hard to check that \( \phi_{k_0} \) extends uniquely to a conformal isomorphism \( \mathcal{B}'_v \rightarrow \mathcal{C} \setminus J(g) \) which conjugates \( f_v \) to \( g \).)

We must show that this correspondence \( (g) \mapsto v \) is a proper map. That is, if \( (g_j) \) is any sequence of points in \( \mathcal{S}_{\text{par}} \) which has no accumulation point within \( \mathcal{S}_{\text{par}} \), then we must
show that the corresponding sequence \( v_j \) has no accumulation point within the model space. First suppose that the \( (g_j) \) converge, within \( \text{Per}_1(1) \), to a point of the connectedness locus. If the corresponding sequence of points \( v_j \) converged to a limit within the model space, then the corresponding sequence \( f_{v_j} \) of model parabolic basins would possess annuli with moduli bounded away from zero which separate the two critical points from the Julia set, yielding a contradiction. Similarly, suppose that the \( (g_j) \) diverge within \( \text{Per}_1(1) \) to the point at infinity. Using 1.8, we see that the distance between the two critical values of \( f_{v_j} \) must tend to zero. In other words, \( v_j \) must converge towards the puncture point \( b \) in the model space. Thus our correspondence \( (g) \mapsto v \) from \( S_{\text{par}} \) to \( S_{\text{par}}^* \) is proper. In order to show that it is a conformal isomorphism, we need only check that it has degree one, which follows easily from the asymptotic formula (15). \( \square \)

**Remark.** The argument shows that the model space obtained from Figure 5 is “inside out” with respect to Figures 1d and 3. The puncture point \( b \) in Figure 5 corresponds to the point at infinity in the earlier figures.

### §5. Real Maps

This section will study bicritical maps \( f : \hat{\mathbb{C}} \to \hat{\mathbb{C}} \) such that the invariants \( X \) and \( Y \) of §1 are both real. First a definition:

A homeomorphism \( \alpha : \hat{\mathbb{C}} \to \hat{\mathbb{C}} \) is **antiholomorphic** if it has the form \( \alpha(z) = \phi(\overline{z}) \), where \( \phi \) is some Möbius automorphism of \( \hat{\mathbb{C}} \) and \( \overline{z} \) is the complex conjugate, and is called an **involution** if \( \alpha \circ \alpha \) is the identity map.

**Lemma 5.1.** The invariants \( X(f) \) and \( Y(f) \) are both real if and only if the bicritical map \( f : \hat{\mathbb{C}} \to \hat{\mathbb{C}} \) commutes with some antiholomorphic involution \( \alpha \).

This \( \alpha \) is unique if and only if \( (f) \) lies off the symmetry locus (or off the real part \( \Sigma_{\mathbb{R}} \) of the symmetry locus).

**Proof.** Let us temporarily introduce the notation \( c(z) = \overline{z} \) for complex conjugation. Then the rational map \( g = c \circ f \circ c \) can be obtained from \( f \) by replacing all of its coefficients by their complex conjugates. Evidently \( X(g) = \overline{X(f)} \) and \( Y(g) = \overline{Y(f)} \). Therefore, if \( X \) and \( Y \) are real, then it follows that \( f \) is holomorphically conjugate to \( g \), say \( f \circ \phi = \phi \circ g \). Setting \( \alpha = \phi \circ c \), this means that

\[
f \circ \alpha = f \circ \phi \circ c = \phi \circ g \circ c = \phi \circ c \circ f = \alpha \circ f,
\]

so that \( f \) commutes with \( \alpha \). It follows that \( f \) commutes with \( \alpha \circ \alpha \), which is a holomorphic map from \( \hat{\mathbb{C}} \) to itself. If \( (f) \) lies off of the symmetry locus of 1.4, this proves that \( \alpha \circ \alpha \) is the identity map, as required. Even for a generic \( f \) in the symmetry locus which commutes with a unique \( \iota \), since \( \alpha \) must either fix or interchange the two critical points, it follows that \( \alpha \circ \alpha \) must fix both critical points, and hence be the identity map. Finally, in the two exceptional cases, corresponding to \( f(z) = z^n \) or \( f(z) = 1/z^n \), the assertion is clearly satisfied. Conversely, if \( f \) commutes with \( \alpha = \phi \circ c \), then composing the equation \( f \circ \phi \circ c = \phi \circ c \circ f \) on the right with \( c \), we see that \( f \circ \phi = \phi \circ g \). Therefore \( X(f) = X(g) \) and \( Y(f) = Y(g) \) are real, as asserted.

If there is a second antiholomorphic map \( \beta \) commuting with \( f \), then \( \alpha \circ \beta \) is a holomorphic map commuting with \( f \), so that \( f \) belongs to the symmetry locus. Conversely, if \( (f) \) does belong to the symmetry locus, let \( \iota \) be a holomorphic involution commuting
with $f$. Then $\alpha \circ \iota \circ \alpha$ is also a holomorphic involution commuting with $f$. In the
generic case where $\iota$ is unique, it follows that $\alpha$ commutes with $\iota$, and that $\alpha \circ \iota$ is
another antiholomorphic involution commuting with $f$. In other words, $f$ can be given
the structure of a “real map” in two essentially distinct ways. The discussion in the two
exceptional cases where $\iota$ is not unique is straightforward, and will be left to the reader. □

We must now distinguish two different cases. The antiholomorphic involution $\alpha$ may
have a circle of fixed points (for example the unit circle if $\alpha(z) = 1/\overline{z}$). In this case, a
Möbius change of coordinates will reduce it to the standard form $\alpha(z) = \overline{z}$ with fixed point
set $\mathbb{R} \cup \{\infty\}$, and it follows easily that the corresponding map $f$ can be expressed as a
rational map with real coefficients. On the other hand, it may happen that $\alpha$ has no
fixed points at all. In this case, a Möbius change of coordinates reduces $\alpha$ to the standard
antipodal map $\alpha(z) = -1/\overline{z}$. It follows from a theorem of Borsuk and Hopf that a map $f$
which commutes with this antipodal map necessarily has odd degree. (Compare [AH].) Such
an $f$ gives rise to a conformal self-map with only one critical point on the non-orientable
“Klein surface” which is obtained from $\hat{\mathbb{C}}$ by identifying each $z$ with $-1/\overline{z}$.

![Figure 6. Symmetry locus in the real $(X,Y)$-plane for degree $n = 2$. The three complementary domains are labeled according to the degree of the associated map from the circle of real points to itself. The picture for higher even values of $n$ would have another cusp, corresponding to $(z \mapsto z^n)$, but would otherwise be similar.](image)

More precisely, we can distinguish six cases as follows. Suppose that $f$ commutes with
the antiholomorphic involution $\alpha$. For the first five cases we suppose that $\alpha$ has a circle
$S^1$ of fixed points. Note that $f$ induces a map from this circle to itself.

**Case** $+n$. For any degree $n$, it may happen that $f$ induces an $n$-fold covering map
degree $+n$ from the circle $S^1$ to itself. In this case the Julia set $J(f)$ either coincides
with $S^1$, in which case $(f)$ has just two Fatou components, each mapped onto itself by $f$,
or else $J(f)$ is a Cantor subset of $S^1$, so that $(f)$ belongs to the shift locus.

**Case** $-n$. If $f$ induces an $n$-fold covering of degree $-n$, then again the Julia set
may be $S^1$ or a Cantor subset. Correspondingly, $f$ either interchanges the two Fatou
components, or belongs to the shift locus.

**Case** $0$. If the degree $n$ is even, then the only other possibility is that $f$ maps $S^1$
onto a proper subset of itself by a map of degree zero. In this case, the forward orbits of the
two critical points lie in the image $f(S^1)$, which is an interval $I \subset S^1$. (Compare [M2].)
Restricting $f$ to this interval, we obtain a map which is either monotone, or unimodal, or
26 MAPS WITH TWO CRITICAL POINTS

Figure 7. Symmetry locus in the real $(X, Y)$-plane for degree $n = 3$, with the five complementary domains appropriately labeled.

Figure 8. Dynamic plane for a degree $n = 3$ bicritical map which commutes with the antipodal map, with the unit circle drawn in. (Parameters $X = -0.235$, $Y = 0.213$.) There are two attracting period 4 orbits. The antipodal map of $\hat{C}$, reflection in the unit circle composed with the $180^\circ$ rotation, interchanges the two attracting basins, which are colored white and grey respectively. The Julia set, like that for an arbitrary degree $n$ bicritical map, has $n$-fold rotational symmetry. It is conjectured that this particular map can be obtained as a mating of the form $(z^3 + b) \perp (z^3 - \overline{b})$, with $b \approx 0.584 - 0.270i$. (Compare [T].)
Figure 9. Antipode-preserving region of the \((X, Y)\)-plane for degrees 3 and 5, with periods of the larger hyperbolic components labeled. (Note that the components of type \(p + p\) have a tricorn-like geometry. Compare [NS]) Along the top edge, these maps give rise to degree one circle homeomorphisms, with rotation number as indicated. Also, along the edge of the principal hyperbolic component, the multiplier of one of the two indifferent fixed points is indicated, using the notation \(e(x) = e^{2\pi ix}\).
bimodal of a rather restricted type since each point of $I$ has at most two preimages in $I$. Thus the dynamics is largely controlled by the theory of smooth interval maps. In particular, any attracting or parabolic cycle must be contained in $I$, and if there is no such cycle then the Julia set must be the entire Riemann sphere.

Note that we can pass between these three cases only by crossing the symmetry locus. (Compare Figure 6.)

For the remaining three cases, we assume that the degree $n$ is odd.

**Case** $+1$. For any odd $n$, the circle $S^1$ may map to itself by a homeomorphism of degree $+1$ with two critical inflection points. The dynamics of the critical orbits is then governed by the theory of monotone degree one circle maps, with a rotation number which is well defined up to sign. (Compare [BB].) If the rotation number is $p/q$, then both critical orbits converge to (the same or different) parabolic or attracting cycles of period $q$, while if the rotation number is irrational then the Julia set is the entire Riemann sphere.

**Case** $-1$. Similarly $S^1$ may map to itself by a homeomorphism of degree $-1$. In this case, both critical orbits must converge to parabolic or attracting cycles of period one or two.

**Antipode Preserving Case.** If

$$f(-1/z) = -1/f(z),$$

then $(f)$ necessarily belongs to the connectedness locus. For every hyperbolic component in this region of the $(X,Y)$-plane, there are either two antipodal attracting orbits of the same period $p$, or else a single attracting orbit of period $2p$ satisfying the identity $\alpha(x) = f^{2p}(x)$. In the latter case it is convenient to say that the hyperbolic component is of type $p + p$.

The division of the real $(X,Y)$-plane into five regions for a typical odd $n$ is shown in Figure 7. The antipode-preserving region in this plane is shown in detail in Figure 9 for two values of $n$, and a typical associated Julia set is shown in Figure 8.

§6. The Extended Moduli Space $\widehat{M} = M \cup L_\infty$

The next two sections will study the limiting behavior as the conjugacy class $(f)$ becomes degenerate. We will say that a sequence of conjugacy classes $(f_j)$ *diverges to infinity* in the moduli space $\mathcal{M}$ if this sequence eventually leaves any compact subset of $\mathcal{M}$. Using the results of §2, it is not hard to check that the sequence $\{(f_j)\}$ diverges to infinity within $\mathcal{M}$ if and only if

- the larger of the two invariants $|X(f_j)|$ and $|Y(f_j)|$ tends to infinity with $j$,

or if and only if

- the largest, $\max_i |\lambda_i(f_j)|$, of the fixed point multipliers tends to infinity with $j$.

It will be convenient to number the fixed points of each $f_j$ so that the corresponding multipliers $\lambda_i(f_j)$ satisfy $|\lambda_1| \leq |\lambda_2| \leq \cdots \leq |\lambda_{n+1}|$.

**Lemma 6.1.** If $\{(f_j)\}$ diverges to infinity within $\mathcal{M}$, then all but two of the fixed point multipliers must tend to infinity, so that

$$|\lambda_{n+1}| \geq \cdots \geq |\lambda_4| \geq |\lambda_3| \to \infty.$$
Furthermore, after passing to a suitable subsequence, exactly one of the following two statements must hold:

1. either $\lambda_2 \to \infty$ also, but $\lambda_1 \to 0$, or else
2. $\lambda_2$ remains bounded and $\lambda_1$ remains bounded away from zero, while the product $\lambda_1 \lambda_2$ converges to $+1$.

**Proof.** After passing to a subsequence, we can assume that $X$ and $Y$ and each of the $\lambda_i$ tends to a well defined limit in $\mathbb{C} \cup \{\infty\}$. First suppose that $|Y| \to \infty$ while $|X|$ remains bounded. Then it follows from 2.6 that the elementary symmetric function $\sigma_k$ remains bounded for $k \neq n$, but that $|\sigma_n| \to \infty$. Since $\sigma_n$ is the sum of $n+1$ terms, of which $\lambda_2 \lambda_3 \cdots \lambda_{n+1}$ is the largest in absolute value, it certainly follows that $|\lambda_2 \lambda_3 \cdots \lambda_{n+1}| \to \infty$. Since the product $\sigma_{n+1}$ remains bounded, this implies that $\lambda_1 \to 0$. We must show that $|\lambda_2| \to \infty$. Otherwise, if say $\lambda_2, \ldots, \lambda_\ell$ remained bounded, with $\ell \geq 2$, then a straightforward argument would show that the $(\binom{n+1}{\ell})$-fold sum $\sigma_{n-\ell+1}$, with dominant summand $\lambda_{\ell+1} \cdots \lambda_{n+1}$, also tended to infinity, yielding a contradiction. Thus $|\lambda_2| \to \infty$, and we are in case 6.1(1).

Now suppose that $|X| \to \infty$. In particular, we assume that $X \neq 0$, so that

$$\lambda_1 \lambda_2 \cdots \lambda_{n+1} = \sigma_{n+1} = n^{n+1} X^{n-1} \neq 0.$$ 

We will need the following.

**Definition.** Let

$$\hat{\sigma}_k = \sigma_{n+1-k}/\sigma_{n+1}$$

be the $k$-th elementary symmetric function of the reciprocals $1/\lambda_1, \ldots, 1/\lambda_{n+1}$. This is well defined and finite whenever $X \neq 0$. If $X \to \infty$, we see from 2.4 and 2.6 that

$$\hat{\sigma}_k \to 0 \quad \text{for} \quad k \geq 3, \quad \text{while}$$

$$\hat{\sigma}_2 \to 1.$$ \hspace{1cm} (19)

(However, the limiting behavior of $\hat{\sigma}_1$ depends not only on $X$ but also on $Y$.) Suppose that exactly $p$ of the $\lambda_i$ tend to zero, while exactly $q$ of them tend to finite non-zero limits. If $p \geq 1$, then it is easy to check that $\hat{\sigma}_p \to \infty$ and also that $\hat{\sigma}_{p+q} \to \infty$. By (19), it follows that $p \leq 1$, and also that $q = 0$ whenever $p = 1$. Thus if $p = 1$, then we are again in case 6.1(1).

Finally, suppose that $p = 0$. Then evidently $\hat{\sigma}_q$ tends to a finite non-zero limit, while $\sigma_k \to 0$ for $k > q$. Making use of (19), it follows immediately that $q = 2$, and that we are in case 6.1(2). \qedsymbol

A convenient coordinate near the line at infinity is provided by the sum of reciprocals

$$\hat{\sigma}_1 = \sum_{i=1}^n \frac{1}{\lambda_i} = \frac{\sigma_n}{\sigma_{n+1}} = \frac{\sigma_n}{n^{n+1} X^{n-1}}.$$ 

If only $\lambda_1$ and $\lambda_2$ remain finite, with $\lambda_1 \to \lambda$ and $\lambda_2 \to \lambda^{-1}$, note that this coordinate $\hat{\sigma}_1$ tends to $\lambda + \lambda^{-1}$. We can now define the extended moduli space $\tilde{\mathcal{M}}$ to be the disjoint union $\mathcal{M} \cup L_\infty$, where $L_\infty$ is a complex line with coordinate $\hat{\sigma}_1 \in \mathbb{C}$. To make this union into a complex manifold, we cover it with two coordinate patches, each biholomorphic to $\mathbb{C}^2$. The first coordinate patch is $\mathcal{M}$ itself, with coordinates $X$ and $\sigma_n$. The second is $(\mathcal{M} \setminus L_0) \cup L_\infty$ with coordinates $\tilde{X} = 1/X$ and $\hat{\sigma}_1$. In the overlap $\mathcal{M} \setminus L_0$, these two
coordinate systems are related by the biholomorphic map
\[
\hat{X} = \frac{1}{X}, \quad \hat{\sigma}_1 = \frac{\sigma_n}{n+1 X^{n-1}}.
\] (20)

Lemma 6.2. The union \( \hat{\mathcal{M}} \), with complex structure defined in this way, is a well defined Hausdorff complex manifold. Furthermore, the coordinate function \( X \) extends to a locally trivial holomorphic projection
\[
X : \hat{\mathcal{M}} \rightarrow \hat{\mathbb{C}},
\]
where each fiber \( L_X \) is conformally isomorphic to \( \mathbb{C} \).

The proof is straightforward. □

(Similarly, if \( \hat{\mathcal{M}}_{\mathbb{R}} \subset \hat{\mathcal{M}} \) denotes the closure of the real part of moduli space, as discussed in §5, then we obtain a real line bundle
\[
\mathbb{R} \hookrightarrow \hat{\mathcal{M}}_{\mathbb{R}} \xrightarrow{X} \hat{\mathbb{R}} = \mathbb{R} \cup \infty.
\]
Topologically, \( \hat{\mathcal{M}}_{\mathbb{R}} \) is either a cylinder or a Möbius band according as \( n \) is odd or even.)

Remark 6.3. Although the fibers of the line bundle \( \mathbb{C} \hookrightarrow \hat{\mathcal{M}} \rightarrow \hat{\mathbb{C}} \) have a sharp geometric and algebraic interpretation, it is not known whether they have any dynamic meaning. However, there are three particular fibers which certainly do have dynamic interpretations: The fiber \( L_0 \) consists of maps with a superattracting fixed point (compare Figure 1a). The fiber \( L_{-1} \) consists of maps for which one critical point maps immediately to the other. (For a study of this family, see Bamón and Boberieth [BB].) Finally, the line at infinity, \( L_{\infty} \) is certainly quite unique. Computer pictures suggest that each fiber \( L_X \) may intersect \( \overline{\mathbb{C}} \) in a set which is full and connected, so that \( L_X \cap \mathcal{S}_{\text{hyp}} \) is conformally isomorphic to \( \mathbb{C} \setminus \overline{\mathbb{D}} \). I know of no reason why this should be true, although it would be compatible with the description of the fundamental group of \( \mathcal{S}_{\text{hyp}} \). (Compare 6.6 and 7.8.) I don’t have a good algorithm for making pictures of \( L_X \cap \mathcal{C} \). However, if we pass to the \( (n+1) \)-fold branched covering in which one fixed point is marked, then we can parametrize by its multiplier \( \lambda \). (Compare 2.10.) It is relatively easy to make pictures in the disk \( |\lambda| < 1 \) where this marked point is attracting. (See Figure 10.) Note that each \( (f) \in L_X \) with a unique attracting fixed point embeds uniquely in this disk, provided that \( X \neq 0 \). In particular, \( L_X \cap \mathcal{S}_{\text{hyp}} \) embeds uniquely. However conjugacy classes with two attracting fixed points are represented twice.

Lemma 6.4. The space of all holomorphic sections of the bundle \( X : \hat{\mathcal{M}} \rightarrow \hat{\mathbb{C}} \) is an \( n \)-dimensional vector space, consisting of all polynomial functions of the form
\[
\sigma_n = \sum_{j=0}^{n-1} c_j X^j, \quad \hat{\sigma}_1 = \sum_{j=0}^{n-1} c_j \hat{X}^{n-1-j}/n^{n+1}.
\]
It follows that a function \( Y = Y(X) \) gives rise to a holomorphic section of this bundle if and only if the sum \( Y(X) + 2X^n \) is a polynomial of degree \( \leq n - 1 \) in \( X \).

The proof is straightforward. (Compare 2.4 and 2.6.) □
Figure 10. Pictures in the disk $|\lambda| < 1$ for $X$ equal to $-0.2$, $0.2i$ and $0.2$ respectively, for degree $n = 2$. (Compare 6.3.) The connectedness locus is shaded grey; while the curves in the shift locus indicate the number of iterations needed for both critical orbits to reach a small neighborhood of the attracting fixed point.

Corollary 6.5. For each $\lambda \neq 0$, the closure within $\hat{M}$ of the affine algebraic curve $\text{Per}_1(\lambda) \subset \hat{M}$ is a smooth compact algebraic curve $\text{Per}_1(\lambda) \subset \hat{M}$, which can be described as the image of a smooth section of the complex line bundle $\hat{M} \rightarrow \hat{C}$. The intersection $\text{Per}_1(\lambda) \cap L_\infty$ of this curve with the line at infinity consists of the point with coordinates $\hat{X} = 0$, $\hat{\sigma}_1 = \lambda + \lambda^{-1}$.

Proof. This follows immediately, using 2.3 and 2.4. □

Note that the coordinate $\hat{\sigma}_1$ on the line at infinity is real, and belongs to the interval $-2 \leq \hat{\sigma}_1 \leq 2$, if and only if $|\lambda| = 1$. (Compare 7.5.)

(As noted in §2, the curve $\text{Per}_1(0)$ should be identified with the fiber $L_0$ of this fibration counted $n - 1$ times. Similarly, it may be useful to identify $\text{Per}_1(\infty)$ with the fiber $L_\infty$ counted $n - 1$ times.)

Other examples of smooth sections of this complex line bundle are the coordinate curve $\sigma_n = 0$, and the half symmetry locus $Y = -2X^{(n-1)/2}(X + 1)^{(n+1)/2}$ of §1 when $n$ is odd (but not the locus $Y = 0$ or the other half symmetry locus).

Remark 6.6. We can actually compactify moduli space by adding one more point which we will call $\hat{\infty}$, contained in a third coordinate neighborhood. However the result is no longer a manifold when $n > 2$, but rather an orbifold. In fact a neighborhood of $\hat{\infty}$ is homeomorphic to a cone over a 3-dimensional lens space whose fundamental group is cyclic of order $n - 1$. This third coordinate neighborhood $W$ can be parametrized by coordinates $s, t$ subject to the identifications $(s, t) = (\alpha s, \alpha t)$, where $\alpha$ ranges over all $(n - 1)$-st roots of unity. They are related to the coordinates $(X, \sigma_n)$ on the overlap where $\sigma_n \neq 0$ and $s \neq 0$, and to the coordinates $(\hat{X}, \hat{\sigma}_1)$ on the overlap where $\hat{\sigma}_1 \neq 0$ and $t \neq 0$, by the identities

$$X = \frac{t}{s}, \quad \sigma_n = \frac{1}{s^{n-1}}, \quad \text{and} \quad \hat{X} = \frac{s}{t}, \quad \hat{\sigma}_1 = \frac{1}{n^{n+1}t^{n-1}}.$$  

Note that there is just one point $\hat{\infty} \in W$ which does not belong to $\hat{M}$, namely the singular point $\hat{\infty}$ which has coordinates $s = t = 0$. It is not difficult to check that these coordinate transformations are compatible, so that $\hat{M} \cup \hat{\infty}$ is a well defined compact Hausdorff space.
A small neighborhood of infinity in $\tilde{\mathcal{M}}$ can be identified with a neighborhood of $\tilde{\infty}$ in $W$ with this singular point removed. Evidently, for reasonable choice of neighborhood, the fundamental group will be cyclic of order $n-1$.

Intuitively, we can think of the fibers of our holomorphic line bundle as a pencil of lines through this exceptional point $\tilde{\infty}$. This pencil of lines sweeps out the compactified moduli space $\tilde{\mathcal{M}} \cup \tilde{\infty}$. Using this construction, we can reinterpret Lemma 6.1 as follows. If a sequence of points $(f_j) \in \mathcal{M}$ converges within $\tilde{\mathcal{M}} \cup \tilde{\infty}$ to the point $\tilde{\infty}$, then we are in Case (1) of 6.1, with all but one of the fixed point multipliers tending to infinity. On the other hand, if a sequence converges to some point of $L_\infty \subset \tilde{\mathcal{M}}$, then we are in Case (2) of 6.1, so that two of the multipliers converge to finite non-zero limits with product $+1$ while the others tend to infinity.

§7. The Extended Hyperbolic Shift Locus $\tilde{S}_{\text{hyp}} \subset \tilde{\mathcal{M}}$

We first prove the following.

**Theorem 7.1.** The connectedness locus $\mathcal{C}$ is contained in a compact subset of the extended moduli space $\tilde{\mathcal{M}}$. Hence the closure $\overline{\mathcal{C}} \subset \tilde{\mathcal{M}}$ is compact.

It follows that the complement $\tilde{\mathcal{M}} \setminus \overline{\mathcal{C}}$ is a neighborhood of infinity in $\tilde{\mathcal{M}}$. By definition, this complementary open neighborhood of infinity, consisting of $S_{\text{hyp}}$ together with the points of $L_\infty \setminus (\overline{\mathcal{C}} \cap L_\infty)$, will be called the extended hyperbolic shift locus $\tilde{S}_{\text{hyp}}$. (See 7.4 for a precise description of $\overline{\mathcal{C}} \cap L_\infty$.) The following statement is completely equivalent to 7.1.

**Corollary 7.2.** There exists a constant $k$ depending only on the degree $n$ with the following property. If all but one of the fixed point multipliers of $f$ are greater than $k$ in absolute value, then $(f)$ belongs to the hyperbolic shift locus.

(Compare [M2, §8.8], which shows that the best value for $k$ in the degree 2 case lies between 3 and 6.)
**Proof of 7.1 and 7.2.** We will first find a rough criterion for belonging to the hyperbolic shift locus depending on the invariants $X, Y_1, Y_2, Y$ of §1, and then relate this to the topology of $\hat{\mathcal{M}}$. Consider a sequence of maps $f_j$ with marked critical points so that the conjugacy classes $(f_j)$ tend to infinity in $\mathcal{M}$. Thus, passing to a subsequence if necessary, at least one of the invariants $X(f_j)$ and $Y(f_j)$ must tend to infinity. Since $Y_1 + Y_2 = Y$ and $Y_1Y_2 = (X + 1)^{n+1}X^{n-1}$ by (3), it follows that $Y_1$ or $Y_2$ must tend to infinity. Interchanging the two critical points if necessary, we may assume that $Y_2(f_j) \to \infty$ as $j \to \infty$.

In particular, putting the $f_j$ into the normal form (1), we may assume that the coefficients $c$ and $d$ are non-zero and hence, after a linear change of coordinate, we may assume that $c = d = 1$. In this way, taking the critical values to be $f(0) = v$ and $f(\infty) = v + \delta$, we obtain the normal form

$$f(z) = f_j(z) = \frac{(v + \delta)z^n + v}{z^n + 1} = v + \frac{\delta z^n}{z^n + 1}.$$  

(We will write $v = v_j$ and $\delta = \delta_j$ whenever it is necessary for clarity.) Note that $f^{-1}(\infty)$ is the set of $n$-th roots of $-1$. The invariants

$$X = v/\delta, \quad Y_2 = 1/\delta^n$$

can be computed from (2). It follows that $\delta \to 0$, and that the critical value $v$ satisfies the equation $v^n = X^n/Y_2$. It will be convenient to set $\epsilon = \sqrt{|\delta|} > 0$. Thus $\epsilon = \epsilon_j$ also tends to zero as $j \to \infty$.

![Figure 12. Dynamics for $(f)$ near $\infty$. Here the critical points are at 0 and $\infty$, while the critical values as well as the attracting fixed point are in the disk $N_\epsilon(v)$. The Julia set is contained in the $n$ shaded disks $U_i$, each of which maps diffeomorphically onto the complement $\hat{\mathbb{C}} \setminus N_\epsilon(v)$. As $(f) \to \infty$, each of these $n+1$ disks shrinks to a point.](image)

**Case 1.** Suppose that $v^n = X^n/Y_2$ is bounded away from $-1$, or equivalently that $v$ is bounded away from the $n$-th roots of $-1$, as $j \to \infty$. Then we will prove that $(f_j)$ belongs to the hyperbolic shift locus for large $j$. Let $N_\epsilon(v)$ be the open neighborhood of radius $\epsilon = \sqrt{|\delta|}$ about $v$. Then the pre-image $W = f^{-1}N_\epsilon(v)$ consists of all $z$ with

$$|z^n + 1| > |\delta|/\epsilon = \epsilon.$$

If $\epsilon$ is small, this set can be described as the complement $W = \hat{\mathbb{C}} \setminus (U_1 \cup \ldots \cup U_n)$ of the union of closed neighborhoods $U_1, \ldots, U_n$ of the various $n$-th roots of $-1$, where each
\( \mathcal{U}_j \) has radius roughly \( \epsilon/n \). Thus \( W \) is a connected open set which contains both critical points. (Compare the figure, where \( W \) is the complement of the shaded region.) Since \( v \) is bounded away from the roots of \(-1\), it follows that the image \( f(W) = N_\epsilon(v) \) is compactly contained in \( W \) provided that \( j \) is sufficiently large. Using the Poincaré metric for \( W \), it follows that all orbits in \( W \) converge to a common attracting fixed point. Using Theorem B.5 of Appendix B, it follows that \( (f_j) \) is contained in the hyperbolic shift locus.

**Case 2.** Suppose in fact that \( v^n \) converges to \(-1\) (and hence that \(|v| \to 1\)), but that
\[
|1 + v^n|/\epsilon \to \infty \quad \text{as} \quad j \to \infty,
\]
so that \( \epsilon \ll |1 + v^n| \) for large \( j \). Note that the distance between \( v \) and the closest \( n \)-th root of \(-1\) is approximately \(|1 + v^n|/n \) for large \( j \). It now follows, just as in Case 1, that \( f(W) \) is compactly contained in \( W \), and hence that \( (f_j) \) belongs to the hyperbolic shift locus, provided that \( j \) is large.

**Remark 7.3.** More explicitly, in both Cases 1 and 2, it follows for large \( j \) that the Julia set \( J \) is the disjoint union of compact subsets \( J_k = J \cap \mathcal{U}_k \), where \( f \) maps each \( \mathcal{U}_k \) diffeomorphically onto the strictly larger set \( \hat{C} \setminus N_\epsilon(v) \). Hence \( f \) is hyperbolic, that every point of \( J \) is uniquely determined by its itinerary with respect to the partition \( J = J_1 \cup \ldots \cup J_n \). In fact, as \( j \to \infty \), it follows that the Julia set becomes more and more hyperbolic, in the sense that the multiplier of any periodic orbit in \( J \) tends to infinity.

**Case 3.** We now return to the proof of 7.1 and 7.2. Suppose finally that the ratio \(|1 + v^n|/\epsilon \) remains bounded as \( j \to \infty \), although \( \epsilon \to 0 \) hence \( 1 + v^n \to 0 \). (By Cases 1 and 2, this must be the case if each \( (f_j) \) belongs to the connectedness locus.) Then we will show that the \( (f_j) \) remain within some compact subset of \( \hat{M} \). Setting
\[
1 + v^n = 1 + X^n/Y_2 = \eta,
\]
we see that \(|\eta| \) is less than some constant time \( \epsilon \), so that \(|\eta|^2 \) is less than a constant times \( \epsilon^2 = |\delta| \sim 1/|X| \). We can now solve for
\[
Y_2 = -X^n(1 + \eta + \eta^2 + \cdots) = -X^n - X^n \eta + O(X^{n-1}),
\]
\[
Y_1 = (X+1)^{n+1}X^{n-1}/Y_2 = -(X+1)^{n+1}(1-\eta)/X = -X^n + X^n \eta + O(X^{n-1}),
\]
and hence
\[
Y = Y_1 + Y_2 = -2X^n + O(X^{n-1}).
\]
Since \( X \) tends to infinity, it is appropriate to pass to the coordinates \( \hat{X} = 1/X \) and \( \hat{\sigma}_1 = \sum 1/\lambda_k \) of §6. Recall from 2.6 that
\[
\hat{\sigma}_1 = \frac{\sigma_n}{\sigma_{n+1}} = \frac{n^n(Y + P_n(X))}{n^{n+1}P_{n+1}(X)} = \frac{Y + 2X^n + O(X^{n-1})}{nX^{n-1}}.
\]
It follows that \( \hat{\sigma}_1 \) remains bounded as \( j \to \infty \) and \( X \to \infty \), so that the \( (f_j) \) remain within a compact subset of the extended moduli space \( \hat{M} \).

Theorem 7.1 now follows immediately, and 7.2 is proved as follows. Recall that \( \lambda_2 \) is defined to be the fixed point multiplier with next-to-smallest absolute value. Suppose, for every positive integer \( j \), that we could find a conjugacy class \( (f_j) \in \mathcal{M} \cap \mathcal{C} \) with \(|\lambda_2(f_j)| > j \). The resulting sequence cannot be in Case 1 or Case 2, and therefore must be in Case 3, with \( X(f_j) \to \infty \) and \( \hat{\sigma}_1(f_j) \) bounded. But this contradicts the hypothesis that
We can describe the set $\mathcal{C} \subset \hat{\mathcal{M}}$ and its complement $\hat{\mathcal{S}}_{\text{hyp}}$ more precisely as follows.

**Theorem 7.4.** The closure of the connected locus $\mathcal{C}$ within the extended moduli space $\hat{\mathcal{M}} = \mathcal{M} \cup L_\infty$ is a compact set which consists of $\mathcal{C} \cup \text{Per}_1(1) \subset \mathcal{M}$, together with a closed line segment consisting of all points in the line $L_\infty \cong \mathbb{C}$ such that the coordinate $\hat{\sigma}_1$ is real with $-2 \leq \hat{\sigma}_1 \leq 2$.

Equivalently, we can say that $\mathcal{C} \cap L_\infty$ consists of all points of $L_\infty$ with $\hat{\sigma}_1$ of the form $\hat{\sigma}_1 = 2 \cos \theta = \lambda + \lambda^{-1}$ where $\lambda = e^{i\theta}$, so that $\lambda$ ranges over the unit circle. It follows that the complement $\hat{\mathcal{S}}_{\text{hyp}} = \hat{\mathcal{M}} \setminus \mathcal{C}$ consists of $\mathcal{S}_{\text{hyp}} \subset \mathcal{M}$, together with all points of $L_\infty$ with $\hat{\sigma}_1 \in \mathbb{C} \setminus [-2, 2]$ or in other words all points for which

$$\hat{\sigma}_1 = \lambda + \lambda^{-1} \quad \text{with} \quad 0 < |\lambda| < 1.$$

The proof of 7.4 begins as follows. To see that $\mathcal{C}$ contains all points of $L_\infty$ with $\hat{\sigma}_1 = e^{i\theta} + e^{-i\theta}$, note that each such point can be described as the intersection $L_\infty \cap \text{Per}_1(e^{i\theta})$. But clearly $\text{Per}_1(e^{i\theta})$ is disjoint from the hyperbolic shift locus, and hence contained in $\overline{\mathcal{C}}$.

The proof in the other direction will depend on a study of dynamic behavior for conjugacy classes $(f) \in \mathcal{M} \subset \hat{\mathcal{M}}$ which are sufficiently close to the line $L_\infty \subset \hat{\mathcal{M}}$. We must first find a normal form for such classes. Suppose the multipliers at the $n + 1$ fixed points are approximately $\lambda, \lambda^{-1}, \infty, \ldots, \infty$. Here we must exclude the case $\lambda = 0$, and also the case $\lambda = 1$ which turns out to be particularly difficult. We will use the normal form (1) with $ad - bc = 1$ and with $a + b = c + d = u$, so that there is a fixed point of multiplier $\lambda = n/u^2$ at $z = 1$. Suppose that there is another fixed point at $z = \kappa$. (Here we must assume that $\kappa^n \neq 1$, since $\kappa^n = 1$ would imply that $f(\kappa) = f(1) = 1$. In practice, we will only be interested in the limiting case as $\kappa \to 1$.)

Solving the fixed point equation $a\kappa^n + b = (c\kappa^n + d)\kappa$ (together with the equations $ad - bc = 1$ and $a + b = c + d = u$), we find the unique solution

$$a = -P + \kappa Q, \quad b = \kappa^n P - \kappa Q, \quad c = -P + Q, \quad d = \kappa^n P - Q,$$

where we have temporarily introduced the abbreviations

$$P = \frac{u}{\kappa^n - 1}, \quad Q = \frac{1}{u(\kappa - 1)}.$$

It follows easily that

$$X = bc = -(\kappa^n P - \kappa Q)(P - Q)$$

is given by the asymptotic formula

$$X \sim \frac{(\lambda - 1)^2}{n\lambda} \frac{1}{(\kappa - 1)^2} \quad \text{as} \quad \kappa \to 1.$$
Thus, given $\lambda \neq 0, 1$, we can realize any large value of the invariant $X$ by suitable choice of the parameter $\kappa \approx 1$. (Note by 2.1 that $X$ and $\lambda$ together determine the remaining invariant $Y$.) The multiplier at $\kappa$, call it $\lambda'$, can be computed by the formula

$$
\lambda' = \frac{n\kappa^{n-1}}{(ck^n + d)^2} = n\kappa^{n-1}\left(\frac{u(\kappa - 1)}{\kappa^n - 1}\right)^2 \sim \frac{u^2}{n} = \frac{1}{\lambda}
$$

as $\kappa \to 1$. For $\kappa \approx 1$, the two critical values $f(\infty) = a/c$ and $f(0) = b/d$ are close to 1 and $\kappa$, and extremely close to each other. In fact the difference is given by

$$
\frac{a}{c} - \frac{b}{d} = \frac{1}{cd} \sim \frac{1}{X} = O(\kappa - 1)^2,
$$

and we can compute

$$
\frac{a}{c} = t \cdot 1 + (1 - t) \cdot \kappa \quad \text{with} \quad t = \frac{1}{1 - Q/P} \sim \frac{1}{1 - \lambda},
$$

and similarly $\frac{b}{d} = t' \cdot 1 + (1 - t') \cdot \kappa$ with $t' \sim 1/(1 - \lambda)$.

It will be convenient to conjugate $f$ by the Möbius involution

$$
\phi(z) = \phi^{-1}(z) = \frac{\kappa z - 1}{z - \kappa},
$$

which interchanges the critical point 0 with the fixed point 1, and interchanges the critical point $\infty$ with the fixed point $\kappa$. Thus the conjugate map

$$
g = \phi \circ f \circ \phi
$$

has critical points at $\phi(0) = 1$ and at $\phi(\infty) = \kappa$, and has a fixed point of multiplier $\lambda$ at $\phi(1) = 0$ and a fixed point of multiplier $\approx \lambda^{-1}$ at $\phi(\kappa) = \infty$. The critical values $g(1)$ and $g(\kappa)$ are both close to $\lambda$. In fact computation shows that

$$
g(\kappa) = \frac{\kappa Q/P}{\kappa^2 + \cdots + \kappa^n} = \lambda + O(\kappa - 1) \quad \text{as} \quad \kappa \to 1,
$$

and similarly $g(1) = g(\kappa)/\kappa^n = \lambda + O(\kappa - 1)$.

**Theorem 7.5.** Suppose that we fix $\lambda \neq 0, 1$. Then as $\kappa \to 1$ the rational function $g = g_\kappa$ converges uniformly to the linear function $w \mapsto \lambda w$ throughout any compact subset of $\hat{\mathbb{C}} \setminus \{1\}$.

(Compare [M2, §4]. Here ‘uniform convergence’ refers to convergence with respect to the spherical metric on the target space $\hat{\mathbb{C}}$.) Thus, as $\kappa \to 1$ the two critical points of $g$ crash together, and $g$ converges to a linear map, except in a small neighborhood of 1.

The proof will be based on the following. Let $D_r$ be the disk $\{z \in \mathbb{C} : |z| < r\}$. If $U$ is an open neighborhood of 0 in $\mathbb{C}$, it will be convenient to define the *inradius*

$$s(U_i) = \max\{s ; D_s \subset U\} = \text{dist}(0, \mathbb{C} \setminus U)$$

as the maximum radius of a disk centered at the origin and contained in $U$.

**Lemma 7.6.** Given simply connected open sets $U_i \subset \mathbb{C}$ with inradius $s(U_i)$ tending to infinity, there exist radii $r_i \to \infty$ and conformal isomorphisms $h_i : D_{r_i} \cong U_i$ so that $\{h_i\}$ converges uniformly to the identity map on any compact subset of $\mathbb{C}$. 
Proof. Let \( u \) range over univalent maps \( u : D \to \mathbb{C} \) on the unit disk with \( u(0) = 0 \) and \( u'(0) = 1 \). Note that the space of all such \( u \) is compact, and that the inradius of the image always satisfies
\[
s(u(D)) \leq 1 .
\]
(See for example [CG, §I.1].) It follows that the second derivative of \( u \) is uniformly bounded on any compact subset of \( D \), say
\[
|u''(w)| \leq 2k \quad \text{for} \quad |w| \leq 1/2 .
\]
Hence
\[
|u(w) - w| \leq k|w^2| \quad \text{for} \quad |w| \leq 1/2
\]
and for all such maps \( u \), where \( k \) is a uniform constant. Let \( \rho_i : D \xrightarrow{\sim} U_i \) be the Riemann map, satisfying \( \rho_i(0) = 0 \) and \( \rho'_i(0) = r_i > 0 \), and define \( h_i : D_{r_i} \to U_i \) by \( h_i(z) = \rho_i(z/r_i) \). Applying (22) and (23) to the map \( u(w) = \rho_i(w)/r_i = h_i(r_iw)/r_i \), we find easily that \( s(U_i) \leq r_i \) so that \( r_i \to \infty \), and that
\[
|h_i(z) - z| \leq k|z^2|^{|r_i|} \quad \text{for} \quad |z| \leq r_i/2 .
\]
Thus \( \{h_i\} \) converges uniformly to the identity for \( z \) restricted to any compact subset of the plane. \( \Box \)

Proof of 7.5. Let \( \Gamma = \Gamma_\kappa \) be a circle arc joining the two critical values \( g(1) \) and \( g(\kappa) \). Then the preimage \( g^{-1}(\Gamma) \) is a union of \( n \) circle arcs joining the two critical points \( 1 \) and \( \kappa \), where two adjacent arcs span an angle of \( 2\pi/n \) at either common endpoint. Furthermore, each of the \( n \) connected components of \( \hat{\mathbb{C}} \setminus g^{-1}(\Gamma) \) maps biholomorphically onto \( \hat{\mathbb{C}} \setminus \Gamma \). In fact the corresponding statement is true for any bicritical map, since any such map can be expressed as a composition of the \( n \)-th power map for which it is clearly true, together with Möbius transformations which carry circles to circles. (Compare the normal form (1).)

Both the diameter of \( \Gamma \) and the diameter of \( g^{-1}(\Gamma) \) depend on the precise choice of circle arc \( \Gamma \). However, with a little care we can choose \( \Gamma = \Gamma_\kappa \) so that both of these diameters tend to zero as the distance \( |\kappa - 1| \) between the two critical points tends to zero. It then follows that there is one largest component \( U = U_\kappa \) of \( \hat{\mathbb{C}} \setminus g^{-1}(\Gamma) \), and that the diameter of the complement \( \hat{\mathbb{C}} \setminus U \) tends to zero as \( \kappa \to 1 \). After conjugating by a rotation of the Riemann sphere which interchanges \( 1 \) and \( \infty \), we can use the Lemma to construct conformal isomorphisms \( h_\kappa : \Delta_\kappa \to U_\kappa \), where \( \Delta_\kappa \subset \hat{\mathbb{C}} \setminus \{1\} \) is the complement of a small round disk about \( 1 \), so that \( h_\kappa \) converges uniformly to the identity map on any compact subset of \( \hat{\mathbb{C}} \setminus \{1\} \). Further, without loss of generality, we may assume that \( h_\kappa \) fixes the points \( 0 \) and \( \infty \).

Similarly we can choose conformal isomorphisms \( h'_\kappa : \hat{\mathbb{C}} \setminus \Gamma_\kappa \to \Delta'_\kappa \) fixing \( 0 \) and \( \infty \), where \( \Delta'_\kappa \) is the complement of a small round disk about \( g_\kappa(1) \approx \lambda \), so that \( h'_\kappa \) converges uniformly to the identity on any compact subset of \( \hat{\mathbb{C}} \setminus \{1/\lambda\} \). Now the composition \( h'_\kappa \circ g_\kappa \circ h_\kappa \) maps the round disk \( \Delta_\kappa \) conformally onto the round disk \( \Delta'_\kappa \), and hence extends to a Möbius automorphism of the Riemann sphere. Since it fixes \( 0 \) and \( \infty \), it must have the form
\[
h'_\kappa \circ g_\kappa \circ h_\kappa(w) = \lambda_\kappa w ,
\]
where \( \lambda_\kappa \to \lambda \) as \( \kappa \to 1 \). Now since \( h_\kappa \) and \( h'_\kappa \) converge uniformly to the identity except near 1 and \( g_\kappa(1) \) respectively, it follows that \( g_\kappa(w) \) converges to \( \lambda w \) except near 1. □

**Corollary 7.7.** For \( 0 < |\lambda| < 1 \) and for \( |X| \) greater than some constant depending continuously on \( \lambda \), the conjugacy class \( (f) \) belongs to the hyperbolic shift locus.

**Proof.** Suppose that \( |\lambda| < 1 - \epsilon < 1 \). Then \( |g(w)| \approx |\lambda w| \leq |w|(1 - \epsilon) \) for \( \kappa \) close to 1, or equivalently for \( |X| \) large, provided that \( w \) is bounded away from 1. Thus every \( w \) in the disk \( D_{1-\epsilon} \) belongs to the attracting basin of 0 for \( |X| \) large. Since the two critical values of \( g \) are close to \( \lambda \), with \( |\lambda| < 1 - \epsilon \), they both belong to this basin. By B.5 in the Appendix, it follows that the conjugacy class \( (f) = (g) \) belongs to \( S_{\text{hyp}} \). □

Evidently Theorem 7.4 follows immediately. □

**Lemma 7.8.** This open set \( S_{\text{hyp}} \subset \hat{\mathcal{M}} \) is connected. Its fundamental group is cyclic of order \( n - 1 \).

The proof can be outlined as follows. Note first that there is a holomorphic map

\[
\pi : S_{\text{hyp}} \to D
\]

to the open unit disk, which maps each \( (f) \) to the multiplier at its unique attracting fixed point. (The extension of \( \pi \) to the line at infinity is straightforward: If \( \sigma_1 = \lambda + \lambda^{-1} \) with \( |\lambda| < 1 \), then \( \pi \) takes the value \( \lambda \).) For any \( \lambda \in D \setminus \{0\} \), the fiber \( \pi^{-1}(\lambda) \) is isomorphic to the open disk, with a point on \( L_\infty \) as center. (Compare the discussion in [GK] and [M2].) In this way we obtain a topological fibration

\[
D \to \pi^{-1}(D \setminus \{0\}) \to D \setminus \{0\}.
\]

However, the fiber \( \pi^{-1}(0) \) is different in two ways. First it is missing a point at infinity, and hence is a punctured disk. Second, there is no local cross-section near zero. Instead we have something like a Seifert fibration. In fact, since \( \sigma_{n+1}/n^{n+1} = X^{n-1} \) by Corollary 2, it follows that

\[
\lambda \cong \sigma_1^{-1} = n^{n+1} X^{n-1}/\sigma_n
\]

for \( \lambda \) close to zero and \( A \) close to +1 in the shift locus. Thus a small loop around the line \( A = 1 \) in the shift locus corresponds to a loop in the \( \lambda \)-plane which winds \( n - 1 \) times around the origin. Thus \( n - 1 \) times a generator for the fundamental group of \( \pi^{-1}(D \setminus \{0\}) \), which is free cyclic, maps to zero in the fundamental group of \( S_{\text{hyp}} \).

§8. The Curves \( \overline{\text{Per}}_p(\lambda) \subset \hat{\mathcal{M}} \)

Roughly speaking, the curve \( \text{Per}_p(\lambda) \) is the set of all conjugacy classes with an orbit of period \( p \geq 1 \) and multiplier \( \lambda \in \mathbb{C} \). However, we must be somewhat careful to give a definition which yields a well behaved algebraic curve which depends continuously on \( \lambda \), even in exceptional cases. (One difficulty arises when the multiplier is a root of unity, since a sequence of orbits of period \( pq \) with multiplier converging to +1 may converge to an orbit of period \( p \) with a \( q \)-th root of unity as multiplier. Another difficulty arises for \( \lambda = 0 \), since the curves \( \text{Per}_p(\lambda) \) converge towards an \( (n - 1) \)-fold branched covering of \( \text{Per}_p(0) \) as \( \lambda \to 0 \).)
Let us first count periodic orbits. As in [M2], [M3], define positive integers \( \nu_n(p) \) by the formula

\[
\nu_n(p) = \sum_{q | p} \nu_n(q) \iff \nu_n(p) = \sum_{q | p} \mu(p/q) \cdot n^q ,
\]

to be summed over all divisors \( 1 \leq q \leq p \), where the Möbius function \( \mu(p/q) \) is defined to be \((-1)^m\) if \( p/q = \ell_1 \cdots \ell_m \) is a product of \( m \) distinct primes \( \ell_j \), and \( \mu(p/q) = 0 \) otherwise. The first few values are as follows.

| Period | 1 | 2 | 3 | 4 | 5 | 6 |
|--------|---|---|---|---|---|---|
| \( \nu_n(p) \) | \( n \) | \( n^2 - n \) | \( n^3 - n \) | \( n^4 - n^2 \) | \( n^5 - n \) | \( n^6 - n^3 - n^2 + n \) |

Since \( f^{op} \) is a rational map of degree \( n^p \), with \( n^p + 1 \) fixed points in the generic case, it follows easily that a generic \( f \) has \( \nu_n(p) \) points of period \( p \) for \( p \geq 2 \). (However, for \( p = 1 \) it has \( \nu_n(1) + 1 = n + 1 \) fixed points.)

We next construct a commutative diagram

\[
\begin{array}{ccc}
\text{Per}_p & \rightarrow & \text{Bicrit} \\
\downarrow & & \downarrow \\
\text{Per}_p & \rightarrow & \mathcal{M}
\end{array}
\]

where both horizontal arrows represent branched coverings having degree \( \nu_n(p) \) for \( p \geq 2 \), but having degree \( \nu_n(1) + 1 \) for \( p = 1 \). (To simplify the notation, the subscript \( n \) on \( \text{Bicrit} \) and \( \mathcal{M} \) has been suppressed.) Start with the variety

\( \text{V}_p \subset \text{Bicrit} \times \hat{\mathbb{C}} \)

consisting of all pairs \((f, z)\) where \( f \) is a bicritical map of degree \( n \) and \( z \) is a point of \( \hat{\mathbb{C}} \) satisfying \( f^{op}(z) = z \). Here \( p \) can be any positive integer. Note that \( \text{V}_q \subset \text{V}_p \) for every divisor \( q \) of \( p \), Let \( \text{Per}_p \subset \text{Bicrit}_n \times \hat{\mathbb{C}} \) be the Zariski closure of the set

\( \text{V}_p \setminus \bigcup_{q | p, q < p} \text{V}_q \)

consisting of points in \( \text{V}_p \) which do not belong to \( \text{V}_q \) for any \( q < p \). Clearly \( \text{V}_p \) can be expressed as the union of \( \text{Per}_q \) as \( q \) ranges over all divisors of \( p \) including \( p \) itself.

By definition, two points \((f, z)\) and \((g, w)\) of \( \text{Per}_p \) are conjugate if there is a Möbius automorphism \( \phi \) of \( \hat{\mathbb{C}} \) so that \( g = \phi \circ f \circ \phi^{-1} \) and \( w = \phi(z) \). The orbifold consisting of all conjugacy classes \(((f, z))\) of points of \( \text{Per}_p \) will be denoted by \( \text{Per}_p \). Evidently the correspondence \(((f, z)) \mapsto (f)\) yields the required branched covering \( \text{Per}_p \rightarrow \mathcal{M} \).

**Remark.** These varieties \( \text{Per}_p \) and \( \text{Per}_p \) are actually irreducible. The analogous statement for unicritical polynomials was proved by Bousch [Bo] in the quadratic case and by Lau and Schleicher [LS1] for all degrees. Irreducibility of these varieties for bicritical rational maps follows, since any irreducible component of \( \text{Per}_p \) must intersect the locus of polynomial maps.

**Definition.** The multiplier map

\( \lambda : \text{Per}_p \rightarrow \mathbb{C} \)

carries each \(((f, z))\) to the derivative of \( f^{op} \) at \( z \). Let \( F_{\lambda_0} \subset \text{Per}_p \) be the fiber, consisting of all \(((f, z))\) with \( \lambda(((f, z))) = \lambda_0 \), and let \( \text{Per}_p(\lambda_0) \) be its image under the projection to
Let \( \mathcal{M} \). (Intuitively, a point of \( \text{Per}_p(\lambda) \) is a conjugacy class of maps \( (f) \) which posses a period \( p \) orbit of multiplier \( \lambda \), while a point of \( F_\lambda \) consists of such an \( (f) \) together with a specific choice of period \( p \) point for a representative map \( f \).)

**Remark.** Each \( k \) modulo \( p \) in the cyclic group \( \mathbb{Z}_p = \mathbb{Z}/p\mathbb{Z} \) acts on the varieties \( \text{Per}_p \to \text{Per}_p \) by the correspondence \( (f, z) \mapsto (f, f^{pk}(z)) \). Thus we obtain quotient orbifolds and a larger commutative diagram

\[
\begin{array}{ccc}
\text{Per}_p & \to & \text{Per}_p/\mathbb{Z}_p \to \text{Bicrit} \\
\downarrow & & \downarrow \\
\text{Per}_p & \to & \text{Per}_p/\mathbb{Z}_p \to \mathcal{M} \\
\downarrow \lambda & & \downarrow \\
\mathbb{C} & & \\
\end{array}
\]

where now the horizontal arrows represent branched coverings of degree \( p \) on the left and \( \nu_n(p)/p \) on the right. Starting with any \( \lambda_0 \in \mathbb{C} \) we can form the preimage in \( \text{Per}_p/\mathbb{Z}_p \) and then project to the subset \( \text{Per}_p(\lambda_0) \subset \mathcal{M} \).

**Theorem 8.1.** Let \( \overline{\text{Per}}_p(\lambda) \) be the closure of \( \text{Per}_p(\lambda) \) within the extended moduli space \( \hat{\mathcal{M}} \). If \( \lambda \neq 0 \), then \( \overline{\text{Per}}_p(\lambda) \) is a compact, not necessarily irreducible, algebraic curve in the extended moduli space \( \hat{\mathcal{M}} \). The projection map \( ((f, z)) \mapsto X(f) \) carries \( \overline{\text{Per}}_p(\lambda) \) onto \( \hat{\mathcal{C}} \) with degree \( \nu_n(p)/n \). Equivalently, the number of intersections of \( \overline{\text{Per}}_p(\lambda) \) with any fiber \( L_X \) of the fibration \( X : \hat{\mathcal{M}} \to \hat{\mathcal{C}} \), counted with multiplicity, is independent of \( \lambda \) and \( X \), being equal to \( \nu_n(p)/n \). The same statements are true for \( \lambda = 0 \) and \( p \geq 2 \) provided that the point set \( \text{Per}_p(0) \) is counted with multiplicity \( n - 1 \).

In other words, for \( p \geq 2 \), it is asserted that the set \( \text{Per}_p(0) \) intersects a generic fiber \( L_X \) in \( \nu_n(p)/(n(n-1)) \) distinct points, each of which must be counted with multiplicity \( n - 1 \) in order to get the correct count of \( \nu_n(p)/n \). (Here is one intuitive explanation for this multiplicity: For \( (f) \in \text{Per}_p(0) \), suppose that we perturb \( f \) within the much larger space consisting of all rational maps of degree \( n \). Generically, the periodic critical point will split up into \( n - 1 \) nearby critical points, any one of which can be periodic. Thus the locus \( \text{Per}_p(0) \subset \mathcal{M} \) splits up locally, in this larger context, into \( n - 1 \) nearby sheets.)

**Outline Proof of 8.1.** We need only consider the case \( p \geq 2 \), since the period one case has been discussed in §2 and §6. Since \( \text{Per}_p(\lambda) \) is an algebraic curve in \( \mathcal{M} \cong \mathbb{C}^2 \), it can be defined by a single polynomial equation in the coordinates \( X \) and \( \sigma_n \). Substituting \( \hat{X} = 1/X \) and \( \hat{\sigma}_1 = \sigma_n/(n^{n+1}X^{n-1}) \), and multiplying through by an appropriate power of \( \hat{X} \), we obtain a corresponding polynomial equation relating \( \hat{X} \) and \( \hat{\sigma}_1 \). This shows that \( \overline{\text{Per}}_p(\lambda) \) is an algebraic curve in the variety \( \hat{\mathcal{M}} \). If \( |\lambda| > 1 \) so that the associated periodic orbit is contained in the Julia set, then it follows from Remark 7.3 that this curve is contained in a compact subset of \( \hat{\mathcal{M}} \), and hence is itself compact. On the other hand, if \( |\lambda| \leq 1 \) with period \( p \geq 2 \), then \( \text{Per}_p(\lambda) \) is contained in the connectedness locus, which has compact closure within \( \hat{\mathcal{M}} \).

To compute the degree of the projection map \( \overline{\text{Per}}_p(\lambda) \to \hat{\mathcal{C}} \), we first look at the exceptional special case \( \lambda = 0 \) and count the number of intersections of \( \text{Per}_p(0) \) with the fiber \( L_0 \). If \( f_b(z) = z^n + b \) with invariants \( X = 0 \) and \( Y = b^{n-1} \), then the equation \( f_b^{\circ p}(0) = 0 \) has degree \( n^{p-1} \) in the unknown \( b \), so there are \( n^{p-1} \) solutions \( b \), counted.
with multiplicity. Subtracting off the numbers of solutions for proper divisors of \( p \), we see that there are \( \nu_n(p)/n \) choices for \( b \). Since we assume that \( p \geq 2 \), it follows that \( b \neq 0 \). Hence there are \( n - 1 \) choices of \( b \) for every choice of \( Y = b^{n-1} \). Thus the projection \( X : \overline{\Per}_p(0) \to \hat{\mathbb{C}} \) has degree \( \nu_n(p)/(n(n-1)) \) for \( p \geq 2 \). The first few values are as follows:

| Period | \( p \) | 2  | 3  | 4  | 5  | 6  |
|--------|--------|----|----|----|----|----|
| \( \nu_n(p)/(n(n-1)) \) | 1    | \( n+1 \) | \( n(n+1) \) | \( (n+1)(n^2+1) \) | \( (n+1)(n^3+n-1) \) |

To check what happens as we perturb the multiplier \( \lambda \) away from zero, we can simply apply the following result. See [LS1, §2.2].

**Proposition (Lau and Schleicher).** If \( W \) is any hyperbolic component in the \( b \)-parameter plane for the family of maps \( z \mapsto z^n + b \), then the multiplier map \( W \to D \) is an \((n-1)\)-fold branched covering, ramified only at the unique inverse image of zero.

Thus, as we perturb \( \lambda \) away from zero, each intersection of \( \Per_p(0) \) with \( L_0 \) splits into \( n - 1 \) distinct intersection, and we obtain the required count of \( \nu_n(p)/n \) points in \( \Per_p(\lambda) \cap L_0 \) for \( \lambda \neq 0 \). □

**Example 8.2.** For the special case \( p = 2 \), it follows that \( \overline{\Per}_2(0) \) is the image of a smooth section of the fibration \( X : \hat{\mathcal{M}} \to \hat{\mathbb{C}} \). We can compute this section explicitly as follows. Using the normal form (1) with \( ad - bc = 1 \), recall that

\[
X = bc , \quad X + 1 = ad , \quad Y_1 = a^{n+1}b^{n-1} ,
\]

and that \( f(0) = b/d \). Thus the critical point \( 0 \) has period exactly two if and only if

\[
f(b/d) = \frac{ab^n + bd^n}{cb^n + d^{n+1}}
\]

is zero, but \( b \neq 0 \). This yields the equation \( ab^{n+1} + d^n = 0 \). Multiplying by \( a^n \), we obtain \( Y_1 + (X + 1)^n = 0 \). If \( Y_1 \neq 0 \), it follows that

\[
Y_2 = (X + 1)^{n+1}X^{n-1}/Y_1 = -(X + 1)x^{n-1} ,
\]

and therefore that

\[
Y = Y_1 + Y_2 = -(X + 1)^n - (X + 1)x^{n-1} .
\]

On the other hand, if \( Y_1 = 0 \) then it is easy to check that \( X + 1 = Y_2 = Y = 0 \) also, so that the equation is still satisfied. Similarly, if the other critical point \( \infty \) is periodic, then interchanging the roles of \( Y_1 \) and \( Y_2 \) we obtain the same equation.

**Remark 8.3.** It seems likely that the curve \( \overline{\Per}_p(\lambda) \) is usually irreducible, however there are certainly exceptions. As an example, if \( n \) is odd then it was noted in §1 that the curve \( \overline{\Per}_2(n^2) \) is reducible, since it contains the half symmetry locus \( \Sigma_- \) as an irreducible component. (This period two curve is strictly larger that \( \Sigma_- \) since it has degree \( n - 1 \geq 2 \) over \( \hat{\mathbb{C}} \) while \( \Sigma_- \) has degree one.)

Here is another example. If \( 1 \leq q < p \) is a proper divisor of \( p \), and if \( \xi \) is a primitive \((p/q)\)-th root of unity, then it is not hard to show that

\[
\Per_q(\xi) \subset \Per_p(1)
\]
since, under a small perturbation of \( f \), any period \( q \) orbit of multiplier \( \xi \) will split off a period \( p \) orbit with multiplier close to \( 1 \). In general, it follows that \( \text{Per}_p(1) \) is reducible for \( p \geq 2 \). The only exception occurs in the degree two case, where \( \text{Per}_2(1) \) actually coincides with the curve \( \text{Per}_1(-1) \). (Thus a quadratic rational map cannot have any period two orbit with multiplier \( 1 \).)

We can describe the intersection of \( \text{Per}_p(\eta) \) with the line at infinity rather precisely as follows.

**Theorem 8.4.** For \( p \geq 2 \) the intersection \( \text{Per}_p(\eta) \cap L_\infty \) depends only on the period \( p \) and not on the multiplier \( \eta \). This intersection is a finite set consisting of points with coordinate \( \hat{\sigma}_1 \) of the form \( \lambda + \lambda^{-1} \) where \( \lambda \) is a \( q \)-th root of unity for some \( q \leq p \).

**Proof.** First consider the case \( \eta = 0 \), and suppose that \( \lambda^q \neq 1 \) for \( 1 \leq q \leq p \). In other word, we suppose that the complex numbers

\[
1, \lambda, \lambda^2, \ldots, \lambda^p
\]

are all distinct. Let \( (f) \in \mathcal{M} \) be a conjugacy class with \( \hat{X} \) close to zero and with \( \hat{\sigma}_1 \) close to \( \lambda + \lambda^{-1} \). Using 7.5 we can find a normal form for \( (f) \) so that both critical points are close to \( 1 \), with the first \( p + 1 \) points of both critical orbits close to

\[
1 \mapsto \lambda \mapsto \lambda^2 \mapsto \cdots \mapsto \lambda^p \neq 1.
\]

Thus, if the pair \( (\hat{X}, \hat{\sigma}_1) \) is sufficiently close to \( (0, \lambda + \lambda^{-1}) \), then it follows that neither critical orbit can have period \( p \), hence \( (f) \notin \text{Per}_p(0) \), as required.

(This argument does not apply if \( \lambda^q = 1 \) for some \( q < p \). For then the \( q \)-th forward image of the critical point is close to \( 1 \), lying in a small region whose image under \( f \) covers the entire Riemann sphere. Hence the further orbit of the critical points cannot be predicted without more information.)

Now consider \( \text{Per}_p(\eta) \) with variable \( \eta \). Consider the coordinate \( \hat{\sigma}_1 \) for the various points of \( \text{Per}_p(\eta) \cap L_\infty \). The elementary symmetric functions of these \( \nu_n(p)/n \) (not usually distinct) coordinate values can be expressed as holomorphic functions of the parameter \( \eta \). But if \( |\eta| < 1 \) and \( p \geq 2 \) then \( \text{Per}_p(\eta) \) is contained in the connectedness locus, so that

\[
\text{Per}_p(\eta) \cap L_\infty \subset \mathcal{C} \cap L_\infty \cong [-2, 2] \subset \mathbb{R}.
\]

In other words, every one of the \( \nu_n(p)/n \) values of \( \hat{\sigma}_1 \) is real, hence the elementary symmetric functions of these coordinate values are also real. But a holomorphic function from \( \eta \in \mathbb{C} \) to \( \mathbb{C} \) which takes only real values throughout the open disk \( |\eta| < 1 \) must be constant. This proves the the intersection is independent of \( \eta \) for all \( \eta \in \mathbb{C} \), and completes the proof of 8.4. \( \square \)

**Remark 8.5.** More precisely, for \( p \geq 2 \) it can be conjectured that the point of \( L_\infty \) with coordinate \( \hat{\sigma}_1 = \lambda + \lambda^{-1} \) belongs to \( \text{Per}_p(\eta) \) if and only if \( \lambda \) is a primitive \( q \)-th root of unity for some \( 2 \leq q \leq p \), or in other words if and only if

\[
\hat{\sigma}_1 = 2 \cos(2\pi r/q) \quad \text{for some integers} \quad 0 < r < q \leq p.
\]

Thus it is believed that the point of \( L_\infty \) with coordinate \( \hat{\sigma}_1 = 2 \) does not lie on any \( \text{Per}_p(\eta) \) with \( p \geq 2 \). (Compare [Sti] and [R3], which give a more precise description of the curves \( \text{Per}_p(0) \) near \( L_\infty \) in the degree two case, and see also [M2].)
8. THE CURVES $\text{Per}_p(\lambda)$

| $p$ | $r/q$ | limiting orbit of $g(1) \approx \lambda$ | number | total |
|-----|-------|---------------------------------------|--------|-------|
| 2   | 1/2   | $\lambda \rightarrow 1$               | 1      |       |
| 3   | 1/3, 2/3 | $\lambda \rightarrow \lambda^2 \rightarrow 1$ | 2 $\times$ 1 |       |
|     | 1/2   | $\lambda \rightarrow 1 \overset{n-1}{\rightarrow} 1$ | $n-1$ |       |
| 4   | 1/4, 3/4 | $\lambda \rightarrow \lambda^2 \rightarrow \lambda^3 \rightarrow 1$ | 2 $\times$ 1 |       |
|     | 1/3, 2/3 | $\lambda \rightarrow \lambda^2 \rightarrow 1 \overset{n-1}{\rightarrow} 1$ | $2 \times (n-1)$ |       |
|     | 1/2   | $\lambda \rightarrow 1 \overset{n}{\rightarrow} \lambda \rightarrow 1$ | $n$ |       |
|     | 1/2   | $\lambda \rightarrow 1 \overset{n-1}{\rightarrow} 1 \overset{n-1}{\rightarrow} 1$ | $(n-1)^2$ | $n^2 + n + 1$ |
| 5   | 1/5, 2/5, 3/5, 4/5 | $\lambda \rightarrow \lambda^2 \rightarrow \lambda^3 \rightarrow \lambda^4 \rightarrow 1$ | 4 $\times$ 1 |       |
|     | 1/4, 3/4 | $\lambda \rightarrow \lambda^2 \rightarrow \lambda^3 \rightarrow 1 \overset{n-1}{\rightarrow} 1$ | $2 \times (n-1)$ |       |
|     | 1/3, 2/3 | $\lambda \rightarrow \lambda^2 \rightarrow 1 \overset{n-1}{\rightarrow} \lambda^2 \rightarrow 1$ | $2 \times (n-1)$ |       |
|     | 1/3, 2/3 | $\lambda \rightarrow \lambda^2 \rightarrow 1 \overset{n-1}{\rightarrow} 1 \overset{n-1}{\rightarrow} 1$ | $2 \times (n-1)^2$ |       |
|     | 1/2   | $\lambda \rightarrow 1 \overset{n}{\rightarrow} \lambda \rightarrow 1 \overset{n-1}{\rightarrow} 1$ | $n(n-1)$ |       |
|     | 1/2   | $\lambda \rightarrow 1 \overset{n-1}{\rightarrow} 1 \overset{n-1}{\rightarrow} 1 \overset{n-1}{\rightarrow} 1$ | $(n-1)^3$ | $n^3 + n^2 + n + 1$ |

Table listing the numbers of points $(g) \in L_X$ such that $g$ admits a periodic critical orbit of period dividing $p$, with $|X|$ very large, grouped by the conjectured limiting behavior of this orbit as $X \to \infty$. By definition, $\lambda = e^{2\pi i r/q}$ in each row. The sum on the right must be equal to $1 + n + n^2 + \cdots + n^{p-2}$ for all values of $p$.

Following is an intuitive argument which attempts to justify this statement, and also to compute the multiplicities of the various points of $\text{Per}_p(0) \cap L_\infty$. I suspect that it could be made into a rigorous proof, but certainly have not done so. Let us count solutions to the equation $g(z) = k$, where $k \in \mathbb{C}$ is some given constant and where $g$ is the bicritical map of 7.5, with $|X|$ very large so that $g(z) \approx \lambda z$ outside of a small neighborhood of 1. If $k$ is bounded away from $\lambda$, then there is a unique solution $z \approx k/\lambda$ which is bounded away from 1. Hence the remaining $n - 1$ solutions must all lie in some small neighborhood of 1. Let us express these facts symbolically, in the limit as $|X| \to \infty$, by writing

$$k/\lambda \rightarrow k \quad \text{but} \quad 1 \overset{n-1}{\rightarrow} k, \quad \text{for} \quad k \neq \lambda.$$  

In the special case $k = \lambda$, all $n$ of the solutions must be very close to 1, so we write

$$1 \overset{n}{\rightarrow} \lambda.$$  

The numbers on the right in the table are computed by multiplying these factors of $n - 1$ or $n$ by the number of values of $r/q$ which are listed on the left. If $N(p, q)$ denotes the number of solutions of period dividing $p$ which are computed in this way, corresponding to the case where $\lambda$ is a primitive $q$-th root of unity, $q \geq 2$, then it is not hard to check that
these numbers can be computed recursively as follows:

\[
N(p, q) = \begin{cases} 
0 & \text{if } p < q \\
\phi(q) & \text{if } p = q \\
nN(p - q, q) + \sum_{j=1}^{q-1}(n - 1)N(p - j, q) & \text{if } p > q,
\end{cases}
\]

where \( \phi(q) \), the Euler \( \phi \)-function, is the number of primitive \( q \)-th roots of unity. If \( N(p, q) \) is defined by this recursion, then it seems empirically that the sum over \( q \) is given by

\[
\sum_{q \geq 2} N(p, q) = 1 + n + n^2 + \cdots + n^{p-2}.
\]

For any given \( p \), this is easy to check by computer; but I don’t know a general proof.

On the other hand, for every \( p \geq 2 \), the actual number of solutions of period exactly \( p \) is known to be \( \nu_n(p)/(n(n - 1)) \). There are no solutions of period 1, hence the number of solutions with period \( d \) dividing \( p \) must be equal to

\[
\sum_{d | p, d \neq 1} \frac{\nu_n(d)}{n(n - 1)} = \frac{n^p - n}{n(n - 1)} = 1 + n + n^2 + \cdots + n^{p-2}.
\]

This agrees precisely with the intuitive computation, which supports the conjecture that the computed values \( N(p, q) \) are indeed correct, and that there are no solutions at all corresponding to the case \( \lambda = 1 \).

It is interesting to note that, for each \( p \), the contribution from \( q = 2 \) is by far the largest. Indeed, for large \( n \), the contribution of \( (n - 1)^{p-2} \), corresponding to a critical orbit for \( g \) which tends asymptotically to

\[
1 \mapsto -1 \mapsto 1 \mapsto 1 \mapsto \cdots \mapsto 1,
\]

contributes much more than all of the other asymptotic behaviors combined. The associated point of \( \text{Per}_p(0) \cap L_\infty \) has coordinate \( \hat{\sigma}_1 = \lambda + \lambda^{-1} = -2 \).

**Appendix A. No Herman Rings**

The following statement is a straightforward consequence of results due to Shishikura.

**Theorem A.1.** A rational map \( f \) with only two critical points cannot have any Herman rings.

The following proof is closely modeled on Shishikura’s argument (compare [Sh, §8], together with the remark on page 4 of [Sh]), although it avoids the use of surgery constructions.

Let \( f : \hat{\mathbb{C}} \to \hat{\mathbb{C}} \) be a rational map of degree \( d \geq 2 \) which possesses a cycle of Herman rings \( H = H_1 \cup \cdots \cup H_p \) of period \( p \geq 1 \). That is, assume that the \( H_i \) are disjoint annuli with \( \partial H_i \subset J(f) \), where \( i \) ranges over the group of integers modulo \( p \), and assume that \( f \) maps each \( H_i \) diffeomorphically onto \( H_{i+1} \). Choosing some base point \( b \in H \), the closure of the forward orbit of \( b \) is a union \( \Gamma = \Gamma_1 \cup \cdots \cup \Gamma_p \) of smooth simple closed curves, where \( \Gamma_i \subset H_i \) and \( f(\Gamma_i) = \Gamma_{i+1} \). Since \( f(\Gamma) = \Gamma \), we have

\[
\Gamma \subset f^{-1}(\Gamma) \subset f^{-2}(\Gamma) \subset \cdots.
\]

(If \( \Gamma \) is chosen to be disjoint from the postcritical set, then each \( f^{-n}(\Gamma) \) will be a union of at most \( pd^n \) disjoint simple closed curves.) The connected components of \( \hat{\mathbb{C}} \setminus f^{-n}(\Gamma) \) are
open sets which will be called *Shishikura puzzle pieces* of *level* $n$. Evidently $f$ maps each puzzle piece of level $n > 0$ onto a puzzle piece of level $n - 1$ by a possibly branched covering map.

Each $\Gamma_i$ separates the Riemann sphere into two disks. In order to label these disks, choose orientations for the loops $\Gamma_i$ compatible with the mapping. Then for each $\Gamma_i$ we can speak of the disk $D_i^L$ to the left of $\Gamma_i$ with boundary $\Gamma_i$, and the disk $D_i^R$ to the right of $\Gamma_i$ with boundary $\Gamma_i$. Fixing some level $n$, note that each $\Gamma_i$ lies on the boundary of exactly two puzzle pieces. Let $L_i = L_i^{(n)} \subset D_i^L$ be the adjacent piece to the left of $\Gamma_i$ and $R_i = R_i^{(n)} \subset D_i^R$ the adjacent piece to the right. Define the *level n left neighborhood* $L_i^{(n)}$ of $\Gamma$ to be the union $L_1^{(n)} \cup \cdots \cup L_p^{(n)}$, and define the *right neighborhood* $R_i^{(n)} = R_1^{(n)} \cup \cdots \cup R_p^{(n)}$ similarly. Then we have the following. (See [Sh,§7].)

**Theorem A.2.** The left neighborhood $L_i^{(n)}$ of $\Gamma$ contains at least one critical point of $f$, and similarly the right neighborhood $R_i^{(n)}$ contains at least one critical point.

**Proof.** We may assume that $n \geq 1$. If $L_i \cup \cdots \cup L_p$ contains no critical point, then we will show that $f$ must map each $L_i$ onto $L_{i+1}$, and hence that $f^{op}$ must map $L_i$ onto itself. This would imply that each $L_i$ is contained in the Fatou set $\mathbb{C} \setminus J(f)$. But that is impossible, since $L_i$ intersects the boundary of the ring $H_i$, which is contained in the Julia set. This contradiction will prove the Theorem.

For each left hand puzzle piece $L_i^{(n)}$ we have the following diagram.

$$L_i^{(n)} \xrightarrow{f} L_{i+1}^{(n-1)} \supset L_i^{(n+1)}.$$  

If there is no critical point in $L_i^{(n)}$, then $f$ maps $L_i^{(n)}$ onto $L_i^{(n-1)}$ by a covering map (which may be one-to-one). Hence, if we pass to universal covering spaces, this diagram takes the form

$$\tilde{L}_i^{(n)} \simeq \tilde{L}_i^{(n-1)} \leftarrow \tilde{L}_i^{(n+1)}.$$  

In other words, we can choose a single valued holomorphic branch of $f^{-1}$ which maps $\tilde{L}_i^{(n)}$ into $\tilde{L}_i^{(n)}$. Each puzzle piece $L_i^{(n)}$ is a hyperbolic Riemann surface, and hence has a Poincaré metric. Fixing $n$, for any smooth curve segment $\alpha : [0, 1] \to L_i^{(n)}$, let $\ell_i(\alpha)$ be the Poincaré arclength. Then one of the following two possibilities must hold:

**Case 1.** If $f(L_i^{(n)})$ is precisely equal to $L_i^{(n)}$, then this branch of $f^{-1}$ is a Poincaré isometry from $\tilde{L}_i^{(n)}$ onto $\tilde{L}_i^{(n)}$. In this case $f$ preserves Poincaré arclength, so that

$$\ell_{i+1}(f \circ \alpha) = \ell_i(\alpha)$$

for every smooth curve in $L_i^{(n)}$.

**Case 2.** If $f(L_i^{(n)})$ is strictly larger than $L_i^{(n)}$, then this branch of $f^{-1}$ is strictly distance reducing. Hence $f$ must strictly increase Poincaré arclength, in the sense that

$$\ell_{i+1}(f \circ \alpha) > \ell_i(\alpha)$$

for any non-constant curve in $L_i^{(n)}$ which maps into $L_{i+1}^{(n)}$.

Now choose some orbit closure $\Gamma' \subset H \cap L^{(n)}$, and let $\alpha : \mathbb{R}/\mathbb{Z} \to \Gamma' \cap H_0$ be a smooth
parametrization of one connected component. Then \( f^{\circ i} \circ \alpha \) is a smooth parametrization of \( \Gamma' \cap H_i \). Comparing the discussion above, we have

\[
\ell_0(\alpha) \leq \ell_1(f \circ \alpha) \leq \ell_2(f^{\circ 2} \circ \alpha) \leq \cdots \leq \ell_p(f^{\circ p} \circ \alpha) = \ell_0(\alpha),
\]

since \( f^{\circ p} \circ \alpha \) and \( \alpha \) parametrize the same loop. Thus equality must hold throughout, and Case 2 can never occur. This proves that \( f \) must map every \( \hat{L}^{(n)}_i \) onto \( L^{(n)}_{i+1} \). As noted above, this leads to a contradiction. Therefore \( L^{(n)}_i \) must contain at least one critical point, which completes the proof of A.2. \( \square \)

**Remark A.3.** If \( n \geq p - 1 \), then \( L^{(n)}_i \) is disjoint from \( R^{(n)}_i \). This statement is clear when \( p = 1 \), since \( L^{(n)}_i \cap R^{(n)}_i = \emptyset \). If \( L^{(p-1)}_i \cap R^{(p-1)}_i \neq \emptyset \) with \( p > 1 \), then \( L^{(p-1)}_{i_0} \) would be precisely equal to \( R^{(p-1)}_{i_0+\delta} \) for some \( i_0 \) and some \( \delta \neq 0 \). This would imply that \( L^{(p-2)}_{i_{0+1}} = R^{(p-2)}_{i_{0+1+\delta}} \). Continuing inductively it would follow that \( L^{(0)}_{i_0} = R^{(0)}_{i_{0+\delta}} \) for every \( i \). But this would imply that the entire disk \( D^R_i \) to the right of \( \Gamma_i \) is contained in \( D^R_{i+\delta} \). Therefore

\[
D^R_0 \subset D^R_{\delta} \subset D^R_{2\delta} \subset \cdots \subset D^R_{p\delta} = D^R_0,
\]

which is impossible. \( \square \)

Now let us specialize to the case of a rational map of degree \( d \) with only two critical points. Note the following basic observation. If a simple closed curve \( \Gamma_i \subset \hat{C} \) bounds a closed disk \( \overline{D} \) which is disjoint from the two critical values, then \( f^{-1}(\overline{D}) \) is the union of \( d \) disjoint topological disks, each of which contains no critical point and maps homeomorphically onto \( \overline{D} \). On the other hand, if \( \Gamma_i \) separates the two critical values, then \( f^{-1}(\Gamma_i) \) is a single simple closed curve, which maps onto \( \Gamma_i \) by a \( d \)-fold covering map. Evidently this second case can never occur for the loops \( \Gamma_i \) associated with a cycle of Herman rings.

It will be convenient to put one of the two critical points at infinity. Then one of the two components of the complement of any \( \Gamma_i \) is bounded, and maps diffeomorphically onto its image under \( f \). I will call this component the **inside** \( D^\text{in}_i \) of \( \Gamma_i \). The other component \( D^\text{out}_i \) is unbounded, and contains both critical points.

Call \( \Gamma_k \) a **separating** loop if it separates the critical points from the critical values. Then the inside \( D^\text{in}_i \) of each \( \Gamma_i \) maps diffeomorphically onto:

- the outside \( D^\text{out}_{i+1} \) if \( \Gamma_{i+1} \) is separating,
- the inside \( D^\text{in}_{i+1} \) if \( \Gamma_{i+1} \) is non-separating.

Call \( \Gamma_k \) **minimal** if the union \( \Gamma \) is disjoint from the open disk \( D^\text{in}_k \).

**Lemma A.4.** There exists a (necessarily unique) \( \Gamma_k \) which is both separating and minimal.

**Proof** [Sh, §8]. There certainly exists at least one minimal \( \Gamma_i \). If every \( \Gamma_i \) were minimal and non-separating, then the inside of every \( \Gamma_i \) would map diffeomorphically onto the inside of \( \Gamma_{i+1} \) and we would have a cycle of Siegel disks rather than Herman rings. Therefore, either there is some \( \Gamma_i \) which is minimal and separating, as required, or else there is some \( \Gamma_i \) which is not minimal. In the latter case, we can choose some non-minimal \( \Gamma_i \) so that \( \Gamma_{i+1} \) is minimal. Then \( D^\text{in}_i \), which contains other \( \Gamma_j \), cannot map diffeomorphically onto \( D^\text{in}_{i+1} \) which does not. Hence in this case \( \Gamma_{i+1} \) must be a minimal separating loop, as required. \( \square \)
Proof of A.1. Let $\Gamma_k$ be the loop of A.4. Since $\Gamma_k$ is minimal, the closure $D_{\text{out}}^k$ contains the union $\Gamma = \Gamma_1 \cup \cdots \cup \Gamma_p$. Since $\Gamma_k$ is separating, the preimage $f^{-1}(D_{\text{out}}^k)$ is a union of $d$ disjoint bounded closed disks. Evidently this union contains $f^{-1}(\Gamma)$ and has boundary $f^{-1}(\Gamma_k)$. It follows that the complementary region $f^{-1}(D_{\text{in}}^k)$ is the unique unbounded puzzle piece of level one. This puzzle piece contains both critical points, and has no $\Gamma_i$ other than $\Gamma_{k-1}$ on its boundary. Therefore the level one puzzle piece to the inner side of $\Gamma_{k-1}$ is bounded and contains no critical point, while for any $i \neq k-1$ both of the pieces $L_i^{(1)}$ and $R_i^{(1)}$ are bounded and contain no critical point. Thus $L^{(1)}$ and $R^{(1)}$ cannot both contain critical points, which contradicts A.2 and completes the proof that a bicritical map has no Herman ring. □

Appendix B. Totally Disconnected Julia Sets.

We will first prove the following result, with no restriction on the number of critical points. Let $f$ be a rational function of degree $n \geq 2$.

**Theorem B.1.** The Julia set $J$ of $f$ is totally disconnected and contains no critical point if and only if all of the critical values of $f$ lie in a single Fatou component.

In the hyperbolic case, this was proved by Rees [R]. I attempted to extend the argument to the parabolic case in [M2], however the details of the argument were not quite right. The following proof is rather different and perhaps easier. It will be based on the following ideas.

**Definition.** A map $g : K \to K'$ between metric spaces is called *locally distance increasing* if every point of $K$ has a neighborhood $V$ so that
\[ \text{dist}(g(x), g(y)) > \text{dist}(x, y) \] (24)
for all $x \neq y$ in $V$. If $K$ is compact, then an equivalent condition is that for some $\epsilon > 0$ we have (24) whenever $0 < \text{dist}(x, y) < \epsilon$.

**Lemma B.2.** Let $g : K \to K$ be a locally distance increasing map from a compact metric space to itself. If $g$ is injective on each connected component of $K$, then the space $K$ must be totally disconnected.

**Proof.** First note the following: There exists a constant $\epsilon' > 0$ so that the inequality (24) holds whenever $x$ and $y$ are distinct points which belong to the same connected component of $K$ and satisfy $\text{dist}(g(x), g(y)) < \epsilon'$. For otherwise, with $\epsilon$ as above, there would exist pairs $(x_i, y_i)$ belonging to the same component $K_i$ of $K$ so that $\text{dist}(g(x_i), g(y_i))$ converges to zero as $i \to \infty$, but with $\text{dist}(x_i, y_i) \geq \epsilon$. After passing to a subsequence, we may assume that the points $x_i$ converge to some point $x$ and that the $y_i$ converge to some $y$, where $\text{dist}(x, y) \geq \epsilon$ and where $g(x) = g(y)$. But this is impossible since $x$ and $y$ belong to the same connected component of $K$. In fact, if $L$ denotes the set of all accumulation points of $K_i$ as $i \to \infty$, then $L$ is a connected subset of $K$ containing both $x$ and $y$.

The **diameter** $\text{diam}(K) \geq 0$ of a non-vacuous compact metric space is defined to be the maximum distance between two of its points. More generally, for any integer $m \geq 1$ define $\text{diam}_m(K)$ to be the largest number $\delta$ so that there exist $m+1$ points $x_0, x_1, \ldots, x_m$
in \( K \) which are \( \delta \)-separated in the sense that \( \text{dist}(x_i, x_j) \geq \delta \) for \( i \neq j \). (Think of \( m+1 \) strongly repelling points, which try to get as far as possible from each other.) Thus

\[
\text{diam}(K) = \text{diam}_1(K) \geq \text{diam}_2(K) \geq \text{diam}_3(K) \geq \cdots \geq 0.
\]

Note that \( \text{diam}_m(K) = 0 \) if and only if \( K \) is a finite set with at most \( m \) elements.

The proof of B.2 now proceeds as follows. Choose \( m \) large enough so that \( K \) can be covered by subsets \( X_1, \ldots, X_m \) of diameter \(< \epsilon'\). It then follows that \( \text{diam}_m(K) < \epsilon' \), since a collection of \( \epsilon' \)-separated points can have at most one point in each \( X_i \). Let \( \delta_{\text{max}} \) be the supremum of the numbers \( \text{diam}_m(K_\alpha) \) as \( K_\alpha \) ranges over all connected components of \( K \). We want to prove that \( \delta_{\text{max}} = 0 \). Otherwise, if \( \delta_{\text{max}} > 0 \), we will obtain a contradiction by constructing a “largest” component \( K_\mu \), with \( \text{diam}_m(K_\mu) \) equal to \( \delta_{\text{max}} \), and then showing that \( \text{diam}_m(f(K_\mu)) > \delta_{\text{max}} \).

Let \( K_\iota \) be a sequence of components of \( K \) such that the numbers \( \delta_i = \text{diam}_m(K_\iota) \) converge to the supremum \( \delta_{\text{max}} \), and choose points \( x_0(i), x_1(i), \ldots, x_m(i) \in K_\iota \) which are \( \delta_i \)-separated. After passing to a subsequence, we may assume that each sequence \( x_j(1), x_j(2), x_j(3), \ldots \) converges to a limit \( x_j \in K \). Let \( L \) be the set of all accumulation points of \( \{K_\iota\} \) as \( i \to \infty \). Then \( L \) is connected, and hence is contained in some connected component \( K_\mu \). Furthermore \( \text{diam}_m(K_\mu) = \delta_{\text{max}} \) since \( L \) contains \( m+1 \) points \( x_j \) which are \( \delta_{\text{max}} \)-separated.

Now, assuming that \( \delta_{\text{max}} > 0 \), we will obtain a contradiction by showing that \( \text{diam}_m(f(K_\mu)) \) must be strictly larger than \( \delta_{\text{max}} \). In fact, for each \( 0 \leq i < j \leq m \) we have either

\[
\text{dist}(f(x_i), f(x_j)) > \text{dist}(x_i, x_j) \geq \delta_{\text{max}},
\]

or else

\[
\text{dist}(f(x_i), f(x_j)) \geq \epsilon' > \text{diam}_m(K) \geq \delta_{\text{max}}.
\]

This contradiction proves that \( \delta_{\text{max}} \) must be zero. Hence every connected component \( K_\alpha \) is finite, and hence consists of a single point. This proves B.2. \( \Box \)

**Proof of B.1.** In one direction this is clear, since a totally disconnected set cannot separate the Riemann sphere. For the proof in the other direction, suppose that all critical values lie in a single Fatou component \( U \). Choose a smoothly embedded closed disk \( \Delta^* \subset U \) which contains all of the critical values in its interior. Let \( \Delta = \hat{\mathbb{C}} \setminus \text{interior}(\Delta^*) \) be the complementary closed disk which contains the Julia set. Since \( \Delta \) contains no critical values, its pre-image \( f^{-1}(\Delta) \) splits as a disjoint union

\[
f^{-1}(\Delta) = \Delta_1 \cup \cdots \cup \Delta_n
\]

of smoothly embedded closed disks, each of which maps homeomorphically onto \( \Delta \) under \( f \). Now every connected component \( J_\alpha \) of the Julia set must be contained in one of the \( \Delta_j \), and hence must map homeomorphically under \( f \). Thus, to prove B.1, we need only show that \( f \) restricted to the Julia set is locally distance increasing with respect to a suitably chosen metric. In fact we will prove the following. (For related statements, see [DH1] and [TY].)

**Lemma B.3.** A rational map \( f \), restricted to its Julia set \( J \), is locally distance increasing with respect to a suitably chosen metric if and only if \( f \) has no critical points in \( J \).
**Proof of B.3.** If there is a critical point \( c \) in the Julia set \( J \), then \( f|_J \) is not even one-to-one near \( c \), so it certainly cannot be locally distance increasing. Suppose then that there are no critical points in \( J \). Let \( P \) be the closure of the postcritical set of \( f \) (the union of all forward orbits of critical values). If we exclude trivial cases where \( P \) has only two elements, then each connected component of the complement \( U = \hat{\mathbb{C}} \setminus P \) has a well defined Poincaré metric. The associated Poincaré distance function will be denoted by \( \text{dist}_U(x, y) \).

Let \( U_0 = f^{-1}(U) \subset U \). Then \( f \) maps \( U_0 \) onto \( U \) by a covering map. Since \( U_0 \) is a proper subset of \( U \), it follows that

\[
\text{dist}_U(x, y) < \text{dist}_{U_0}(x, y) = \text{dist}_U(f(x), f(y))
\]

for any two points \( x \neq y \) in \( U_0 \) which are sufficiently close to each other. Thus \( f \) is locally distance increasing on \( U_0 \) with respect to the metric \( \text{dist}_U \).

Since there are no critical points in \( J \), it follows from the Sullivan classification of Fatou components that every critical orbit must converge to an attracting or parabolic cycle. Therefore the intersection \( \Pi = P \cap J \) can be described as the set of all parabolic periodic points. If there are no parabolic points, then \( J \subset U_0 \), and it follows that \( f \) is locally distance increasing on \( J \) with respect to the metric \( \text{dist}_U \). However, if \( f \) has parabolic points, then the Poincaré metric becomes infinite at such points. We will modify this metric near these points so as to obtain a better behaved metric.

It will be convenient to choose coordinates so that the Julia set \( J \) is contained in the finite plane \( \mathbb{C} \). The Poincaré metric on \( U = \hat{\mathbb{C}} \setminus P \) has the form \( \rho(z)|dz| \) throughout \( U \cap \mathbb{C} \), where \( \rho \) extends to a function

\[
\rho : \mathbb{C} \to (0, \infty]
\]

which is continuous everywhere, but takes the value \(+\infty\) on the points of \( P \cap \mathbb{C} \). In particular, \( \rho(z) \) tends to infinity as \( z \) tends to any point in the set \( \Pi = P \cap J \) of parabolic points. First suppose that these parabolic points are all fixed under \( f \), with multiplier \(+1\).

Let \( M > 0 \) be a constant which is large enough so that

\[
M > \frac{\rho(z)}{|f'(z)|}
\]

for every \( z \) in the finite set \( f^{-1}(\Pi) \setminus \Pi \). (This ratio \( \rho(z)/|f'(z)| \) is always finite at the points of \( f^{-1}(\Pi) \setminus \Pi \), since such points are non-critical and outside \( P \).) Let \( N_\epsilon(\Pi) \) be the open neighborhood of Euclidean radius \( \epsilon \) about the parabolic set \( \Pi \). We define a new Riemannian metric \( \eta(z)|dz| \) on the open set \( U' = N_\epsilon(\Pi) \cup (\hat{\mathbb{C}} \setminus P) \) by setting

\[
\eta(z) = \begin{cases} 
M & \text{for } z \in N_\epsilon(\Pi), \\
\rho(z) & \text{for } z \not\in N_\epsilon(\Pi).
\end{cases}
\]

This function \( \eta \) has a jump discontinuity on the circle of radius \( \epsilon \) about each parabolic point; but this will not cause any difficulty. As usual, we use this Riemannian metric to define a distance \( \text{dist}_\eta(x, y) \) between points of \( U' \) as the infimum of lengths

\[
\text{length}_{\eta}(\Gamma) = \int_{\Gamma} \eta(z)|dz| ,
\]

where \( \Gamma \) ranges over all piecewise smooth paths joining the two points within \( U' \).

*If \( \epsilon \) is sufficiently small, then we will prove that \( f|_J \) is locally distance increasing with respect to this metric \( \text{dist}_\eta \).*
Since \( \eta(\Pi) = \infty \), we can certainly choose \( \epsilon \) small enough so that \( \rho(z) > M \) throughout the neighborhood \( N_{2\epsilon}(\Pi) \). Evidently this will guarantee that any Euclidean straight line segment lying within \( N_{\epsilon}(\Pi) \) is the unique \( \eta \)-geodesic of minimal \( \eta \)-length joining its endpoints. To study behavior of \( f \) near a parabolic point \( z_0 \), we proceed as follows. Assuming for convenience that \( z_0 = 0 \), we can write the local power series expansion as

\[
f(z) = z \left( 1 + az^m + \text{(higher terms)} \right),
\]

where \( m \leq 1 \) and \( a \neq 0 \). Using the Leau-Fatou Flower Theorem, we obtain the estimate

\[
\frac{az^m}{|az^m|} \to 1
\]
as \( z \to 0 \) within the Julia set \( J \). Hence

\[
f(z) = z \left( 1 + |az|^m + o(z^m) \right), \quad f'(z) = 1 + (m + 1)|az|^m + o(z^m)
\]
as \( z \to 0 \) within \( J \). It follows easily that \( f|_J \) is distance increasing throughout some neighborhood of each parabolic point. Furthermore, if \( \epsilon' \) is sufficiently small, it follows that

\[
|f(z)| > |z| \quad \text{and} \quad |f'(z)| > 1 \quad \text{for} \quad 0 < |z| < \epsilon'
\]

To prove that \( f \) is locally distance increasing at points of \( J \setminus \Pi \) we will prove the infinitesimal form of the required inequality. That is we will prove that

\[
\eta(f(z)) |f'(z)| > \eta(z)
\]
throughout \( J \setminus \Pi \), and hence that

\[
\int \eta(f(z)) |df(z)| = \int \eta(f(z)) |f'(z)| \, dz > \int \eta(z) |dz|
\]
for any path \( \Gamma \) in some neighborhood of \( J \setminus \Pi \). There are four cases to consider: If both \( z \) and \( f(z) \) belong to \( N_{\epsilon}(\Pi) \), then (29) follows from (28). If neither \( z \) nor \( f(z) \) belongs to \( N_{\epsilon}(\Pi) \), then it follows from the corresponding property of the Poincaré metric. If \( z \) belongs to \( N_{\epsilon}(\Pi) \) but \( f(z) \) does not, then it follows since

\[
\eta(f(z)) |f'(z)| = \rho(f(z)) |f'(z)| > \rho(z) > M = \eta(z).
\]
Finally, if \( z \in f^{-1}N_{\epsilon}(\Pi) \setminus N_{\epsilon}(\Pi) \), then we proceed as follows. A compactness argument shows that \( f^{-1}N_{\epsilon}(\Pi) \) shrinks down to \( f^{-1}(\Pi) \) as \( \epsilon \searrow 0 \). Thus, given \( \epsilon' \) we can find \( \epsilon \) so that every point \( z \) of \( f^{-1}N_{\epsilon}(\Pi) \) has Euclidean distance at most \( \epsilon' \) from some point \( \hat{z} \in f^{-1}(\Pi) \). If \( \hat{z} \in \Pi \), then since \( f(z) \in N_{\epsilon}(\Pi) \) it follows from (28) that \( z \in N_{\epsilon}(\Pi) \) also, contradicting the hypothesis that \( z \notin N_{\epsilon}(\Pi) \). On the other hand, if \( \hat{z} \notin \Pi \) then it follows from (25) that \( M |f'(\hat{z})| > \eta(\hat{z}) \). If \( \epsilon \) is sufficiently small, it evidently follows that \( M |f'(z)| > \eta(z) \) also.

This proves B.3 in the special case where every parabolic point is a fixed point of multiplier \( +1 \). To handle the general case, choose a positive integer \( k \) so that every parabolic point of \( f^{\circ k} \) is a fixed point of multiplier \( +1 \), and let \( \text{dist}_{\eta}(x,y) \) be a metric with the required property for \( f^{\circ k} \). Then \( f \) itself will be locally distance increasing on \( J \) with respect to the metric

\[
\text{dist}'(x,y) = \sum_{j=0}^{k-1} \text{dist}_{\eta}(f^{\circ j}(x), f^{\circ j}(y)).
\]
This proves B.3, and completes the proof of B.1.

Next we will prove the following. Let \( f \) be rational of degree \( n \geq 2 \) with Julia set \( J \).

**Lemma B.4.** Suppose that there exists a closed disk \( \Delta^* \subset \hat{\mathbb{C}} \) which:

(a) contains all of the critical values of \( f \) in its interior,
(b) satisfies \( f(\Delta^*) \subset \Delta^* \), and
(c) eventually absorbs every orbit in the Fatou set.

Then \( f|_J \) is topologically conjugate to the one-sided shift on \( n \) symbols.

**Proof.** It follows from (b) that the interior of such a disk \( \Delta^* \) is contained in the Fatou set. Therefore, by (a) and B.1, the Julia set \( J \) is totally disconnected. As in the proof of B.2, the complementary closed disk \( \Delta \) contains \( J \), and \( f^{-1}(\Delta) \) splits as a disjoint union \( \Delta_1 \cup \cdots \cup \Delta_n \), where each \( \Delta_i \) maps homeomorphically onto \( \Delta \). But now we have the additional information that each \( \Delta_i \) is a subset of \( \Delta \). It follows inductively that each finite intersection

\[
\Delta_{i_0 i_1 \cdots i_k} = \Delta_{i_0} \cap f^{-1}(\Delta_{i_1}) \cap \cdots \cap f^{-k}(\Delta_{i_k})
\]

is a closed topological disk. In fact

\[
f : \Delta_{i_0 i_1 \cdots i_k} \xrightarrow{\sim} \Delta_{i_1 i_2 \cdots i_k} \xrightarrow{\sim} \cdots \xrightarrow{\sim} \Delta_{i_k} \xrightarrow{\sim} \Delta,
\]

Now given an infinite sequence \( I = (i_0, i_1, i_2, \ldots) \), it follows that the intersection \( J_I \) of the nested sequence

\[
\Delta_{i_0} \supset \Delta_{i_0 i_1} \supset \Delta_{i_0 i_1 i_2} \supset \cdots
\]

is compact, connected, and non-vacuous. This intersection is contained in the Julia set, since by condition (c) every orbit outside of the Julia set eventually leaves the disk \( \Delta \). Hence by B.1 each \( J_I \) is a single point.

Equivalently, to each point \( z \) of \( J \) we can assign a sequence \( I(z) = (i_0, i_1, i_2, \ldots) \) of integers between 1 and \( n \) by the condition that \( z_j \in D_{i_j} \) where

\[
f : z = z_0 \mapsto z_1 \mapsto z_2 \mapsto \cdots
\]

is the orbit of \( z \). Evidently \( J_I \) consists of the unique point which has symbol sequence equal to \( I \). Since \( f \) maps \( J_I \) to \( J_{\sigma(I)} \), where

\[
\sigma(i_0, i_1, \ldots) = (i_1, i_2, \ldots)
\]

is the shift operator, this proves that the correspondence \( z \mapsto I(z) \) is a topological conjugacy from \( f|_J \) onto the one-sided shift on \( n \) symbols.

We will only try to apply this lemma in the following very special case.

**Theorem B.5.** If \( f \) has only two critical values, both in the same Fatou component, then \( f|_J \) is topologically conjugate to a one-sided shift.

Note: The hypothesis that \( f \) has only two critical values implies that \( f \) has only two critical points (making use of the fact that the twice punctured sphere has free cyclic fundamental group). By way of contrast, a Chebyshev polynomial of degree \( n \geq 3 \) has only three distinct critical values on the Riemann sphere but has \( n \) distinct critical points.

**Proof of B.5.** Let \( U_0 \) be a simply connected open set bounded by a smooth Jordan curve, which satisfies \( f(U_0) \subset U_0 \), and which eventually absorbs every orbit in the Fatou
set. Thus in the hyperbolic case $U_0$ will be a neighborhood of the attracting point, while in the parabolic case $U_0$ will be a carefully chosen attracting petal. We can assume that the boundary of $U_0$ is disjoint from the two critical orbits. Now define a sequence of connected open sets with smooth boundary

$$U_0 \subset U_1 \subset U_2 \subset \cdots$$

by setting $U_{k+1}$ equal to the connected component of $f^{-1}(U_k)$ which contains $U_k$. If $U_k$ is simply connected and contains at most one critical value, then it is easy to show that $U_{k+1}$ is also simply connected. Thus we can continue this construction until we obtain some $U_m$ which contains both critical values. The closure $\overline{U}_m$ will then be the required disk $\Delta^*$, so that we can apply B.4. □

### Appendix C. Cross-Ratio Formulas.

In 1.6 we saw that the invariant $X$ of 1.1 can be defined as a cross-ratio. This appendix will give corresponding formulas for the invariants $Y_1$ and $Y_2$. I will use the nonstandard notation

$$\begin{pmatrix} p & q \\ r & s \end{pmatrix} = \frac{(p-q)(r-s)}{(p-r)(q-s)} \in \hat{\mathbb{C}}$$

(product of row differences, divided by product of column differences). This cross-ratio symbol can be characterized as follows. It is well defined unless three of the four points $\begin{pmatrix} p & q \\ r & s \end{pmatrix}$ in $\hat{\mathbb{C}}$ coincide, and it takes the value:

\[
\begin{cases}
0 & \text{if two entries in the same row are equal}, \\
\infty & \text{if two entries in the same column are equal}, \\
1 & \text{if two diagonally opposite entries are equal}.
\end{cases}
\]

Furthermore, if three of the four variables $p, q, r, s$ are fixed and distinct, then it represents a Möbius transformation of the remaining variable.

As an example, since a Möbius transformation which fixes three points is the identity, it follows that

$$\begin{pmatrix} x \\ \infty \end{pmatrix} = x.$$

Furthermore, it follows easily that

$$\frac{\phi(p) \phi(q)}{\phi(r) \phi(s)} = \begin{pmatrix} p & q \\ r & s \end{pmatrix}$$

for any Möbius transformation $\phi$. This symbol is independent of the order of rows or columns, that is it satisfies the symmetry relations

$$\begin{pmatrix} p & q \\ r & s \end{pmatrix} = \begin{pmatrix} r & s \\ p & q \end{pmatrix} = \begin{pmatrix} s & r \\ q & p \end{pmatrix} = \begin{pmatrix} q & p \\ s & r \end{pmatrix}.$$

Now let $c_1$ and $c_2$ be the critical points of the bicritical map $f$, let $v_i = f(c_i)$ be the critical values, and let $p_i \in f^{-1}(c_i)$ be any one of the $n$ preimages of $c_i$. For example, using the usual normal form

$$f(z) = (az^n + b)/(cz^n + d),$$
we can take
\[ c_1 = \infty, \quad v_1 = a/c, \quad p_1 \in \sqrt[4]{d/c} \]
\[ c_2 = 0, \quad v_2 = b/d, \quad p_2 \in \sqrt[4]{-b/a}. \]

Using these notations, we can write 1.6 in the form
\[ \frac{c_1}{c_2} \frac{v_1}{v_2} = \frac{-v_2}{v_1 - v_2} = \frac{-b/d}{a/c - b/d} = \frac{-bc}{ad - bc} = -X. \]

Now consider the cross-ratio
\[ \frac{c_1}{c_2} \frac{v_1}{v_2} = \frac{p_1}{v_2} = \frac{n}{\sqrt[d]{-c}}. \]

This is well defined only up to multiplication by an \( n \)-the root of unity. However its \( n \)-th power
\[ \left( \frac{c_1}{c_2} \frac{v_1}{v_2} \right)^n = \frac{-d/c}{b^n/d^n} = \frac{-d_{n+1}}{b^n c^n} \]
is always well defined as an element of \( \hat{\mathbb{C}} \). If \( c \neq 0 \) then we can multiply numerator and denominator by \( c^{n-1} \), thus reducing this expression to the form
\[ \left( \frac{c_1}{c_2} \frac{v_1}{v_2} \right)^n = \frac{-c_{n-1} d_{n+1}}{b^n c^n} = \frac{-c_{n-1} d_{n+1}}{(ad - bc)^n} \left( \frac{bc}{ad - bc} \right)^{-n} = \frac{-Y}{X^n}. \quad (30) \]

This proves that we can compute \( Y_2 \) by a cross-ratio whenever \( X \neq 0 \). Still assuming that \( c \neq 0 \), we can also consider the expression
\[ \left( \frac{c_1}{c_2} \frac{v_1}{v_2} \right)^n = \frac{p_1}{v_1} = \frac{-d/c}{a^n/c^n} = \frac{-d_{n+1}}{a^n d^n} = \frac{-Y_2}{(X + 1)^n}. \quad (30') \]

Note that the left side of \( (30') \) is indeterminate if and only if \( c = 0 \), or equivalently if and only if \( c_1 = v_1 = p_1 \). But whenever this happens, it follows that \( Y_2 = 0 \). Since \( X \) and \( X + 1 \) cannot both be zero, this shows that we can compute \( Y_2 \) in all cases. Interchanging the roles of the two critical points, we find similar expressions for \( Y_1 \).

**Appendix D: Entire and Meromorphic Maps**

Douady has pointed out to me that there is an analogous theory of entire transcendental or meromorphic maps which have only two singular values.

**Lemma D.1.** Suppose that \( f : U \to \hat{\mathbb{C}} \) is a holomorphic map with only two singular values, say \( v_1 \) and \( v_2 \), where \( U \) is a connected open subset of \( \hat{\mathbb{C}} \). If \( f \) has infinite degree, then \( U \) must be the complement of a single point \( s \in \hat{\mathbb{C}} \), and \( f \) must map \( \hat{\mathbb{C}} \setminus \{ s \} \) onto \( \hat{\mathbb{C}} \setminus \{ v_1, v_2 \} \) by a free cyclic covering map.

Here, by a **singular value** \( v \in \hat{\mathbb{C}} \) we mean either a critical value, or an asymptotic value for the map \( f \). (By definition, \( z \) is an asymptotic value if it can be described as the limit \( z = \lim_{t \to 1} f(p(t)) \) where \( p : [0, 1) \to U \) is a path which eventually leaves any compact subset of \( U \).) The Lemma asserts that the \( f \) in question cannot have any critical values, so we could equally well describe it as a map with two asymptotic values.
For a quite different characterization of this family of maps see [DK2].

Proof of D.1. It is not difficult to see that \( f \) must carry the complement \( U \setminus f^{-1}\{v_1, v_2\} \) onto \( \hat{\mathbb{C}} \setminus \{v_1, v_2\} \) by a covering map. Since the fundamental group of the image space is cyclic, this can only be a cyclic covering. If it has infinite degree, then it must be a universal covering. Hence \( U \setminus f^{-1}\{v_1, v_2\} \) must be conformally equivalent to the universal covering of \( \hat{\mathbb{C}} \setminus \{v_1, v_2\} \), or in other words to \( \mathbb{C} \) itself. Since \( U \) cannot be the entire Riemann sphere, this proves that \( U = \hat{\mathbb{C}} \setminus \{s\} \) for some unique point \( s \), and that

\[
  f : U \rightarrow \hat{\mathbb{C}} \setminus \{v_1, v_2\}
\]

is a free cyclic covering map. Note that \( f \) has an essential singularity at \( s \). \( \Box \)

If we put the two singular values at zero and infinity, then one example of a universal covering of \( \hat{\mathbb{C}} \setminus \{v_1, v_2\} = \mathbb{C} \setminus \{0\} \) is given by the exponential map

\[
  \exp : \mathbb{C} \rightarrow \mathbb{C} \setminus \{0\}.
\]

Hence \( f \) can be described as the composition \( f = \exp \circ \mu \), where \( \mu \) is some conformal isomorphism from \( \hat{\mathbb{C}} \setminus \{s\} \) onto \( \mathbb{C} \). Evidently we can express any such \( \mu \) as a Möbius transformation

\[
  \mu(z) = \frac{az + b}{cz + d} \quad \text{with} \quad ad - bc \neq 0,
\]

so that

\[
  f(z) = \exp \circ \mu(z) = \exp \left( \frac{az + b}{cz + d} \right), \quad (31)
\]

with essential singularity at \( s = -d/c \in \hat{\mathbb{C}} \).

In practice, it will be convenient to conjugate \( f = \exp \circ \mu \) by \( \mu \), so as to obtain a normal form

\[
  g = \mu \circ f \circ \mu^{-1} = \mu \circ \exp.
\]

Thus

\[
  g(w) = \frac{ae^w + b}{ce^w + d},
\]

or equivalently \( g(2w) = \frac{ae^w + be^{-w}}{ce^w + de^{-w}} \). The essential singularity of \( g \) is at infinity, and its singular values are \( v_1 = a/c \) and \( v_2 = b/d \). Note the identity

\[
  g(w + 2\pi i) = g(w).
\]

In fact we can describe \( g \) as a composition

\[
  \mathbb{C} \xrightarrow{\text{projection}} \mathbb{C}/2\pi i \mathbb{Z} \xrightarrow{\cong} \hat{\mathbb{C}} \setminus \{a/c, b/d\}.
\]

Since this description is rather rigid, we are free to change the coordinate \( w \) only by a translation, or a sign change followed by translation. If we conjugate \( g \) by a translation, then the resulting map \( w \mapsto g(w + t) - t \) has the form \((32)\) with matrix of coefficients

\[
  \begin{bmatrix}
    e^t(a - tc) & b - td \\
    e^{t/2}c & d
  \end{bmatrix}
\]

(or equivalently \( \begin{bmatrix}
    e^{t/2}(a - tc) & e^{-t/2}(b - td) \\
    e^{t/2}c & e^{-t/2}d
  \end{bmatrix} \))
if we prefer to work only with unimodular matrices). Thus the additive group of translations
acts on the manifold $\text{PGL}(2, \mathbb{C})$ by a correspondence which we can write as

$$
\Phi_t : \begin{bmatrix} a & b \\ c & d \end{bmatrix} \mapsto \begin{bmatrix} 1 & -t \\ 0 & 1 \end{bmatrix} \begin{bmatrix} a & b \\ c & d \end{bmatrix} \begin{bmatrix} e^{t/2} & 0 \\ 0 & e^{-t/2} \end{bmatrix}.
$$

The difference

$$v_1 - v_2 = \frac{ad - bc}{cd}$$

remains invariant under this transformation, since $v_1$ and $v_2$ are both translated by the
same constant $-t$. Let us define $X$ to be the reciprocal

$$X = \frac{1}{v_1 - v_2} = \frac{cd}{ad - bc} \in \mathbb{C}.$$  \hfill (34)

This number $X$ is a conformal conjugacy invariant. For if we replace $g(w)$ by $-g(-w)$
then the matrix $\begin{bmatrix} a & b \\ c & d \end{bmatrix}$ of coefficients will be replaced by

$$\begin{bmatrix} -1 & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} a & b \\ c & d \end{bmatrix} \begin{bmatrix} 0 & 1 \\ 1 & 0 \end{bmatrix} = \begin{bmatrix} -b & -a \\ d & c \end{bmatrix},$$

so that $(v_1, v_2)$ is replaced by $(-v_2, -v_1)$, and again the expression (34) remains invariant.
Since any coordinate change which carries (32) to another expression of the same form is
a composition of translations and sign changes, it follows that $X$ is indeed a conformal
conjugacy invariant.

We will prove several statements which are reminiscent of the descriptions of moduli
space in §1 and §2. For each fixed $X$, we need one further complex number to give a
complete conjugacy class invariant. Furthermore, given $X(f)$ and given $\lambda \neq 0$, there is
a unique conjugacy class of maps $(f)$ which have a fixed point of multiplier $\lambda$. However,
unlike the finite degree situation of §1, it is necessary to treat the cases $X = 0$ and $X \neq 0$
separately in order to obtain reasonable moduli spaces.

**Entire Transcendental Case.** If $X = 0$, or equivalently if the essential singularity
occurs at one of the two singular values, then putting $s = v_1$ at infinity and putting $v_2$ at
zero, the normal form (32) reduces to

$$g(w) = ke^w \quad \text{for some constant } \quad k \in \mathbb{C} \setminus \{0\}.$$  

Here $k = g'(0)$ is a conjugacy class invariant. Thus we obtain the exponential family, which
has been studied by several authors. (See for example [D].) We could also use the normal
form

$$f(z) = g(kz)/k = e^{kz},$$

again with $s = \infty$ and zero as singular values, and again with invariant $k = f'(0)$. If
we specify that $g$ has a fixed point $w_0 = g(w_0)$ of multiplier $g'(w_0) = \lambda$, then since
$g'(w_0) = g(w_0) = w_0$ it follows that $w_0 = \lambda$, and hence that the invariant $k = w_0 e^{-w_0}$ is
uniquely determined by $\lambda$.

**Meromorphic Case.** If $X \neq 0$, or equivalently if the three distinguished points
$s, v_1, v_2$ are pairwise distinct, then $g : \mathbb{C} \to \hat{\mathbb{C}} \setminus \{v_1, v_2\}$ is a meromorphic map. (For a
survey of meromorphic dynamics, see [Be].) In analogy with §1 we will construct a conjugacy
invariant $Y = Y_1 + Y_2$. Let

$$Y_1 = \frac{c}{d} \exp \frac{a}{c}, \quad Y_2 = \frac{d}{c} \exp -\frac{b}{d},$$

with product

$$Y_1 Y_2 = \exp \left( \frac{a-b}{c} \right) = \exp \left( \frac{ad-bc}{cd} \right) = e^{1/X}.$$  \hspace{1cm} (37)

Then it is not difficult to check that both $Y_1$ and $Y_2$ are invariant under the action (33), and that $Y_1$ and $Y_2$ are interchanged by the transformation (35). Hence the sum $Y = Y_1 + Y_2$ is a conjugacy class invariant. The two quantities $Y_1$ and $Y_2$ individually will be described as half-invariants, since only the unordered pair $\{Y_1, Y_2\}$ is actually a conjugacy invariant.

Lemma D.2. The moduli space for meromorphic maps with two singular values is biholomorphic to $(\mathbb{C} \setminus \{0\}) \times \mathbb{C}$, with coordinates $X$ and $Y$.

Cross-Ratios. Just as in Appendix C, we can express the $Y_i$ as cross-ratios. For example, using the normal form (31), one easily checks that:

$$\frac{v_1}{f(v_1)} + s = -Y_1.$$  \hspace{1cm} (38)

However, it does not seem possible to compute the invariant $X$ as a cross-ratio.

Bad Topology. It might seem natural to combine the moduli space for the exponential family, together with the moduli space for our meromorphic family, into a larger moduli space, isomorphic to a union $(\mathbb{C} \setminus \{0\}) \cup (\mathbb{C} \setminus \{0\}) \times \mathbb{C}$. However this does not yield any useful result since the natural topology on the union is not Hausdorff. To see this, consider the two maps $z \mapsto e^z$ and $z \mapsto 2e^z$ in the exponential family. Although these are not conjugate, I will show that given any neighborhood $N_1$ of the first and any neighborhood $N_2$ of the second within the space of maps with two singular values, some map in $N_1$ is conjugate to a map in $N_2$. Consider the analytic function $\xi \mapsto 2\xi^2 e^{1/\xi}$, which has an essential singularity at the origin. Since this function omits the values 0 and $\infty$, it follows from Picard’s Theorem that we can choose a sequence of values of $\xi$ tending to zero which satisfy the equation $2\xi^2 e^{1/\xi} = 1$. For each such $\xi$, consider the two meromorphic maps

$$\frac{e^w}{\xi^2 e^w + 1} \quad \text{and} \quad \frac{2e^w}{2\xi^2 e^w + 1}.$$  \hspace{1cm} (39)

A brief computation shows that both have invariants $X = \xi$ and $Y = \xi e^{1/\xi} + 1/\xi$. Hence the two are conjugate, although these sequences tend to non-conjugate limits as $\xi \to 0$. \hspace{1cm} \Box

Comparison with Bicritical Maps. Our invariants for meromorphic maps look rather different from the invariants of §1, but in fact there is a definite relationship. As in [DGH], we
can approximate the exponential map by the unicritical polynomials \( E_n(w) = (1 + w/n)^n \). Hence we can approximate the meromorphic function \( g \) of (32) by the bicritical maps

\[
 g_n(w) = \frac{aE_n(w) + b}{cE_n(w) + d}
\]

throughout any compact subset of \( \mathbb{C} \). A straightforward computation then shows that

\[
 X(g) = \lim_{n \to \infty} X(g_n)/n \quad \text{and that} \quad Y_1(g) = \lim_{n \to \infty} Y_1(g_n)/X(g_n)^n.
\]

**The Symmetry Locus.** There is a non-trivial Möbius automorphism which commutes with \( g \) if and only if \( Y_1(g) = Y_2(g) \). In view of (37), this means that

\[
 Y_1 = Y_2 = (Y/2) = \pm e^{1/2x}.
\]

If we choose the plus sign, then the most general example is conjugate to

\[
 g(w) = k\frac{e^w - 1}{e^w + 1} = k\tanh(w/2),
\]

with a fixed point of multiplier \( k/2 \) at the center of symmetry. Here \( Y_1 = Y_2 = e^k \) and \( X = 1/2k \). (For a discussion of the tangent family, see for example [DK1].) If we choose the minus sign, then we can take

\[
 g(w) = k\frac{e^w + 1}{e^w - 1} = k\coth(w/2).
\]

This is just the image of \( k\tanh(w/2) \) under the involution \( g \mapsto J_g \circ g \) of 1.5.

**Fixed Points and the Curves** Per1(\( \lambda \)). Suppose that \( g \) has a fixed point \( w_0 = g(w_0) \) with multiplier \( \lambda = g'(w_0) \). We will prove that the conjugacy class \( (g) \) is uniquely determined by \( X(g) \) together with \( \lambda \). We again use the normal form (32), but now we translate coordinates so that the fixed point is at the origin. Then the fixed point equation 0 = \( g(0) \) reduces to the equation \( a + b = 0 \). If \( ad - bc = 1 \), we have \( X = cd \), and we see easily that \( g'(0) = 1/(c + d)^2 \) so that \( c + d = \pm 1/\sqrt{\lambda} \) is uniquely determined up to sign. Hence we can solve for the unordered pair \( \{c, d\} \) up to sign. We can then solve for \( a \) and \( b = -a \) since \( ad - bc = a(c + d) = 1 \). Thus the conjugacy class is uniquely determined. Multiplying all coefficients by a common constant, this solution can be written as

\[
 \begin{bmatrix}
 a \\
 b \\
 c \\
 d
 \end{bmatrix} = \begin{bmatrix}
 2\lambda & -2\lambda \\
 1 + r & 1 - r
 \end{bmatrix}
\]

with determinant \( ad - bc = 4\lambda \), where \( r^2 = 1 - 4\lambda X \neq 1 \). From this, one can easily write down a precise but somewhat complicated formula for the invariant \( Y \) as a function of \( \lambda \) and \( X \). This function is holomorphic, since it can be expressed as the sum of a power series, convergent for \( |r| < 1 \), in which only even powers of \( r \) appear.

**Real forms.** A meromorphic map with two singular values commutes with some anti-holomorphic involution \( \alpha \) if and only if the invariants \( X \) and \( Y \) are both real. (Compare §5.) If \( Y^2 > 4e^{1/X} \), then the half-invariants \( Y_1, Y_2 \) are also real, and the singular values are fixed by \( \alpha \). In this case, using the normal form (32) with real coefficients, the map \( g \) carries \( \mathbb{R} \) diffeomorphically onto an open interval in \( \mathbb{R} \cup \{\infty\} \), bounded by the two singular values. On the other hand, if \( Y^2 < 4e^{1/X} \), then the half-invariants \( Y_1, Y_2 \) are complex conjugate, and the singular values are interchanged by \( \alpha \). In this case we can use a normal
form
\[ z \mapsto \frac{a \tan(z) + b}{c \tan(z) + d} \]
with real coefficients. These maps carry \( \mathbb{R} \) onto \( \mathbb{R} \cup \infty \) by a composition
\[ \mathbb{R} \xrightarrow{\text{projection}} \mathbb{R}/\pi \mathbb{Z} \xrightarrow{\sim} \mathbb{R} \cup \{\infty\}, \]
with degree \( \pm \infty \). On the symmetry locus, with \( Y^2 = 4 e^{1/2} \), there are two possible choices for \( \alpha \) and we can use either normal form.
