RELAXED ATTENTION:
A SIMPLE METHOD TO BOOST PERFORMANCE OF END-TO-END AUTOMATIC SPEECH RECOGNITION

ABSTRACT
Recently, attention-based encoder-decoder (AED) models have shown high performance for end-to-end automatic speech recognition (ASR) across several tasks. Addressing overconfidence in such models, in this paper we introduce the concept of relaxed attention, which is a simple gradual injection of a uniform distribution to the encoder-decoder attention weights during training that is easily implemented with two lines of code. We investigate the effect of relaxed attention across different AED model architectures and two prominent ASR tasks, Wall Street Journal (WSJ) and Librispeech. We found that transformers trained with relaxed attention outperform the standard baseline models consistently during decoding with external language models. On WSJ, we set a new benchmark for transformer-based end-to-end speech recognition with a word error rate of 3.65%, outperforming state of the art (4.20%) by 13.1% relative, while introducing only a single hyperparameter. Upon acceptance, models will be published on github.

Index Terms— End-to-end speech recognition, encoder-decoder models, relaxed attention, speech transformer

1. INTRODUCTION
End-to-end automatic speech recognition (ASR) gained a lot of interest in the research community as it makes phonetic modeling obsolete and significantly simplifies the processing pipeline while achieving superior performance compared to hidden Markov model (HMM)-based (hybrid) approaches in many prominent ASR benchmark tasks, especially those that comprise large amounts of data [1, 2]. Common end-to-end ASR approaches that directly translate acoustic input sequences into graphemic output sequences are based on connectionist temporal classification (CTC) [3], recurrent neural network transducers (RNN-T) [4], or attention-based encoder-decoder (AED) models [5]. The latter approach emerged from neural machine translation and was soon adopted for ASR [6]. In contrast to early encoder-decoder models that used a fixed-length intermediate representation [7], the attention mechanism uses variable-length attention weight vectors to draw attention to relevant parts of the input sequence, yielding significant improvements for long sentences. Prominent AED model architectures are the RNN-based listen-attend-and-spell (LAS) [8], the all-attention-based transformer model [9, 10] and, as a variant of the latter, the conformer model [11].

The problem of overconfidence in AED models is demonstrated in [12], where utterances with high confidence scores of an LAS model contributed to high word error rates (WER). One reason for such behavior is the use of cross entropy between the predicted output token and the ground truth label as a loss function, as it promotes sparse softmax distribu-
This leads to two problems: First, beam search decoding (especially with language models) is less effective as alternatives to a given output token are harder to explore. Second, it is unfavorable for gradient learning as the derivative of the loss function approaches zero when a correct prediction with high confidence is made by the model \cite{14}. Methods to deal with sharp state probability distributions in (hybrid) ASR (often necessary for stream fusion) are stream weighting \cite{15,16,17}, limiting \cite{18}, and the use of temperature in the softmax function \cite{19,14}. One effective method to deal with overconfidence in \textit{end-to-end ASR}, introduced in \cite{20}, is label smoothing that blends the one-hot label with a uniform distribution or assigns part of the probability mass to tokens that are neighbors of the labeled token in the target sequence \cite{14}. Interestingly, label smoothing is also effective against overfitting \cite{21} and thus is commonly used for AED end-to-end ASR besides related regularization methods such as spectral augmentation \cite{22}, dropout \cite{23}, multi-task learning with an additional CTC loss \cite{24,25}, and the recently proposed multi-encoder-learning that uses additional encoders only during training \cite{26}. Regularization methods applied to the crucial encoder-decoder attention mechanism in AED models were only recently discovered in \cite{27}, where CTC predictions in a multi-task learning setup are used to focus the attention in transformer models \cite{27} to relevant frames in the encoded input sequence.

In this paper we introduce relaxed attention, a simple adjustment to the encoder-decoder attention weights during training to reduce overconfidence in AED-based end-to-end speech recognition without adding learnable parameters to the standard model architecture. Different to label smoothing, relaxed attention injects a uniform distribution to the probabilistic attention weights (here: not the labels!) to prevent the attention from being overly focused on the encoder input frames. Relaxed attention can easily be implemented in end-to-end ASR toolkits with two lines of code. We investigate the effect of relaxed attention across several attention-based encoder-decoder models, namely the LAS and the transformer model, and across two different tasks (i.e., Wall Street Journal and Librispeech). We also investigate the influence of relaxed attention on the overconfidence problem by analyzing the AED models with and without integration of external RNN-based language models.

The paper is structured as follows: Section 2 revises AED models and the attention mechanism to introduce our relaxed attention approach. Section 3 provides details of our conducted experiments, whose results are presented and discussed in Section 4. Section 5 concludes the paper.

2. RELAXED ATTENTION

2.1. Attention-Based Encoder-Decoder Models

Attention-based encoder-decoder (AED) approaches to end-to-end automatic speech recognition (e.g., the herein used transformer and LAS architectures, shown in Figures 2(a) and 2(b) respectively) comprise an encoder and a decoder network to transform an input feature vector sequence $x_{1:T}^e$ of dimension $F$ and length $T$ to a sequence of output tokens $c_{1:L}^d$ with $c_{\ell} \in C = \{c^{(1)}, c^{(2)}, \ldots, c^{(D)}\}$ being a single output token (i.e., grapheme-based characters or subword units \cite{28}) at output sequence index $\ell \in \{1, \ldots, L\}$ from a vocabulary of size $D$. First, the original feature sequence $x_{1:T}^e$ is commonly preprocessed by several convolutional neural network
(CNN) layers to a subsampled representation that is indexed by \( t \in \{1, \ldots, T\} \), with \( T < \bar{T} \). While first approaches towards streaming encoder-decoder models exist \([29, 30]\), in this work the encoder network computes a hidden representation \( h_i^T = \text{ENC}(x_i^\bar{T}) \) for all \( T \) frames that must be available at the start of decoding. For each decoding step (starting at \( \ell = 1 \)), the decoder of the respective model uses the encoded input sequence \( h_i^T \) and the previous output token \( c_{\ell-1} \) to output a vector \( P_\ell = \text{DEC}(h_i^T, c_{\ell-1}) \) comprising probabilities of all output tokens \( c_\ell \). These probabilities are then subject to a greedy or beam search algorithm which step-by-step invokes the decoder until some end-of-sentence (EOS) threshold is reached and the final hypothesis is emitted.

To gather information, which timesteps \( t \) in the encoded input sequence are relevant for decoding of the output sequence at step \( \ell \), AED models use the attention mechanism that internally computes attention weights containing probabilistic information about relevant input times \( t \).

In the following, we will revise attention types for the two most common AED models that we used in our work. As our proposed relaxed attention is applied only during training, the notations in the following sections hold for the training scenario, where the transformer model is able to train all \( L \) output timesteps during decoding in parallel, while the LAS model decodes the output sequence step-by-step.

### 2.2. Scaled Dot Product Attention (Transformer)

The standard scaled dot product multi-head attention (MHA), introduced in \([9]\), is the common attention type in several layers of transformer AED models (i.e., each encoder and decoder block cf. Figure 2(a) to model temporal dependencies without using recurrent layers. While it is implemented as self-attention employed in the encoder blocks, here we focus on the encoder-decoder attention in the decoder blocks (cf. Figure 3) which draws the decoders’ attention to relevant parts in the encoded input sequence \( h_i^T \in \mathbb{R}^{T \times d} \). The standard MHA (yellow block) employs multiple attention heads

\[
Z_i(Q, K, V) = \text{softmax} \left( \frac{QW_i^{(Q)}(KW_i^{(K)})^T}{\sqrt{d}} \right) \cdot VW_i^{(V)} \in \mathbb{R}^{L \times \frac{d}{N_h}}
\]

with \( W_i^{(Q)}, W_i^{(K)}, W_i^{(V)} \in \mathbb{R}^{d\times d} \) being linear projection weight matrices for the query \( Q \), key \( K \), and value \( V \) inputs, \( i \in \mathbb{N}_h = \{1 \ldots N_h\} \) being the index of the in total \( N_h \) attention heads, and \( d \) is the feature vector size being used in most layers of the transformer model. For encoder-decoder attention, key and value inputs stem from the encoder’s last layer, yielding \( K_{\|V\|=h_i^T} \). The entries in each of the \( L \) rows of the attention weight matrix \( G_i(Q, K) \in \mathbb{R}^{L \times T} \), with \( I = [0, 1] \), sum up to one and are treated as probabilities that correspond to the relevance of a time frame \( t \) to the decoding at step \( \ell \). The outputs \( Z_i \) of all \( N_h \) separate attention heads are concatenated and subject to a fully connected output layer, yielding the MHA output \( Z \in \mathbb{R}^{L \times d} \). Note that for brevity of notation the attention dropout commonly applied to the attention weights in transformer models is not shown in (1).

### 2.3. Bahdanau Attention (LAS)

Additive attention, also known as Bahdanau attention, was proposed in \([5]\) and is the common attention type for the LAS model, shown here in Figure 2(b) during inference, yielding a singleton dimension \((\ldots \times 1 \times \ldots)\) in the decoder block tensors, as the decoder is invoked step by step. Dropout layers \([23]\) are in dashed-line boxes. Details of the multi-head attention block (yellow) are shown in Fig. 1 for the training case.

![Fig. 3: Single decoder block](image-url)

Additive attention, also known as Bahdanau attention, was proposed in \([5]\) and is the common attention type for the LAS model, shown here in Figure 2(b) during inference, yielding a singleton dimension \((\ldots \times 1 \times \ldots)\) in the decoder block tensors, as the decoder is invoked step by step. Dropout layers \([23]\) are in dashed-line boxes. Details of the multi-head attention block (yellow) are shown in Fig. 1 for the training case.
for each timestep $\ell$, with $g_{\ell,t}$ being an element of the vectorial attention weights $g_{\ell} \in \mathbb{R}^{1 \times d_e}$, $h_t \in \mathbb{R}^{1 \times d_e}$ being a single vector of the encoded input $h_t^1 = V \in \mathbb{R}^{T \times d_e}$ at time index $t$. The attention weights

$$g_{\ell} = \text{softmax} \left( \sigma \cdot \tanh \left( 1 \cdot \text{diag}(Q \cdot W^{(Q)} + b) + VW^{(V)} \right) \right)$$

are computed utilizing the learnable weights $W^{(Q)} \in \mathbb{R}^{d_e \times d_s}$, $W^{(V)} \in \mathbb{R}^{d_e \times d_a}$, $v, b \in \mathbb{R}^{1 \times d_s}$, with $1$ being a $T \times d_a$ matrix with all-ones, $\text{diag}(r)$ of $1 \times d_s$ vector $r$ being its $d_s \times d_s$ diagonal matrix, and $(\cdot)^T$ being the transpose. The query input vector $Q_{\ell} \in \mathbb{R}^{1 \times d_s}$ stems from the first RNN decoder block of the LAS decoder, and $d_e, d_s, d_a$ are dimensions of the encoder, attention, and decoder tensors, respectively (cf. Fig. 2(b)).

2.4. Novel Relaxed Attention

According to (1) and (5), the attention weights for both previously described attention types (i.e., $G_{\ell}(Q, K) \in \mathbb{R}^{L \times T}$ for the scaled dot product MHA, and $g_{\ell}(Q, V) \in \mathbb{R}^{1 \times T}$ for the Bahdanau attention) are of probabilistic nature after the softmax activation function. To prevent overly sharp attention distributions applied in training to the encoded input sequence, our novel relaxed attention weights for the transformer model are defined as simple as

$$\tilde{G}_{\ell}(Q, K) = \left[ (1 - \gamma) G_{\ell}(Q, K) + \gamma \frac{1}{T} \right], \quad i \in N_h,$$

gradually injecting a uniform distribution (with $1$ here being an $L \times T$ matrix of ones) into the standard attention weights, controlled by a relaxation coefficient $\gamma \in [0, 1]$, as shown here in Figure 1. For the LAS model with relaxed Bahdanau attention, which we also use for our experiments, the relaxed attention weights for training are defined analogously as

$$\tilde{g}_{\ell} = (1 - \gamma) g_{\ell} + \gamma \frac{1}{T},$$

with $1$ here being a length $T$ row vector of ones.

3. EXPERIMENTAL SETUP

3.1. Databases

We investigate our relaxed attention method on two prominent ASR tasks. First is the 81-hour Wall Street Journal (WSJ) dataset [31] using the dev93 and eval92 splits for evaluation. Second is the 980-hour LibriSpeech dataset [32] with the clean and other conditions of the dev and test datasets. We measure system performance in terms of word error rate (WER) $1 - \frac{N - D - I}{N - S}$, as well as w.r.t. character error rate (CER) for some experiments, where the number of units $N$, deletions $D$, insertions $I$ and substitutions $S$ are calculated on character-level instead of on word-level as for the WER. All raw speech signals are sampled at 16 kHz and analyzed with a 25 ms window and a frame shift of 10 ms.

3.2. Acoustic Frontend

For all experiments the encoder receives a sequence $x_t$ of $T$ feature vectors, each of dimension $F = 83$, composed of standard 80-dimensional filterbank features, extended with 3-dimensional pitch features, both extracted with the Kaldi toolkit [35]. The convolutional neural networks (CNNs) at the input layer, shown as CNN block in Figure 2 consist of a total of four convolutional layers, each using $3 \times 3$ filter kernels. As the second and forth convolutional layer use a stride of 2 in both temporal and frequency direction, the input sequence length is compressed to $T = \frac{T}{4}$.

3.3. Model Configurations

In the following, we will describe all used model architectures and training configurations. All models were trained using the PyTorch-based Espresso and fairseq toolkits [34] [35] [36]. For the approaches dubbed Baseline, the model architectures are configured exactly according to the recipes available within the Espresso toolkit. For our new Relaxed Attention approach, we extended the respective baseline models with our simple modification according to (4) or (5). All models were trained using the Adam optimizer with cross-entropy loss and temporal label smoothing of 0.1 for Librispeech, and 0.05 for WSJ. We follow [10] for tri-stage learning rate scheduling with a maximum learning rate of 0.001. For Librispeech experiments, we also used spectral augmentation [22]. No speed perturbation or multi-task learning (as common in [37] [38]) was employed.

3.3.1. Listen-Attend-and-Spell (LAS)

The encoder of the LAS model incorporates three RNN encoder blocks (cf. 2(b)) each consisting of a dropout layer followed by a single bidirectional long-short term memory (LSTM) layer of size $d_e = 640$. The Bahdanau attention uses an internal attention dimension of $d_a = 320$. Each of the three RNN decoder blocks first concatenates both inputs before applying a single unidirectional LSTM layer with output size $d_a = 320$. All RNN decoder blocks also employ residual connections and dropout layers before the LSTM layers. The LAS model was trained for 35 epochs and employed a dropout of 0.4.

3.3.2. Transformer

The transformer used in our work follows the standard architecture as introduced in [9] and is shown in Figures 2(a) and 1. The encoder uses absolute position embedding on the input that has been preprocessed by the acoustic frontend (cf. Sec. 3.2) and incorporates 12 encoder blocks, each consisting of multi-head self-attention (MHSA) and pointwise fully connected layers, while the transformer decoder stacks 6 decoder blocks (cf. Figure 3). For the WSJ experiments, as well as on the 100h training subset of Librispeech, we employ a smaller model size with $d = 256$, $N_h = 4$ attention heads, and

|                |          |               | 0.10       | 6.54    | 3.79    | 4.10    | 2.26    |
|                |          |               | 0.15       | 6.09    | 3.54    | 3.96    | 2.16    |
|                |          |               | 0.20       | 6.14    | 3.45    | 3.91    | 2.16    |
|                |          |               | 0.25       | 6.02    | 3.32    | 3.83    | 2.11    |
|                |          |               | 0.30       | 6.32    | 3.58    | 3.65    | 1.91    |
|                |          |               | 0.35       | 5.80    | 3.24    | 3.65    | 1.85    |
|                |          |               | 0.40       | 5.83    | 3.19    | 3.74    | 1.95    |

3.3.3. Conformer

To further extend our investigations to a larger variety of model architectures, we also employed the recent conformer model [11] for experiments on Librispeech. While using the exact same decoder as the transformer (cf. Fig. 2(a) and Section 3.3.2), the conformer model adds a convolutional module after the MHSA in each encoder block, as well as an additional fully connected module before. For the sake of comparability, our implementation uses absolute positional encoding but otherwise follows [39] with a total of 12 encoder blocks and a convolution kernel size of 31.

3.3.4. Tokenization and Language Model

For WSJ experiments, we trained all acoustic models to output tokens on character level, with a total amount of \(D = 52\) tokens (including special end-of-sentence and blank symbols). We apply a word-based language model (LM) that is able to output character-level tokens by using the lookahead method from [39]. The LM is composed of three LSTM layers, each comprising 1200 neurons totaling in an amount of 112M parameters. For Librispeech we used a total amount of \(D = 5000\) subword output tokens generated with SentencePiece [28], and employ a token-level LM with four LSTM layers and 800 neurons each. During decoding, we use shallow fusion [40] for LM integration according to \(\log P_{\text{final}} = \log P_t + \lambda \log P_{\text{LM}}\) with \(\lambda\) being the language model weight that we keep fixed to the values from the recipes in Espresso \((\lambda = 0.9\) for WSJ, \(\lambda = 0.4\) for Librispeech).

Table 2: Results on WSJ with and without language model (LM) using transformer models without (baseline) or with relaxation (coefficient \(\gamma = 0.35\)). Training of each model was repeated 5 times and averaged.

| Approach | LM | dev93 WER | dev93 CER | eval92 WER | eval92 CER |
|----------|----|-----------|-----------|-----------|-----------|
| Baseline | ✓  | 14.92     | 5.32      | 11.89     | 3.95      |
| Relaxed Attention | ✓  | 16.14     | 5.48      | 12.73     | 4.04      |

4. RESULTS AND DISCUSSION

4.1. Wall Street Journal (WSJ)

Experimental results on the Wall Street Journal task are shown in Table 1. To achieve statistically profound results, model trainings of both Baseline and Relaxed Attention approaches were repeated 5 times (with different seeds for weight initialization) and results were averaged. First, we observe that the WERs for both AED model types (LAS and transformer) are consistently lower with relaxed attention for a wide range of relaxation coefficients. For the LAS model, a WER reduction of 0.28% absolute (from 5.7% to 5.42%) on dev93 corresponds to a relative WER reduction of 7.4% on eval92, when using relaxed attention with \(\gamma = 0.1\). For the transformer model, the best average result on dev93 is achieved with \(\gamma = 0.35\), yielding an average WER of 5.80% on dev93 and 3.65% on eval92, which is an 18% relative improvement on eval92 compared to our own Baseline model (4.45%), and exceeds the current WSJ transformer state of the art by Moriya et al. [25] (4.20%) by 13.1% relative, without adding any model complexity.

Interestingly, we note that the WERs on the eval92 set are consistently decreasing with increasing relaxation (until \(\gamma = 0.35\)) and the single-best result for the transformer model (before averaging, not shown in Table 1) even reaches 5.65% on dev93, with a benchmark WER of 3.19% on eval92.

In a small ablation study shown in Table 2 we investigate the behavior of both Baseline and Relaxed Attention approaches with and without language model (LM). For the optimal transformer relaxation coefficient \(\gamma = 0.35\) that has been found before under use of an LM, relaxed attention training performs suboptimal w/o LM, while with LM we obtain the benchmark results from Table 1. This indicates that even though relaxed attention does not improve performance w/o
Table 3: WER results on Librispeech using transformer and conformer models; relaxation coefficient $\gamma = 0.25$ for the 100 h training set, and $\gamma = 0.2$ for all others. Best results for each training set size and model type are in bold font.

Table 4: WER results of learned relaxation on Librispeech (100 h training set) using transformer model with LM.

| Approach          | $\gamma$ | dev clean | other | test clean | other |
|-------------------|----------|-----------|-------|------------|-------|
| Baseline          | 0        | 11.18     | 24.51 | 12.48      | 26.65 |
| Relaxed Attention | learned  | 10.76     | 24.29 | 11.46      | 26.52 |
|                   | 0.25     | 9.83      | 21.99 | 10.66      | 23.48 |

LM on WSJ, it helps decreasing overconfidence and makes the model perfectly suitable for language model integration.

We additionally performed a further analysis of entropy in the transformer MHA weights w/o LM. During training, by application of (4), the relaxed attention weights $G_i$ have higher entropy compared to $G_i$, as expected. During inference on dev93, the attention weights of the best Relaxed Attention model ($\gamma = 0.35$) yield a 4% higher entropy as compared to the Baseline model, thereby confidence is decreased even without relaxation (3) in inference, giving important degrees of freedom to the LM.

4.2. Librispeech

We choose Librispeech to validate our relaxed attention approach on a large dataset and also evaluate performance on increasing training set sizes in Table 3. We report on transformer-based models as they yield superior performance compared to LAS models on Librispeech (e.g., in [2, 22]). We also use a re-simulated conformer model, which holds the benchmark WERs of 1.9%/3.9% in [11] on the clean / other portions of the test set. All re-simulated models are compared without and with relaxed attention.

In our experiments we note that even without LM, relaxed attention helps in some cases on the larger training sets for both model types, while showing similar behavior as on WSJ on the similar-sized 100 h training set. With LM on the dev set, in 7 out of 8 cases relaxed attention leads to improvements over all training set sizes and models, with particularly consistent improvements in the other condition. On the test set with LM, our relaxed attention for transformer models exceeds Baseline performance in all conditions and all training set sizes, while for the conformer model only an improvement in the other condition is achieved ($\gamma$ hasn’t been optimized for the conformer). Using a standard transformer model trained with the entire 960 h training set, relaxed attention achieves a relative improvement of 4.9% averaged across both test set conditions with LM (5.76% vs. 5.48% absolute WER).

In Table 4 we learned the relaxation coefficient $\gamma$ during training and observe that performance of the learned Relaxed Attention is close to—but yet still lower—than the Baseline approach. This is expected, as relaxed attention (similar to other generalization techniques, e.g., dropout) harms the training loss and thus the learned $\gamma$ values in each decoder block converged towards small values in a range of $[0, 0.03]$ during training in our experiments. We conclude, however, that $\gamma$ should not be learned but manually set to put stress on the network to still learn under relaxed attention.

5. CONCLUSION

In this work we introduced relaxed attention for end-to-end ASR, a simple method that smoothes attention weights in attention-based encoder-decoder models during training to decrease overconfidence of these models. Across a variety of encoder-decoder models, we observe performance gains when our method is used in combination with external language models. Particularly on the WSJ task, transformer models trained with relaxed attention reduce the average word error rate by 13.1% relative compared to state of the art, setting a new benchmark of 3.65% WER on WSJ for transformer-based automatic speech recognition without adding any model complexity in inference.
