Formation of organic nitrates (RONO₂) during oxidation of biogenic volatile organic compounds (BVOCs: isoprene, monoterpenes) is a significant loss pathway for atmospheric nitrogen oxide radicals (NOₓ), but the chemistry of RONO₂ formation and degradation remains uncertain. Here we implement a new BVOC oxidation mechanism (including updated isoprene chemistry, new monoterpene chemistry, and particle uptake of RONO₂) in the GEOS-Chem global chemical transport model with ∼25 × 25 km² resolution over North America. We evaluate the model using aircraft (SEAC^4RS) and ground-based (SOAS) observations of NOₓ, BVOCs, and RONO₂ from the Southeast US in summer 2013. The updated simulation successfully reproduces the concentrations of individual gas- and particle-phase RONO₂ species measured during the campaigns. Gas-phase isoprene nitrates account for 25-50% of observed RONO₂ in surface air, and we find that another 10% is contributed by gas-phase monoterpene nitrates. Observations in the free troposphere show an important contribution from long-lived nitrates derived from anthropogenic VOCs. During both campaigns, at least 10% of observed boundary layer RONO₂ were in the particle phase. We find that aerosol uptake followed by hydrolysis to HNO₃ accounts for 60% of simulated gas-phase RONO₂ loss in the boundary layer. Other losses are 20% by photolysis to recycle NOₓ and 15% by dry deposition. RONO₂ production accounts for 20% of the...
net regional NO\(_x\) sink in the Southeast US in summer, limited by the spatial segregation between BVOC and NO\(_x\) emissions. This segregation implies that RONO\(_2\) production will remain a minor sink for NO\(_x\) in the Southeast US in the future even as NO\(_x\) emissions continue to decline.

1 Introduction

Nitrogen oxide radicals (NO\(_x\) ≡ NO + NO\(_2\)) are critical in controlling tropospheric ozone production (Monks et al., 2015, and references therein) and influencing aerosol formation (Rollins et al., 2012; Ayres et al., 2015; Xu et al., 2015), with indirect impacts on atmospheric oxidation capacity, air quality, climate forcing, and ecosystem health. The ability of NO\(_x\) to influence ozone and aerosol budgets is tied to its atmospheric fate. In continental regions, a significant loss pathway for NO\(_x\) is reaction with peroxy radicals derived from biogenic volatile organic compounds (BVOCs) to form organic nitrates (Liang et al., 1998; Browne and Cohen, 2012). NO\(_x\) loss to organic nitrate formation is predicted to become increasingly important as NO\(_x\) abundance declines (Browne and Cohen, 2012), as has occurred in the US over the past two decades (Hidy et al., 2014; Simon et al., 2015). Despite this increasing influence on the NO\(_x\) budget, the chemistry of organic nitrates remains the subject of debate, with key uncertainties surrounding the organic nitrate yield from BVOC oxidation, the recycling of NO\(_x\) from organic nitrate degradation, and the role of organic nitrates in secondary organic aerosol formation (Paulot et al., 2012; Perring et al., 2013). Two campaigns in the Southeast US in summer 2013 provided datasets of unprecedented chemical detail for addressing these uncertainties: the airborne NASA SEAC\(^4\)RS (Studies of Emissions and Atmospheric Composition, Clouds, and Climate Coupling by Regional Surveys; Toon et al., 2016) and the ground-based SOAS (Southern Oxidants and Aerosols Study). Here we use a ∼25 × 25 km\(^2\) resolution 3-D chemical transport model (GEOS-Chem) to interpret organic nitrate observations from both campaigns, with focus on their impacts on atmospheric nitrogen (N) budgets.

Nitrogen oxides are emitted from natural and anthropogenic sources primarily as NO, which rapidly achieves steady state with NO\(_2\). Globally, the dominant loss pathway for NO\(_x\) is reaction with the hydroxyl radical (OH) to form nitric acid (HNO\(_3\)). In the presence of VOCs, NO\(_x\) can also be lost by reaction with organic peroxy radicals (RO\(_2\)) to form peroxy nitrates (RO\(_2\)NO\(_2\)) and alkyl and multifunctional nitrates (RONO\(_2\)) (O’Brien et al., 1995). Their daytime formation temporarily sequesters NO\(_x\), facilitating its export to more remote environments (Horowitz et al., 1998; Paulot et al., 2012; Mao et al., 2013). RO\(_2\)NO\(_2\) species are thermally unstable at boundary layer temperatures and decompose back to NO\(_x\) on a time scale of minutes, except for the longer-lived peroxyacylnitrates (PANs) (Singh and Hanst, 1981). RONO\(_2\) species can dominate NO\(_x\) loss when BVOC emissions are high and NO\(_x\) emissions are low (Browne and Cohen, 2012; Paulot et al., 2012; Browne et al., 2014) and may be more efficient for reactive N export than PANs (Mao et al., 2013). The amount of NO\(_x\) sequestered by RONO\(_2\) depends on the interplay between BVOC and NO\(_x\) emissions, the RONO\(_2\) yield from BVOC oxidation, and the eventual RONO\(_2\) fate.

RONO\(_2\) chemistry and impacts are illustrated schematically in Fig. 1, starting from reaction of NO\(_x\) with BVOCs (mainly isoprene and monoterpenes) to form RONO\(_2\). The RONO\(_2\)
yield ($\alpha$) from isoprene oxidation by OH has been inferred from laboratory and field experiments to be 4-15% (Tuazon and Atkinson, 1990; Chen et al., 1998; Sprengnether et al., 2002; Patchen et al., 2007; Perring et al., 2009a; Paulot et al., 2009; Nguyen et al., 2014; Xiong et al., 2015). Models have shown nearly this full range of yields to be compatible with RONO$_2$ observations, depending on the chemical mechanism assumed. For example, two models using different isoprene reaction schemes both successfully reproduced observations from a 2004 aircraft campaign (ICARTT) - one assuming a 4% molar yield (Horowitz et al., 2007) and the other assuming an 11.7% molar yield (Mao et al., 2013). The RONO$_2$ yield from monoterpene oxidation by OH is even more uncertain. Laboratory measurements exist only for $\alpha$-pinene, and these show divergent results: 26% (Rindelaub et al., 2015), 18% (Nozière et al., 1999), and 1% (Aschmann et al., 2002, a lower limit due to significant wall losses). RONO$_2$ yields remain a significant uncertainty in BVOC oxidation schemes, with implications for their impacts on NO$_x$ sequestration.

The fate of RONO$_2$ is of central importance in determining whether sequestered NO$_x$ is returned to the atmosphere or removed irreversibly. Many first generation RONO$_2$ (i.e., those formed from NO reaction with BVOC-derived peroxy radicals) have a short lifetime against further oxidation to form a suite of second generation RONO$_2$ (Beaver et al., 2012; Mao et al., 2013; Browne et al., 2014), especially if they are produced from di-olefins such as isoprene or limonene. Laboratory studies indicate little NO$_x$ release during this process (Lee et al., 2014); however, NO$_x$ can be recycled by subsequent oxidation and photolysis of second generation species (Müller et al., 2014). Estimates of the NO$_x$ recycling efficiency, defined as the mean molar percentage of RONO$_2$ loss that releases NO$_x$, range from <5% to >50% for isoprene nitrates (INs) (Horowitz et al., 2007; Paulot et al., 2009), and best estimates depend on assumptions about the IN yield (Perring et al., 2009a). NO$_x$ recycling efficiencies from monoterpene nitrates (MTNs) have not been observed experimentally, but model sensitivity studies have shown a 14% difference in boundary layer NO$_x$ between scenarios assuming 0% versus 100% recycling (assuming an initial 18% MTN yield, Browne et al., 2014). Uncertainty in the NO$_x$ recycling efficiency has a bigger impact on simulation of NO$_x$ and ozone than uncertainty in the RONO$_2$ yield (Xie et al., 2013).

Organic nitrates are more functionalized and less volatile than their BVOC precursors and are therefore more likely to partition to the particle phase. In the Southeast US, Xu et al. (2015) recently showed that particulate RONO$_2$ (pRONO$_2$) make an important contribution to total organic aerosol (5-12%), consistent with in situ observations from other environments (Brown et al., 2009, 2013; Fry et al., 2013; Rollins et al., 2012, 2013). Chamber experiments have shown high mass yields of aerosol from NO$_3$-initiated oxidation of isoprene (15-25%; Ng et al., 2008; Rollins et al., 2009) and some monoterpenes (33-65%; Fry et al., 2014). There is evidence that RONO$_2$ from OH-initiated oxidation also form aerosol, although with lower yields, possibly via multi-functionalized oxidation products (Kim et al., 2012; Lin et al., 2012; Rollins et al., 2012; Lee et al., 2014). pRONO$_2$ are removed either by deposition or by hydrolysis to form HNO$_3$ (Jacobs et al., 2014; Rindelaub et al., 2015). Both losses augment N deposition to ecosystems (Lockwood et al., 2008). Aerosol partitioning competes with photochemistry as a loss for gas-phase RONO$_2$ with impacts for NO$_x$ recycling. Partitioning also competes with gas-phase deposition, and because lifetimes against deposition are much longer for organic aerosols than for gas-phase
precursors (Wainwright et al., 2012; Knote et al., 2015), this process may shift the enhanced N deposition associated with RONO₂ (Zhang et al., 2012; Nguyen et al., 2015) to ecosystems further downwind of sources.

The 2013 SEAC⁴RS and SOAS campaigns provide a unique resource for evaluating the impact of BVOC-derived organic nitrates on atmospheric NOₓ. Both campaigns provided datasets of unprecedented chemical detail, including isoprene, monoterpenes, total and particle-phase RONO₂, and speciated INs; during SOAS these were further augmented by measurements of MTNs. Continuous measurements from the SOAS ground site provide high temporal resolution and constraints on diurnal variability (e.g., Nguyen et al., 2015; Xiong et al., 2015). These are complemented by extensive boundary layer profiling across a range of chemical environments from the SEAC⁴RS airborne measurements (Toon et al., 2016). Combined, the campaigns covered the summer period when BVOC emissions in the Southeast US are at a maximum (Palmer et al., 2006). These data offer new constraints for testing models of organic nitrate chemistry, with implications for our understanding of NOₓ, ozone, and aerosol budgets in BVOC-dominated environments worldwide.

We examine here the impact of BVOC oxidation on atmospheric NOₓ, using the 2013 campaign data combined with the GEOS-Chem model. The version of GEOS-Chem used in this work represents a significant advance over previous studies, with higher spatial resolution (≈25 × 25 km²) that better captures the spatial segregation of BVOC and NOₓ emissions (Yu et al., 2016); updated isoprene nitrate chemistry incorporating new experimental and theoretical findings (e.g., Lee et al., 2014; Müller et al., 2014; Peeters et al., 2014; Xiong et al., 2015); addition of monoterpane nitrate chemistry (Brown et al., 2014; Pye et al., 2015); and consideration of particle uptake of gas-phase isoprene and monoterpane nitrates. We first evaluate the updated GEOS-Chem simulation using SOAS and SEAC⁴RS observations of BVOCs, organic nitrates, and related species. We then use GEOS-Chem to quantify the fates of BVOC-derived organic nitrates in the Southeast US. Finally, we investigate the impacts of organic nitrate formation on the NOₓ budget.

2 Updates to GEOS-Chem simulation of organic nitrates

We use a new high resolution version of the GEOS-Chem CTM (www.geos-chem.org) v9-02, driven by assimilated meteorology from the NASA Global Modeling and Assimilation Office (GMAO) Goddard Earth Observing System Forward Processing (GEOS-FP) product. The model is run in a nested configuration (Wang et al., 2004), with native GEOS-FP horizontal resolution of 0.25° latitude by 0.3125° longitude over North America (130-60°W, 9.75-60°N). Boundary conditions are provided from a 4° × 5° global simulation, also using GEOS-Chem. The native GEOS-FP product includes 72 vertical layers of which ≈38 are in the troposphere. Temporal resolution of GEOS-FP is hourly for surface variables and 3-hourly for all others. Our simulations use a time step of 5 minutes for transport and 10 minutes for emissions and chemistry.

GEOS-Chem has been applied previously to simulation of organic nitrates in the Southeast US (e.g., Fiore et al., 2005; Zhang et al., 2011; Mao et al., 2013). Mao et al. (2013) recently updated the GEOS-Chem isoprene oxidation mechanism to include explicit production and...
loss of a suite of second generation isoprene nitrates and nighttime oxidation by nitrate radicals. While their updated simulation showed good agreement with aircraft observations from the 2004 ICARTT campaign over the eastern US, we find that the more detailed chemical payloads available during SOAS and SEAC4RS highlight deficiencies in that mechanism, resulting in large model biases in RONO₂.

A major component of this work is modification of the organic nitrate simulation in GEOS-Chem. Our focus here is on the BVOC-derived nitrates for which field measurements are newly available. GEOS-Chem simulation of PANs was recently updated by Fischer et al. (2014) and is not discussed here. Our improvements to the RONO₂ simulation are detailed below and include updates to isoprene oxidation chemistry, addition of monoterpene oxidation chemistry, and inclusion of aerosol uptake of RONO₂ followed by particle-phase hydrolysis. Other updates from GEOS-Chem v9-02 and comparison to Southeast US observations are presented in several companion papers. Kim et al. (2015) describe the aerosol simulation and Travis et al. (2016) the gas-phase oxidant chemistry. Constraints on isoprene emissions from satellite formaldehyde observations are described by Zhu et al. (2016). The low-NOₓ isoprene oxidation pathway and implications for organic aerosols are described by Marais et al. (2016). Finally, Yu et al. (2016) evaluate the impact of model resolution and spatial segregation of NOₓ and BVOC emissions on isoprene oxidation. Our simulation is identical to that used in Travis et al. (2016), Yu et al. (2016), and Zhu et al. (2016).

2.1 Isoprene oxidation chemical mechanism

The basic structure of the GEOS-Chem isoprene oxidation mechanism is described by Mao et al. (2013), with updates to low-NOx pathways described and validated by Travis et al. (2016). All updates to the isoprene oxidation mechanism are provided in Travis et al. (2016) Tables S1 and S2. Figure 2 shows our updated implementation of OH-initiated isoprene oxidation in the presence of NOₓ leading to isoprene nitrate (IN) formation. Isoprene oxidation by OH produces isoprene peroxy radicals (ISOPO₂) in either β- or δ-hydroxy peroxy configurations depending on the location of OH addition. In the presence of NOₓ, ISOPO₂ reacts with NO to either produce NO₂ (the dominant fate; Perring et al., 2013) or form INs, with the yield of INs (α) defined as the branching ratio between these two channels. Early laboratory measurements of α suggested an IN yield between 4.4 and 12% (Tuazon and Atkinson, 1990; Chen et al., 1998; Sprengnether et al., 2002; Patchen et al., 2007; Paulot et al., 2009; Lockwood et al., 2010). More recent experiments indicate continuing uncertainty in α, with a measured yield of α = 9 ± 4% from the Purdue Chemical Ionization Mass Spectrometer (CIMS; Xiong et al., 2015) and α = 13 ± 2% from the Caltech CF₃O⁻ Time-of-Flight CIMS (CIT-ToF-CIMS; Teng et al., in preparation), despite excellent agreement during calibrated intercomparison exercises using one isoprene nitrate isomer (4,3 ISOPN). The sensitivity of the CIT-ToF-CIMS is similar for all isomers of ISOPN (Lee et al., 2014), while the Purdue instrument is less sensitive to the major isomer (1,2 ISOPN) (Xiong et al., 2015). Here, we use a first generation IN yield of α = 9%, which we find provides a reasonable simulation of the SOAS observations and is also consistent with the SOAS box model simulations of Xiong et al. (2015). We discuss the model sensitivity to the choice of α in Sect. 3.
For the oxidation of isoprene by OH, the mechanism described in Mao et al. (2013) assumed a first generation IN composition of 40% β-hydroxyl INs (β-ISOPN) and 60% δ-hydroxyl INs (δ-ISOPN). However, new theoretical constraints show that under atmospheric conditions, (δ-channel peroxy radicals are only a small fraction of the total due to fast redissociation of peroxy radicals that fosters interconversion between isomers and tends towards an equilibrium population with more than 95% β-isomers (Peeters et al., 2014). Using a simplified box model based on the extended Leuven Isoprene Mechanism LIM1, we found δ-isomers were 4-8% of the total peroxy pool in representative Southeast US boundary layer conditions (temperature ~295-300 K, ISOPO2 lifetime ~20-60 seconds). In what follows, we use an IN distribution of 90% β-ISOPN and 10% δ-ISOPN. Our box modeling suggests 10% is an upper limit for the δ-ISOPN pool; however, we maintain this value as it allows improved simulation of species with predominantly δ-pathway origins, including glyoxal and the second generation INs propanone nitrate (PROPNN) and ethanal nitrate (ETHLN).

First generation ISOPN isomers formed via OH oxidation of isoprene have a short photochemical lifetime against atmospheric oxidation (Paulot et al., 2009; Lockwood et al., 2010; Lee et al., 2014). Here we use updated reaction rate constants and products from Lee et al. (2014) that increase the β-ISOPN+OH reaction by roughly a factor of two and decrease ozonolysis by three orders of magnitude (relative to the previous mechanism based on Lockwood et al., 2010; Paulot et al., 2009). Changes in δ-ISOPN reaction rate constants are more modest but in the same direction. For both isomers, reaction with OH forms a peroxy radical (ISOPNO2) along with a small (10%) yield of isoprene epoxy diols (Jacobs et al., 2014). Rate constants and products of the subsequent oxidation of ISOPNO2 to form a suite of second generation INs follow the Lee et al. (2014) mechanism. We explicitly simulate methylvinylketone nitrate (MVKN) and methacrolein nitrate (MACRN), which are primarily from the β-pathway; PROPNN and ETHLN, which are primarily from the δ-pathway (and NO3-initiated oxidation); and C5 dihydroxy dinitrate (DHDN), formed from both isomers (Lee et al., 2014).

Isoprene reaction with NO3 is the dominant isoprene sink at night and can also be significant during the day (Ayers et al., 2015), producing INs with high yield (Perring et al., 2009b; Rollins et al., 2009). This reaction can account for more than 20% of isoprene loss in some environments (Brown et al., 2009) and may explain 40-50% of total RONO2 in the Southeast (Mao et al., 2013; Xie et al., 2013). The mechanism used here is identical to that described by Mao et al. (2013). Reaction of isoprene with NO3 forms a nitrooxy peroxy radical (INO2). Subsequent reaction of INO2 with NO, NO3, itself, or other peroxy radicals forms a first generation C5 carbonyl nitrate (ISN1) with 70% yield, while reaction with HO2 forms a C5 nitrooxy hydroperoxide (INPN) with 100% yield. In this simplified scheme, we do not distinguish between β- and δ- isomers for ISN1 and INPN, nor do we include the C5 hydroxy nitrate species recently identified in chamber experiments (Schwantes et al., 2015). Mao et al. (2013) lumped all second generation nitrates derived from ISN1 and INPN into a single species (R4N2), but here we assume that the lumped species is PROPNN on the basis of recent chamber experiments that show PROPNN to be a high-yield photooxidation product of INs from NO3-initiated oxidation (Schwantes et al., 2015). This effectively assumes instantaneous conversion of INs to PROPNN, a simplification that results in a shift
in the simulated diurnal cycle of PROPNN (see Sect. 3). We do not include here the nitrooxy hydroxyepoxide product recently identified by Schwantes et al. (2015).

Possible fates for second generation INs include further oxidation, photolysis, uptake to the aerosol phase followed by hydrolysis (Sect. 2.3), and removal via wet and dry deposition. Müller et al. (2014) show that photolysis is likely significantly faster than reaction with OH for carbonyl nitrates (e.g., MVKN, MACRN, ETHLN, PROPNN) due to enhanced absorption cross sections and high quantum yields caused by the proximity of the carbonyl group (a strongly absorbing chromophore) to the weakly-bound nitrate group. Here we increase the absorption cross sections of the carbonyl INs following the methodology of Müller et al. (2014, Sect. 2). Briefly, we first use the PROPNN cross section measured by Barnes et al. (1993) to calculate a wavelength-dependent cross section enhancement ratio ($r_{nk}$), defined as the ratio of the measured cross section to the sum of the IUPAC-recommended cross sections for associated monofunctional nitrates and ketones. We then calculate new cross sections for ETHLN, MVKN, and MACRN by multiplying $r_{nk}$ by the sum of cross sections from appropriate monofunctional analogues (Table S5). The new cross sections are 5-15 times larger than in the original model, which used the IUPAC-recommended cross section of the monofunctional analogue tert-butyl nitrate for all carbonyl nitrates (Roberts and Fajer, 1989). For all species, we calculate photolysis rates assuming unity quantum yields, whereby the weak O–NO$_2$ bond dissociates upon a rearrangement after photon absorption to the carbonyl chromophore (Müller et al., 2014). Peak midday photolysis rates now range from $\sim 3 \times 10^{-5}$ s$^{-1}$ (PROPNN) to $\sim 3 \times 10^{-4}$ s$^{-1}$ (MACRN).

Removal by dry deposition has been updated based on new observations from the SOAS ground site. The dry deposition calculation is now constrained to match observed deposition velocities for ISOPN, MVKN, MACRN, and PROPNN (Nguyen et al., 2015; Travis et al., 2016), with all other RONO$_2$ deposition velocities scaled to that of ISOPN. Wet scavenging of gases is described in Amos et al. (2012) and has been modified here to use the same Henry’s Law coefficients as for dry deposition. Aerosol partitioning is described in Sect. 2.3 below.

### 2.2 Monoterpene oxidation chemical mechanism

Monoterpene chemistry is not included in the standard GEOS-Chem gas-phase chemical mechanism. Here we implement a monoterpene nitrate scheme developed by Browne et al. (2014) that was built on the RACM2 chemical mechanism (Goliff et al., 2013) and evaluated using aircraft observations over the Canadian boreal forest (Browne et al., 2014). Our implementation is summarized in Fig. 3 and described briefly below, with the full mechanism available in the Supplement (Tables S1-S3) and at http://wiki.seas.harvard.edu/geos-chem/index.php/Monoterpane_nitrate_scheme. We include two lumped monoterpene tracers: API representing monoterpens with one double bond ($\alpha$-pinene, $\beta$-pinene, sabinene, and $\Delta$-3-carene) and LIM representing monoterpens with two double bonds (limonene, myrcene, and ocimene). Combined, these species account for roughly 90% of all monoterpene emissions (Guenther et al., 2012), and we neglect other terpenes here. During the day, LIM and API are oxidized by OH to form peroxy radicals. Subsequent reaction with
NO forms first generation monoterpene nitrates with a yield of 18% (Nozière et al., 1999). These can be either saturated (MONITS) or unsaturated (MONITU), with precursor-dependent partitioning as shown in Fig. 3. For all subsequent discussion, we refer to their sum $\text{MONIT} = \text{MONITU} + \text{MONITS}$.

At night, both LIM and API react with NO$_3$ to form a nitrooxy peroxy radical that either decomposes to release NO$_2$ or retains the nitrate functionality to form MONIT. The branching ratio between these two fates is 50% nitrate-retaining for LIM + NO$_3$ (Fry et al., 2014) and 10% nitrate-retaining for API + NO$_3$ (Browne et al., 2014). The 10% nitrate yield from API + NO$_3$ is on the low end of the observed range (Fry et al., 2014), so simulated pinene-derived MONIT should be considered a lower bound. In Browne et al. (2014), the API + NO$_3$ reaction used the $\alpha$-pinene + NO$_3$ rate constant from the Master Chemical Mechanisms (MCMv3.2). We have updated this rate constant to $k_{\text{API+NO}_3} = 8.33 \times 10^{-13} e^{490/T}$, a rough average of the MCMv3.3 $\alpha$- and $\beta$-pinene values, as API comprises both $\alpha$- and $\beta$-pinenes (the dominant API components, present in roughly equal amounts during both SEAC4RS and SOAS). API and LIM also react with O$_3$, but this reaction does not lead to RONO$_2$ formation.

We do not distinguish between OH-derived and NO$_3$-derived MTN species. MONIT are subject to removal via wet and dry scavenging, aerosol uptake, photolysis, ozonolysis (MONITU only) and oxidation by OH. Here, we also add MONIT reaction with NO$_3$ with the same rate constant as used for nighttime isoprene nitrates. The products of MONIT oxidation are currently unknown; here we follow Browne et al. (2014) and assume oxidation produces a second generation monoterpene nitrate (HONIT) that undergoes dry deposition, photolysis, and oxidative loss. In our simulation, HONIT is also removed via aerosol uptake (Sect. 2.3).

2.3 Aerosol partitioning of RONO$_2$

Evidence from laboratory and field studies suggests aerosol uptake is a potentially significant loss pathway for gas-phase RONO$_2$ (e.g., Day et al., 2010; Rollins et al., 2010; Darer et al., 2011; Fry et al., 2013, 2014). In particular, BVOC oxidation by NO$_3$ radicals has been shown to result in high organic aerosol yields (Ng et al., 2008; Fry et al., 2009; Rollins et al., 2012). Recent work from SOAS highlighted the role of the monoterpenes + NO$_3$ reaction, with an estimated 23-44% yield of organic nitrate aerosol (Ayres et al., 2015) that can explain roughly half of nighttime secondary organic aerosol production (Xu et al., 2014). Isoprene + NO$_3$ results in smaller but still significant yields; Xu et al. (2014) estimate that isoprene was responsible for 20% of nighttime NO$_3$-derived organic aerosol observed during SOAS. Organic nitrate aerosol yields from daytime oxidation by OH are lower but non-negligible. At Bakersfield, for example, Rollins et al. (2013) found 21% of RONO$_2$ partitioned to the aerosol phase during the day, and that these could explain 5% of the total daytime organic aerosol mass.

Aerosol partitioning of RONO$_2$ has not previously been considered in GEOS-Chem. Here we add this process using a reactive uptake coefficient ($\gamma$) parameterization. Our parameterization was designed to provide a necessary sink for gas-phase RONO$_2$ species (overestimated in earlier iterations of our model), and therefore makes a number of
simplifying assumptions. In particular, we do not allow pRONO₂ to re-partition to the gas phase (likely to impact the more volatile isoprene-derived nitrates), and uptake coefficients are defined to fit the measurements of gas-phase species. More accurate simulation of organic nitrate aerosols would require additional updates that take into account vapor pressure differences between species (as done recently by Pye et al., 2015) and incorporate new findings from SOAS (Ayres et al., 2015; Lee et al., 2016). For our simulation, we apply reactive uptake to all BVOC-derived RONO₂ except PROPNN and ETHLN, which lack hydroxyl groups and are therefore expected to be significantly less soluble. We assume an uptake coefficient of \( \gamma = 0.005 \) for isoprene nitrates (from both daytime and nighttime chemistry) and \( \gamma = 0.01 \) for all monoterpene nitrates (Table S4). Our isoprene nitrate uptake coefficient is in the middle of the range predicted by Marais et al. (2016) using a mechanistic formulation, and is a factor of 4 lower than the upper limit for ISOPN inferred by Wolfe et al. (2015) using SEAC⁴RS flux measurements. Although simplified, we find this parameterization provides a reasonable fit to the SEAC⁴RS and SOAS observations of individual gas-phase RONO₂ species measured by the CIT-ToF-CIMS and total pRONO₂ measured by an Aerosol Mass Spectrometer (AMS) (see Sect. 3 and 4).

After partitioning to the aerosol, laboratory experiments have shown that pRONO₂ can hydrolyze to form alcohols and nitric acid via \( \text{pRONO}_2 + \text{H}_2\text{O} \rightarrow \text{ROH} + \text{HNO}_3 \). Some pRONO₂ species hydrolyze rapidly under atmospherically-relevant conditions, while others are stable against hydrolysis over timescales significantly longer than the organic aerosol lifetime against deposition (Darer et al., 2011; Hu et al., 2011; Liu et al., 2012; Jacobs et al., 2014; Rindelaub et al., 2015). Lifetimes against hydrolysis inferred from bulk aqueous and reaction chamber studies range widely from minutes (Darer et al., 2011; Rindelaub et al., 2015) to a few hours (Liu et al., 2012; Lee et al., 2016) to nearly a day (Jacobs et al., 2014). Here we apply a bulk lifetime against hydrolysis for the entire population of pRONO₂ (similar to Pye et al., 2015). In other words, our implementation of aerosol partitioning involves a two-step process of (1) uptake of gas-phase RONO₂ to form a simplified non-volatile pRONO₂ species, with rate determined by \( \gamma \), followed by (2) hydrolysis of the simplified pRONO₂ species to form HNO₃, with rate determined by the lifetime against hydrolysis. These steps are de-coupled, and we do not include any dependence of \( \gamma \) on the hydrolysis rate (unlike the more detailed formulation of Marais et al. (2016)). In subsequent sections, we compare the simplified pRONO₂ formed as an intermediate during this process to total pRONO₂ derived from observations. The assumption of a single hydrolysis lifetime overestimates the loss rate of non-tertiary nitrates (Darer et al., 2011; Hu et al., 2011) and may lead to model bias in total pRONO₂, particularly in the free troposphere where the longer-lived species would be more prevalent (see Sect. 4).

We assume here a bulk lifetime against hydrolysis of 1 h, which we found in preliminary simulations to provide a better simulation of pRONO₂ than longer lifetimes. Our 1 h bulk hydrolysis lifetime is shorter than the 2-4 h lifetime found in recent analysis of SOAS data and laboratory experiments (Boyd et al., 2015; Lee et al., 2016; Pye et al., 2015) - likely reflecting the simplifying assumptions of our uptake parameterization. In any case, the choice of hydrolysis lifetime does not affect the concentration of gas-phase RONO₂ species (because pRONO₂ cannot re-partition to the gas phase in the model), and we find this value provides a reasonable match to AMS measurements of total pRONO₂ at the surface during
SOAS and SEAC4RS (see Sect. 3 and 4). Impacts on HNO₃ are minor: compared to a simulation without hydrolysis, our simulation with a 1 h lifetime against hydrolysis increased boundary layer HNO₃ by 20 ppt, or 2.4%.

3 BVOCs and organic nitrates in the Southeast US

We evaluate the updated GEOS-Chem simulation using Southeast US measurements of isoprene, monoterpenes, and a suite of oxidation products from two field campaigns in summer 2013. SEAC4RS was a NASA aircraft campaign that took place in August-September 2013 (Toon et al., 2016). All observations discussed in this work were taken onboard the NASA DC-8 (data doi: 10.5067/Aircraft/SEAC4RS/Aerosol-TraceGas-Cloud), which was based in Houston, Texas with an ∼8-hour flight range. SOAS was a ground-based campaign that took place in June-July 2013 at the Centreville monitoring site near Brent, Alabama (32.903°N, 87.250°W).

3.1 Isoprene and monoterpenes

Understanding BVOC sources and chemistry was a primary goal of SEAC4RS, resulting in a large number of boundary layer flights over regions of enhanced biogenic emissions (Kim et al., 2015). Isoprene and monoterpene distributions in Southeast US surface air (80-94.5°W, 29.5-40°N, and below 1 km) measured by PTR-MS are shown in Fig. 4, and their campaign-median vertical profiles are shown in Fig. 5(b,c). Whole Air Sampler (WAS) measurements of isoprene and α-pinene + β-pinene (Fig. S1) are similar, but with more limited sampling than the PTR-MS. All observations have been averaged to the spatial and temporal resolution of the model.

The SOAS site is located at the edge of a mixed coniferous and deciduous forest (Nguyen et al., 2015). SOAS observations of isoprene and monoterpenes, measured by PTR-ToF-MS and averaged to hourly mean values, are shown in Fig. 6. Both species display a clear diurnal cycle with peak isoprene during day, reflecting the light- and temperature-dependent source, and peak monoterpenes at night. For monoterpenes, the figure also shows the sum of α-pinene + β-pinene as measured by 2D-GC-FID, which indicates that these are the dominant monoterpenes.

Figures 4, 5, and 6 compare observed BVOCs from both campaigns to the GEOS-Chem simulation, sampled to match the observations. Similar figures for NOₓ can be found in Travis et al. (2016) and in Fig. S2. Model bias relative to observations is quantified using the normalized mean bias \( NMB = 100 \% \times \frac{\sum_i(M_i - O_i)}{\sum_i(O_i)} \) where \( O_i \) and \( M_i \) are the observed and modeled values and the summation is over all hours (SOAS) or unique gridbox-timestep combinations along the flight tracks (SEAC4RS). BVOC emissions are from MEGANv2.1 (Guenther et al., 2012) and have been decreased by 15% for isoprene and doubled for monoterpenes to better match aircraft (isoprene, monoterpene) and satellite (formaldehyde) observations (Kim et al., 2015; Zhu et al., 2016). With these scalings applied, simulated surface isoprene and monoterpenes overestimate somewhat the SEAC4RS data (Fig. 4, mainly due to a few simulated high-BVOC events), but the medians are well within the observed variability (Fig. 5). Model high bias above 500 m is likely caused by
excessive vertical mixing through the simulated boundary layer (Travis et al., 2016). Relative to the SOAS data, simulated monoterpenes are biased low by a factor of two, while isoprene falls within the interquartile range of the measurements. The opposite sign of the SOAS monoterpane bias relative to the more spatially representative SEAC4RS data suggests a low bias in MEGANv2.1 monoterpane emissions that is unique to the Centreville gridbox; errors in vertical mixing may also contribute. For isoprene, the model reproduces both the observed nighttime decline and the subsequent morning growth with a small delay (∼1 hour).

The observed declines in isoprene at night (Fig. 6) and above the boundary layer (Fig. 5) reflect its short lifetime against oxidation. We find in the model that OH oxidation accounts for 90% of isoprene loss (Marais et al., 2016), but only 65% of monoterpane loss (with NO3 responsible for most of the rest). For isoprene, the subsequent fate of the peroxy radicals (ISOPO2) has been evaluated in detail by Travis et al. (2016), who also present an in-depth analysis of the NOx budget and impacts on ozone. They show that on average 56% of ISOPO2 reaction during SEAC4RS is with NO, and that there is large spatial variability in this term that is accurately reproduced by the high-resolution GEOS-Chem simulation. Here we focus exclusively on this pathway and the resultant formation of RONO2 from both isoprene and monoterpenes.

### 3.2 First generation RONO2

Observed near-surface mixing ratios of first generation isoprene nitrates (ISOPN) during SEAC4RS are shown in Fig. 7 and are generally well represented by GEOS-Chem (r = 0.61; NMB = -0.6%). ISOPN vertical profiles in Fig. 5e indicate a rapid decline from the boundary layer to the free troposphere, reflecting the short atmospheric lifetime (2-4 h in our simulation; Table 1). Comparing the lowest altitude SEAC4RS observations to the SOAS median from the CIT-ToF-CIMS (black triangle) indicates an apparent vertical gradient from the surface to ∼500 m. This could be caused by spatial variability between the campaigns, or could reflect rapid dry deposition of ISOPN with limited vertical mixing. GEOS-Chem does not simulate this SOAS-SEAC4RS difference, possibly due to overly strong vertical mixing through the modeled boundary layer as identified by Travis et al. (2016) from model comparison to SEACIONS ozonesonde observations.

During SOAS, ISOPN was measured simultaneously by the CIT-ToF-CIMS (Crounse et al., 2006; Nguyen et al., 2015) and the Purdue CIMS (Xiong et al., 2015), and Fig. 6 shows the diurnal cycles from both. Median ISOPN from the Purdue CIMS is a factor of two higher than that from the CIT-ToF-CIMS during daylight hours, with the most significant differences in mid-late morning. In both datasets, ISOPN peaks around 10:00 am local time, is elevated until early evening, and declines to a pre-dawn minimum. Simulated ISOPN from GEOS-Chem is in good agreement with the Purdue CIMS measurements except in the afternoon when modeled ISOPN shows a broad peak (rather than the observed decline) coincident with simulated peak isoprene (Fig. 6). After ∼7:00 pm, the model captures the observed timing of the nighttime ISOPN decline seen in both datasets, as well as the rapid morning growth seen in the Purdue CIMS measurements.
As described in Sect. 2.1, there is considerable uncertainty in the ISOPN yield. We find here that a 9% yield provides the best simulation of the ensemble of SEAC4RS and SOAS observations, given experimental constraints on oxidative loss rates (Lee et al., 2014) and dry deposition fluxes (Nguyen et al., 2015). Using model sensitivity studies, we found that applying a lower yield of 7% improved the agreement with the CIT-ToF-CIMS during SOAS, but worsened agreement with the other datasets and is inconsistent with the yields from laboratory experiments (Teng et al., in preparation). We also tested a higher yield of 12%, and found the model overestimated observed SEAC4RS and SOAS ISOPN (from both instruments) unless we invoked much larger aerosol uptake and/or added another ISOPN sink. ISOPN sinks (especially aerosol uptake) remain poorly constrained, and the uncertain parameter space describing these processes likely contains multiple solutions that fit the observations equally well (i.e., a higher yield could be accommodated by faster ISOPN loss to aerosol).

Our finding that GEOS-Chem can reproduce the Purdue CIMS ISOPN observations using a 9% ISOPN yield is consistent with the box model of Xiong et al. (2015). The chemical mechanisms used in both studies are similar. In both simulations, modeled ISOPN was overestimated unless an extra sink was included (also consistent with Wolfe et al., 2015, who inferred a missing sink based on SEAC4RS flux measurements). While we assumed this sink was due to aerosol uptake, Xiong et al. (2015) invoked enhanced ISOPN photolysis. They argued that models typically underestimate the ISOPN absorption cross section by not taking into account the combined influence of the double bond and hydroxyl group in the ISOPN structure (Fig. 2). Xiong et al. (2015) were better able to reproduce the observed ISOPN morning peak and afternoon decline when they increased the MCMv3.2 photolysis rate constant by a factor of 5. Including both faster ISOPN photolysis and uptake to the aerosol phase could be a means to accommodate a higher initial ISOPN yield, such as the 12-14% yield inferred from laboratory experiments with the CIT-ToF-CIMS (Teng et al., in preparation), although both sinks remain unverified. The nature of the sink has implications for NOx recycling from isoprene nitrates (photolysis recycles NOx while uptake removes it), and this remains a source of uncertainty in our estimates of the impacts of RONO2 on the NOx budget.

Even more uncertain than ISOPN are the first generation monoterpene nitrates (MONIT). MONIT in GEOS-Chem is a lumped species that represents the sum of monoterpene nitrates from both daytime OH-initiated and nighttime NO3-initiated oxidation (Sect. 2.2). The nighttime oxidation cascade involves a diversity of reactants (including NO, HO2, NO3, and other peroxy radicals) and produces a diversity of monoterpene nitrate species (Lee et al., 2016) that we do not distinguish here. In the model, most MONIT is produced from the NO3-initiated chemistry, resulting in mean MONIT concentrations of 30-60 ppt at night and ∼10-20 ppt during the day.

During SOAS, two monoterpene nitrates were measured by the CIT-ToF-CIMS: C10H17NO4 and C10H17NO5. We find that simulated MONIT shows the same diurnal pattern as the sum of the two measured species (with peak concentrations at night) but is a factor of 2-3 higher (Fig. S3). Pye et al. (2015) similarly found simulated MONIT was a factor of 7 higher than observations using a version of the CMAQ model with explicit MONIT chemistry. The
higher modeled values in both studies presumably reflect inclusion in modeled MONIT of many species that were not measured by CIT-ToF-CIMS (including several identified during SOAS by Lee et al., 2016), as well as biases in the model mechanisms (most of the rate constants and products have not been measured). NO$_3$-initiated monoterpene oxidation is particularly uncertain and is likely too strong in GEOS-Chem, as indicated by large nighttime MONIT overestimates (Fig. S3) combined with monoterpene underestimates (Fig. 6). Simulated nighttime peak values of NO$_3$-derived isoprene nitrates (ISN1) during SOAS are also up to a factor of 2 higher than the observations reported by Schwantes et al. (2015). This suggests that model biases in nighttime PBL heights and associated vertical mixing may also contribute to simulated nighttime overestimates for some RONO$_2$ species.

### 3.3 Second generation RONO$_2$ and pRONO$_2$

First generation ISOPN and MONIT undergo further oxidation to form a suite of second generation RONO$_2$ species that retain the nitrate functionality (Figs. 2, 3). Four of these species (MVKN, MACRN, PROPNN, and ETHLN) were measured by the CIT-ToF-CIMS, with vertical profiles shown in Fig. 5 (f-h) and spatial distribution shown in Fig. 7. The model provides a good simulation of SEAC4RS MVKN+MACRN but underestimates the variability of PROPNN and ETHLN. In contrast, all three species show positive mean model biases relative to the SOAS surface observations. The model tends to overestimate PROPNN and ETHLN at night but underestimate them during the day (Fig. S3), reflecting the assumption in our mechanism that PROPNN is produced at night during NO$_3$-initiated isoprene oxidation. In reality, the nighttime chemistry produces INs that only photo-oxidize to PROPNN after sunrise (Schwantes et al., 2015). This missing delay between nighttime NO$_3$ addition and subsequent daytime photo-oxidation likely also explains the model bias relative to the SEAC4RS observations, which mostly took place during daytime. Additional simplifications in the NO$_3$-initiated chemistry could also contribute to the biases, and preliminary simulations conducted with the AM3 model show that including more details of this chemistry improves model ability to match observed PROPNN (Li et al., in preparation). Some of the bias may also be due to error in the assumed distribution between $\beta$- and $\delta$-channel OH-initiated oxidation, as both PROPNN and ETHLN are produced by the latter channel only.

The full time series of first and second generation INs measured at Centreville during SOAS are shown in Fig. 8. We also include the time series of observed particulate RONO$_2$ (pRONO$_2$) estimated from AMS measurements (Fry et al., 2013; Ayres et al., 2015; Lee et al., 2016; Day et al., in preparation) and of $\Sigma$ANs, the sum of all RONO$_2$ species (including pRONO$_2$) as measured by thermal dissociation laser-induced fluorescence (TD-LIF; Day et al., 2002). Despite the biases identified above, the simulation captures the temporal variability in gas-phase, particulate, and total RONO$_2$ observed over the 6-week campaign, with correlation coefficients of $r \sim 0.6-0.7$. Low observed and modeled values for all species in early July (days 185-189) indicate suppressed BVOC emissions caused by low temperatures (Marais et al., 2016). The model underestimates both pRONO$_2$ and $\Sigma$ANs at night (Fig. S3), suggesting that hydrolysis of particulate monoterpane nitrates should be slower than assumed here (Sect. 2.3). Afternoon overestimates of pRONO$_2$ relative to the AMS observations (Fig. S3) are coincident with the peak in isoprene nitrates (Fig. 6).
suggesting overly strong partitioning to the aerosol phase likely due to our assumption of irreversibility (Sect. 2.3).

3.4 RONO\textsubscript{2}-HCHO relationship

The relationship between organic nitrates and formaldehyde (HCHO), a high-yield product of the ISOPO\textsubscript{2} + NO reaction, provides an additional test of the model chemistry and in particular the IN yield. Daytime isoprene oxidation in the presence of NO\textsubscript{3} co-produces HCHO and INs, resulting in an expected strong correlation between these species (Perring et al., 2009a). When INs dominate total RONO\textsubscript{2}, the correlation should also be strong between HCHO and ΣANs, and this relationship has previously been used to constrain the IN yield when IN measurements were not available. For example, HCHO and ΣANs measurements from the 2004 ICARTT aircraft campaign showed moderate correlation with \( r \sim 0.4-0.6 \) (Perring et al., 2009a; Mao et al., 2013). However, linking the HCHO-ΣANs correlation to the IN yield is complicated by the contribution to ΣANs from other RONO\textsubscript{2} sources (e.g., monoterpene nitrates, anthropogenic nitrates, etc.). During SEAC\textsuperscript{4}RS, a better constraint can be obtained directly from the HCHO-IN relationship. Figure 9 shows the correlation between HCHO and the sum of ISOPN, MVKN, and MACRN (we exclude PROPNN and ETHLN to avoid the biases identified previously). The figure shows the observed slope of 0.027 (ppt IN) (ppt HCHO\textsuperscript{-1}) is reproduced by the model but with more scatter in the simulation \( (r \sim 0.5) \) than in the observations \( (r \sim 0.7) \). The similarity of the observed and simulated relationships in Fig. 9 lends confidence to the IN mechanism used here, at least for the β-peroxy channel.

4 Total alkyl and multifunctional nitrates (ΣANs)

4.1 Speciated versus total RONO\textsubscript{2}

SEAC\textsuperscript{4}RS represents one of the first airborne campaigns to make measurements of individual BVOC-derived RONO\textsubscript{2} species. Without these speciated measurements, previous model evaluations of isoprene nitrate chemistry have relied on TD-LIF observations of ΣANs (total RONO\textsubscript{2}), with the assumption that gas-phase INs account for the majority of ΣANs (Horowitz et al., 2007; Perring et al., 2009a; Mao et al., 2013; Xie et al., 2013). Figure 10a compares the TD-LIF ΣANs measurement (solid line) to the sum of explicitly measured gas-phase RONO\textsubscript{2} species and total pRONO\textsubscript{2} (dashed line, combined CIT-ToF-CIMS, WAS, and AMS measurements) during SEAC\textsuperscript{4}RS. The figure shows a large gap between measured ΣANs and the total of speciated RONO\textsubscript{2} (including both gas-phase and aerosol contributions), especially near the surface (ΣANs = 409 ppt, total speciated RONO\textsubscript{2} = 198 ppt). Figure 10a also shows the median surface ΣANs measured during SOAS (198 ppt; black triangle). As for SEAC\textsuperscript{4}RS, SOAS total speciated RONO\textsubscript{2} is much lower (82 ppt) when calculated from the CIT-ToF-CIMS and AMS measurements. The gap is smaller, but still exists, when calculated using ISOPN from the Purdue CIMS (total RONO\textsubscript{2} = 102 ppt) or pRONO\textsubscript{2} from the TD-LIF (total RONO\textsubscript{2} = 139 ppt). An independent thermal dissociation instrument operated by the SouthEastern Aerosol Research and Characterization (SEARCH) Network also measured ΣANs at the SOAS site and showed values that were 80 ppt higher than measured by the TD-LIF (but generally well correlated, with slope close to 1 and \( r \sim 0.8 \)).
Some of the difference between the total speciated RONO$_2$ and $\Sigma$ANs measurements can be attributed to gas-phase nitrates not measured by CIT-ToF-CIMS or WAS. A number of these were identified during SOAS using a second ToF-CIMS operated by the University of Washington (Lee et al., 2016). In addition, SEAC$^4$RS observations of total NO$_y$ (equiv to NO$_x$ +HNO$_3$+PAN+RONO$_2$, including pRONO$_2$) are better balanced by including the $\Sigma$ANs than the speciated RONO$_2$ components (~81% vs. 70% of surface NO$_y$, compared to 56% with no RONO$_2$ contribution). Also contributing to the discrepancy are the large uncertainties still associated with RONO$_2$ measurement techniques. Lee et al. (2016) found that SOAS measurements of pRONO$_2$ differ by factors of 2-4, as also shown in Fig. S3, with the AMS lower than TD-LIF. Similarly, we showed in Sect. 3 that the two SOAS measurements of ISOPN differ by up to a factor of 2 (CIT-ToF-CIMS lower than Purdue CIMS, for reasons that remain unclear). Assuming similar uncertainties characterize the SEAC$^4$RS RONO$_2$ measurements, these could readily explain some of the inability of the speciated measurements to close the $\Sigma$ANs budget in Fig. 10a.

Comparison of GEOS-Chem to the two total RONO$_2$ estimates in Fig. 10a shows that the model greatly underestimates SEAC$^4$RS $\Sigma$ANs relative to the TD-LIF measurement, with a much smaller underestimate relative to the speciated sum. The better fit to the speciated measurements than to the $\Sigma$ANs is consistent with the model's ability to match both individual gas-phase RONO$_2$ species measured by the CIT-ToF-CIMS and total pRONO$_2$ measured by the AMS (Sect. 3). During SOAS, Fig. 8 shows that GEOS-Chem can reproduce much of the temporal variability in the $\Sigma$ANs ($r=0.57$) with little bias.

4.2 RONO$_2$ composition

Figure 10b compares the observed and simulated RONO$_2$ composition in the Southeast US during SEAC$^4$RS. For clarity, only the speciated measurements are shown in the figure. The observations show a constant 20-30 ppt background at all altitudes from small (C$_1$-C$_3$) RONO$_2$ produced from anthropogenic VOCs. The contributions of these small nitrates are consistent with the observed concentrations of their parent VOCs and with known reaction rate constants (Atkinson and Arey, 2003), RONO$_2$ yields (Perring et al., 2013), and RONO$_2$ lifetimes (Talukdar et al., 1997; Dahl et al., 2005; Worton et al., 2010) assuming steady state. GEOS-Chem does not simulate these nitrates under the assumption that their contributions to total NO$_y$ are insignificant. The SEAC$^4$RS data clearly show that this assumption is not valid, at least for the US where natural gas production is a large alkane source, and is contributing to model bias in both RONO$_2$ and NO$_y$. Given the long lifetimes (weeks-months) of the small nitrates, the bias is particularly acute in the free troposphere and has implications for global N export.

In both observations and model, gas-phase INs (orange) account for half of speciated RONO$_2$ (25% of $\Sigma$ANs), split roughly equally between 1st and 2nd generation species. The model underestimates somewhat the 2nd generation INs, as seen previously in Figs. 5 and 7. In the model, gas-phase MTNs from monoterpenes (blue; not measured during SEAC$^4$RS) account for an additional 10% of simulated RONO$_2$ (~5% relative to $\Sigma$ANs). Previous studies during ICARTT also found a 10% MTN contribution to RONO$_2$ (Horowitz et al., 2007; Perring et al., 2009a), although MTNs have been neglected in more recent simulations.
(e.g., Mao et al., 2013; Xie et al., 2013). Other C_4-C_5 nitrates (yellow, including alkyl nitrates from WAS and alkene hydroxynitrates from CIT-ToF-CIMS) similarly contribute 5-10% of observed RONO_2; these are underestimated by 50% in GEOS-Chem because the model does not include nitrate formation from anthropogenic alkenes.

A significant fraction (10-20%) of RONO_2 was in the aerosol phase during SEAC^4RS. The model underestimates the observed pRONO_2 contribution in the free troposphere; however, some caution should be used when interpreting these data. Observed pRONO_2 is the product of measured total aerosol nitrate and the measured organic fraction of the nitrate aerosol, but during SEAC^4RS the organic fraction was often not reported in the free troposphere due to interference from dust layers and instrumental issues. In these instances, the organic fraction of measured nitrate is assumed to be 0.8, based largely on surface measurements from multiple campaigns (Day et al., in preparation). In the free troposphere (>1.5 km), this assumption is applied to 85% of the SEAC^4RS 1-minute data, and could lead to a high bias in the pRONO_2 observations. Nonetheless, it is also likely that simulated pRONO_2 is underestimated because of our assumption that all pRONO_2 species undergo rapid hydrolysis. In fact, many of the nitrates produced from BVOC oxidation are not expected to hydrolyze at all (Boyd et al., 2015; Pye et al., 2015) and so would have lifetimes sufficiently long for export out of the boundary layer.

Our simulated RONO_2 composition in Fig. 10b suggests a less important role for INs than identified from recent simulations of the ICARTT data. In an earlier version of GEOS-Chem, INs alone could explain all measured ΣANs during ICARTT (~200 ppt at the surface; Mao et al., 2013), and both that model and a CMAQ simulation (Xie et al., 2013) suggested INs were dominated by 2nd generation species (70-90% of total INs). These earlier simulations did not account for either aerosol uptake and possible hydrolysis (Darer et al., 2011; Jacobs et al., 2014) or fast photolysis (Müller et al., 2014) of 2nd generation INs, and so lifetimes were significantly longer than in our simulation. We performed sensitivity simulations without these additional IN sinks and found that the model overestimated observed 2nd generation INs by a factor of 3-5 during SEAC^4RS. It seems likely that 2nd generation IN overestimates in previous work were compensated for by omitting the contributions from MTNs and pRONO_2. Here, we find MTN and pRONO_2 combined contribute as much to total RONO_2 as either 1st or 2nd generation INs alone, and that excluding them would lead to major model shortcomings. The pRONO_2 contribution is especially important as different removal processes for gas-phase versus particulate species would have different implications for NO_x budgets and N deposition.

5 Fate of organic nitrates and implications for nitrogen budgets

Table 1 summarizes the dominant fates and lifetimes of individual gas-phase RONO_2 in the Southeast US boundary layer during the SEAC^4RS campaign (12 Aug - 23 Sep) as calculated from GEOS-Chem. The contribution of different fates to total gas-phase RONO_2 loss is illustrated in Fig. 11a. Loss processes that recycle RONO_2 by converting between RONO_2 species (e.g., from first to second generation) are not included. Total simulated RONO_2 loss is dominated by aerosol hydrolysis, with an additional large loss to deposition that is consistent with the rapid deposition fluxes of both INs and MTNs observed during
The large predicted losses to aerosol influence simulation of both pRONO\(_2\) (for which uptake is the only source in the model) and HNO\(_3\) (which is produced during pRONO\(_2\) hydrolysis). We find here that our simulation including a large sink to aerosol is consistent with observed surface pRONO\(_2\) concentrations and variability (Figs. 8 and 10), HNO\(_3\) concentrations (Travis et al., 2016, Fig. 2), and nitrate wet deposition fluxes (Travis et al., 2016, Fig. 3) during SEAC\(^4\)RS and SOAS.

Overall, more than 80\% of simulated gas-phase RONO\(_2\) are lost via processes that irreversibly remove nitrogen from the atmosphere (deposition, aerosol hydrolysis). The remainder is primarily lost via photolysis, driven largely by the fast photolysis of 2nd generation carbonyl INs (Müller et al., 2014). Romer et al. (2016) similarly found that terminal NO\(_x\) sinks dominated RONO\(_2\) loss processes during SOAS, responsible for 55\% ± 20\% of total loss, primarily due to aerosol hydrolysis. RONO\(_2\) lifetimes are too short (minutes-hours, Table 1 and Romer et al., 2016) for significant transport to occur, and simulated RONO\(_2\) loss typically occurs only a short distance from sources. Summed over the Southeast US domain, we find gross RONO\(_2\) production and loss are roughly balanced (640 Mg N d\(^{-1}\)). This balance implies that BVOC-derived gas-phase RONO\(_2\) are not generally exported from the Southeast US, in agreement with earlier work (Horowitz et al., 2007; Hudman et al., 2007; Fang et al., 2010; Mao et al., 2013). However, this calculation excludes the longer-lived small alkyl nitrates and non-hydrolyzing particulate nitrates not simulated in GEOS-Chem (Sect. 4). These may be an important source of exported reactive nitrogen, and their inclusion should be a priority for future model development.

The impacts of RONO\(_2\) production and other loss processes on the NO\(_x\) budget are shown in Fig. 11b for the Southeast US boundary layer in August-September 2013. Non-RONO\(_2\) losses in the figure are mainly HNO\(_3\) formation, with an additional contribution from PANs (relevant in regions with elevated NO\(_x\); Browne and Cohen, 2012). We find in the model that gross NO\(_x\) loss due to RONO\(_2\) production is 35 Gg N over this period. As shown in Fig. 11a, only 23\% of this RONO\(_2\) (8 Gg N) goes on to recycle NO\(_x\). We therefore find that RONO\(_2\) production serves as a net NO\(_x\) sink of 27 Gg N in the Southeast US in summer, equivalent to 21\% of NO\(_x\) emitted in this region and season.

These regional-scale averages conceal important spatial variability. Figure 12 shows how the NO\(_x\) sink due to RONO\(_2\) production varies spatially across the Southeast US in summer, and how this depends on the ratio between BVOC and NO\(_x\) emissions (\(E_{BVOC}/E_{NOx}\)). The fractional NO\(_x\) sink to RONO\(_2\) is strongly correlated (\(r = 0.90\)) to the \(E_{BVOC}/E_{NOx}\) ratio. Our finding that RONO\(_2\) production dominates NO\(_x\) loss in very low NO\(_x\) environments is consistent with an earlier analysis for boreal Canada (Browne and Cohen, 2012), which found the fractional sink to RONO\(_2\) approached unity for [NO\(_x\)] < 50 ppt, and with analysis of a subset of the SEAC\(^4\)RS data from the low-NO\(_x\) Ozarks Mountains (Wolfe et al., 2015).

Figure 12c shows how the fractional NO\(_x\) sink to RONO\(_2\) (blue) and the \(E_{BVOC}/E_{NOx}\) emission ratio (red) vary as a function of NO\(_x\) emissions (gray, shown as their cumulative distribution binned into 5\% quantiles). Both are inversely related to NO\(_x\) emissions. We see from the figure that RONO\(_2\) production is the dominant NO\(_x\) sink for regions that account for the lowest 5\% of total Southeast US NO\(_x\) emissions (leftmost bar in Fig. 12c), but the
importance of the sink drops off rapidly as NO\textsubscript{x} emissions increase. By the time 30\% of the regional NO\textsubscript{x} emissions are accounted for, the fractional sink has dropped to 0.2, and from there continues to decline to a minimum of 0.03 in the highest-emitting regions.

The mean $E_{BVOC}/E_{NOx}$ ratio averaged over the Southeast US is 5.3 and is highlighted as the white point in Fig. 12c. The figure shows that most Southeast US NO\textsubscript{x} emission (~65\%) occurs at $E_{BVOC}/E_{NOx}$ ratios that are significantly lower than the regional mean, highlighting the significant spatial segregation between NO\textsubscript{x} and BVOC emissions in this region (Yu et al., 2016).

Emissions projections for the Southeast US anticipate continued decreases in NO\textsubscript{x} emissions (and concomitant increases in the $E_{BVOC}/E_{NOx}$ ratio). While these changes should increase the importance of RONO\textsubscript{2} for the NO\textsubscript{x} budget, the relationship shown in Fig. 12c suggests very large emissions decreases will be necessary before RONO\textsubscript{2} becomes a major regional sink for NO\textsubscript{x}. The figure shows that the sink to RONO\textsubscript{2} is only sensitive to NO\textsubscript{x} emissions in regions where they are already low: a 10\% decrease in total Southeast US NO\textsubscript{x} emissions (e.g., a leftward shift by two bars in the figure) would increase the importance of the sink by less than 0.5\%. The actual rate at which NO\textsubscript{x} emissions in the Southeast US will decrease varies widely among different projections. Under the Representative Concentration Pathway 8.5 (RCP8.5), for example, the Southeast US would see a decrease (relative to 2013 emissions) of 45\% by 2050 to ~1300 Mg N d\textsuperscript{-1}; according to Fig. 12, the RONO\textsubscript{2} sink would still only account for about 10\% of the loss in the highest emitting regions. Under the more aggressive RCP4.5, emissions would decline by 65\% to ~800 Mg N day\textsuperscript{-1} in 2050. At this stage, the RONO\textsubscript{2} sink would become significant (>20\%) throughout the region.

### 6 Conclusions

We have used airborne and ground-based observations from two summer 2013 campaigns in the Southeast US (SEAC\textsuperscript{4}RS, SOAS) to better understand the chemistry and impacts of alkyl and multi-functional organic nitrates (RONO\textsubscript{2}). We used the observations, along with findings from recent laboratory, field, and modeling studies, to update and evaluate biogenic volatile organic compound (BVOC) oxidation schemes in the GEOS-Chem chemical transport model (CTM). From there, we used the updated CTM with 0.25° × 0.3125° (~25 × 25 km\textsuperscript{2}) horizontal resolution to examine RONO\textsubscript{2} speciation, chemical production/loss processes, and importance as a sink for NO\textsubscript{x}.

Our improved mechanism provides a state-of-the-science description of isoprene oxidation in the presence of NO\textsubscript{x}, with updates including a 9\% isoprene nitrate (IN) yield (Xiong et al., 2015), an increase in the population of $\beta$- vs $\delta$-hydroxyl isomers (Peeters et al., 2014), revised IN reaction rate constants and products (Jacobs et al., 2014; Lee et al., 2014), fast photolysis of carbonyl INs (Müller et al., 2014), rapid IN dry deposition (Nguyen et al., 2015), and a simplified scheme for aerosol partitioning of soluble INs (Xu et al., 2014; Marais et al., 2016) followed by particle-phase hydrolysis (Jacobs et al., 2014; Rindelaub et al., 2015). For the first time in GEOS-Chem, we have also added both OH- and NO\textsubscript{3}-initiated monoterpene oxidation leading to the formation of monoterpene nitrates (MTNs), with similar loss processes as for INs. With these updates, GEOS-Chem simulates surface-
level BVOC and RONO\textsubscript{2} mixing ratios that are generally within the observed variability of the SEAC\textsuperscript{4}RS and SOAS data.

Observed first generation IN (ISOPN) variability is generally reproduced without bias by GEOS-Chem, except at midday when modeled ISOPN peaks while SOAS observations indicate a gradual decline. For second generation INs, the model shows more skill for species produced primarily from $\beta$-hydroxyl isomers (MVKN+MACRN) than those from $\delta$-hydroxyl isomers and NO\textsubscript{3}-initiated chemistry (PROPNN+ETHLN). For the latter, GEOS-Chem underestimates both magnitudes and variability relative to the SEAC\textsuperscript{4}RS observations. While this could imply a more important role for $\delta$-channel oxidation than included in our mechanism, theoretical considerations suggest that our assumed $\delta$-hydroxyl contribution is already an upper limit (Peeters et al., 2014), and more measurements are needed to reconcile these theoretical and observational constraints. Better understanding of nighttime NO\textsubscript{3}-initiated isoprene oxidation could also play an important role in improving simulation of second generation INs.

The SEAC\textsuperscript{4}RS observations imply that gas-phase INs account for 25-50\% of total surface RONO\textsubscript{2}, much less than inferred from previous modeling studies (Mao et al., 2013; Xie et al., 2013). GEOS-Chem reproduces this contribution and attributes an additional 10\% of RONO\textsubscript{2} to MTNs. Both observations and model show 10-20\% of the remaining RONO\textsubscript{2} at the surface is in the particle phase (pRONO\textsubscript{2}). In the free troposphere, GEOS-Chem greatly underestimates total RONO\textsubscript{2} by ignoring contributions from small, long-lived nitrates derived from anthropogenic VOCs and from non-hydrolyzing particulate species. This has a significant impact on simulation of reactive nitrogen export from the United States and should be remedied in future model development.

We find in the model that formation of pRONO\textsubscript{2} via aerosol uptake, followed by particle-phase hydrolysis, is the dominant loss process for gas-phase RONO\textsubscript{2}. Including this large sink to aerosol results in simulated RONO\textsubscript{2}, pRONO\textsubscript{2} and HNO\textsubscript{3} mixing ratios and nitrate deposition fluxes that are consistent with observations. RONO\textsubscript{2} loss via deposition is also significant, with RONO\textsubscript{2} (both gas-phase and particulate) responsible for $\sim$3\% of total N deposition over the Southeast US in summer.

Overall, less than a quarter of simulated gas-phase RONO\textsubscript{2} loss recycles atmospheric NO\textsubscript{x}. We find in the model that RONO\textsubscript{2} production accounts for 21\% of the net sink of NO\textsubscript{x} emitted in the Southeast US in summer. RONO\textsubscript{2} production is the dominant NO\textsubscript{x} sink only in regions where elevated BVOC emissions are paired with very low NO\textsubscript{x} emissions. Elsewhere, the importance of the sink declines rapidly as a function of NO\textsubscript{x} emissions. Most of the Southeast US NO\textsubscript{x} is emitted in locations where BVOC emissions are relatively low, limiting the importance of RONO\textsubscript{2} as a NO\textsubscript{x} sink.

Southeast US NO\textsubscript{x} emissions have been declining for the past two decades (Hidy et al., 2014; Simon et al., 2015) and further reductions are projected (Lamarque et al., 2011; EPA, 2014). Previous studies have suggested these declines will trigger a more important role for RONO\textsubscript{2} as a NO\textsubscript{x} sink in future (Browne and Cohen, 2012). In contrast, we find here that the NO\textsubscript{x} sink to RONO\textsubscript{2} is only sensitive to NO\textsubscript{x} emissions in regions where they are already
low because of the spatial segregation between NOx and BVOC emissions. We find that a 10% decrease in Southeast US NOx emissions would enhance the importance of this sink by less than 0.5%. HNO3 formation and deposition is likely to remain the dominant sink for NOx even as NOx emissions decrease.

Figure 1.
Schematic representation of organic nitrate chemistry and impacts. Organic nitrates are shown in blue, NO\textsubscript{x} and processes that recycle NO\textsubscript{x} are shown in red, and nitrogen deposition is shown in orange. Symbols courtesy of the Integration and Application Network, University of Maryland Center for Environmental Science (ian.umces.edu/symbols/).
Figure 2.
Schematic of the formation of isoprene nitrates (INs) from OH-initiated isoprene oxidation as implemented in GEOS-Chem. The isomers shown are indicative as the mechanism does not distinguish between isomers (except for $\beta$- vs. $\delta$-configurations). For ISOPNO$_2$ oxidation, only IN products are shown, along with their yields from both NO and HO$_2$ pathways. Small yields (<10%) of MVKN and MACRN from $\delta$-ISOPNO$_2$ are not shown.
Figure 3.
Simplified representation of the formation of monoterpenic nitrates (MTN) from monoterpenic oxidation as implemented in GEOS-Chem. For each lumped species, only one indicative form is shown.
Figure 4.
Observed (left) and simulated (right) mixing ratios of isoprene and monoterpenes below 1 km during the SEAC4RS aircraft campaign (12 Aug - 23 Sep 2013). The GEOS-Chem model has been sampled along the aircraft flight tracks, and the observations binned to the spatial and temporal resolution of the model. The normalized mean bias of the simulation relative to the PTR-MS measurements in the lowest 500 m is +34% for isoprene and +3% for monoterpenes.
Figure 5.
Observed (black) and modeled (red) median 0-4 km profiles of NO\textsubscript{x}, biogenic VOCs, and oxidation products over the Southeast US (80-94.5°W, 29.5-40°N) during SEAC\textsuperscript{4}RS. Data are binned in 500m increments, and horizontal lines indicate the interquartile range within each bin. Gray shading represents the measurement uncertainty. The model has been sampled in the same manner as the observations, as described in the text. For organic nitrates (e-h), SOAS campaign median surface values are shown as triangles. For ISOPN (e), the gray triangle represents the Purdue CIMS and the black triangle the CIT-ToF-CIMS.
Figure 6. Observed (black, gray) and simulated (red) median diurnal cycles of isoprene, monoterpenes, first generation isoprene nitrates (ISOPN), and second generation isoprene nitrates (MVKN+MACRN+PROPNN+ETHLN) at Centreville during the 2013 SOAS campaign. Gray shading represents the measurement uncertainty, vertical bars show the interquartile range of the hourly data, and the normalized mean bias (NMB) of the simulation is given inset. The model has been sampled in the Centreville grid box only for hours with available data during 16 June - 11 July for isoprene and monoterpenes from the UC Berkeley PTR-ToF-MS (solid black), 13 June - 15 July for α-pinene + β-pinene from the Purdue 2D-GF-FID (dashed gray), 1 June - 11 July for ISOPN from the Purdue CIMS (dashed gray), and 1 June - 4 July for ISOPN and 2nd generation isoprene nitrates from the CIT-ToF-CIMS (solid black). For ISOPN and monoterpenes, differences in data availability between the two measurements result in slightly different model values (solid/dashed red lines).
Figure 7.
Observed (left) and simulated (right) mixing ratios of isoprene nitrates below 1 km during SEAC4RS, separated into first generation (ISOPN) and second generation (MVKN +MACRN+PROPNN+ETHLN) species. The GEOS-Chem simulation has been sampled along the aircraft flight tracks, and the observations binned to the spatial and temporal resolution of the model, as described in the text. The normalized mean bias of the simulation relative to the measurements in the lowest 500 m is -0.6% for ISOPN and -35% for second generation isoprene nitrates.
Figure 8.
Timeseries of observed (black) and simulated (red) hourly mean RONO\textsubscript{2} at Centreville during the 2013 SOAS campaign for 1st generation isoprene nitrates (ISOPN, from the Purdue CIMS), 2nd generation isoprene nitrates (MVKN+MACRN+PROPNN+ETHLN from the CIT-ToF-CIMS), particulate RONO\textsubscript{2} (pRONO\textsubscript{2}, from the AMS) and total alkyl nitrates (ΣANs, from the TD-LIF). The model has been sampled in the Centreville grid box only for hours with available data from each instrument. The model-observation correlation coefficient (r) for each species is given inset both for the measurement shown and (where available) for additional measurement of the same species (with timeseries shown in Fig. S4).
Figure 9.
Observed (black) and simulated (red) correlations between HCHO and the sum of major isoprene nitrates produced via daytime isoprene oxidation (ISOPN+MVKN+MACRN) in Southeast US surface air (<1 km) during SEAC4RS. Thick solid lines indicate the best fit as calculated from a reduced major axis regression, and shaded areas show the 95% confidence interval on the regression slope as determined by bootstrap resampling. The regression slopes and correlation coefficients are given inset.
Figure 10.
(a) Median vertical profiles of estimated total RONO₂ over the Southeast US during SEAC⁴RS. For the observations, the solid black line indicates the TD-LIF ΣANs measurements (with gray shading for the measurement uncertainty) and the dashed black line the sum of CIT-ToF-CIMS, WAS, and AMS measurements of individual RONO₂ species (gas-phase and particulate). For the model, the solid red line indicates the total simulated RONO₂ and the dashed red line the sum of total simulated RONO₂ plus measured ≤C₃ RONO₂ that are not included in the simulation. Triangles compare the total RONO₂ during SOAS from TD-LIF ΣANs and GEOS-Chem. (b) Mean RONO₂ composition from the observations (CIT-ToF-CIMS, WAS, and AMS) and the model. Isoprene nitrates (INs) include 1st generation (ISOPN, plus ISN1 for GEOS-Chem) and 2nd generation INs (MVKN+MACRN, PROPNN, ETLHN, NISOPOOH, plus DHDN for GEOS-Chem). Monoterpene nitrates (MTNs) are shown for the model only and include first and second generation contributions. Other gas-phase RONO₂ (yellow, brown) are mainly anthropogenic and do not represent the same species between the model and the observations.
Figure 11.
Simulated relative importance of gas-phase loss processes (%) in the Southeast US boundary layer (80-94.5°W, 29.5-40°N, <2 km) during August-September 2013 for (a) gas-phase RONO$_2$ and (b) NO$_x$. In (a), outer circles group losses into those that recycle NO$_x$ (pale red) and those that serve as terminal NO$_x$ sinks (pale blue). Loss processes that recycle RONO$_2$ by converting between RONO$_2$ species (e.g. first to second generation) are not included. In (b), net loss to RONO$_2$ is calculated as the difference between NO$_x$ consumed during RONO$_2$ production and NO$_x$ recycled during RONO$_2$ loss, with recycling efficiencies from (a). Net non-RONO$_2$ chemistry is the difference between NO$_x$ chemical production and chemical loss excluding all RONO$_2$ chemistry, and net export is the difference between emissions and all other sinks. Absolute loss rates from all processes combined (Mg N d$^{-1}$) are given in the sub-plot titles.
Figure 12.
Importance of organic nitrates as a sink for NOx, as a function of BVOC and NOx emissions. (a) Simulated fraction of emitted NOx that is lost to RONO2 production in Southeast US surface air. (b) Ratio of BVOC (isoprene + monoterpene) emissions ($E_{BVOC}$) to NOx emissions ($E_{NOx}$). (c) Mean values of variables from (a) and (b) as a function of cumulative NOx emissions in the Southeast US. Model grid squares have been sorted by NOx emissions then grouped into bins that each represent 5% of total Southeast US NOx emissions. Values shown for the fractional NOx sink due to RONO2 production (blue) and the mean $E_{BVOC}/E_{NOx}$ emissions ratio (red) represent the mean within each bin. NOx emissions are shown as cumulative totals (gray) in Mg N day$^{-1}$. The Southeast US mean $E_{BVOC}/E_{NOx}$ emissions ratio (5.3) is highlighted with a white circle.

Table 1

Gas-phase organic nitrates in GEOS-Chem: formation and loss pathways and lifetimes.\(^a\)

| Species                        | Model name | Principal formation pathways\(^b\) | Removal Processes\(^c\)                                      | Lifetime (h)\(^d\) |
|-------------------------------|------------|-----------------------------------|-----------------------------------------------------------|-----------------|
| β-hydroxy isoprene nitrate    | ISOPNB     | ISOP + OH                         | aerosol hydrolysis deposition oxidation photolysis        | 1.8             |
| δ-hydroxy isoprene nitrate    | ISOPND     | ISOP + OH                         | deposition oxidation aerosol hydrolysis photolysis        | 4.0             |
| C\(_5\) nitrooxy carbonyl      | ISN1       | ISOP + NO\(_3\)                   | deposition photolysis oxidation aerosol hydrolysis        | 0.29            |
| C\(_5\) nitrooxy hydroperoxide | INPN       | ISOP + NO\(_3\)                   | n/a                                                       | n/a             |
| methyl vinyl ketone nitrate    | MVKN       | ISOPNB + OH                       | deposition aerosol hydrolysis photolysis oxidation        | 3.1             |
| methacrolein nitrate          | MACRN      | ISOPNB + OH                       | photolysis deposition aerosol hydrolysis oxidation        | 1.5             |
| propanone nitrate             | PROPNN     | ISOPND + OH ISN1 + NO\(_3\)       | deposition photolysis oxidation                            | 3.3             |
| ethanal nitrate               | ETHLN      | ISOPND + OH                       | deposition photolysis oxidation                            | 1.5             |
| C\(_5\) dihydroxy dinitrate   | DHDN       | ISOPND + OH ISOPND + OH           | aerosol hydrolysis deposition                             | 4.6             |
| saturated first generation monoterpe nitrate | MONITS     | API + OH API + NO\(_3\) LIM + NO\(_3\) | deposition aerosol hydrolysis photolysis oxidation       | 1.8             |
| unsaturated first generation monoterpe nitrate | MONITU     | API + OH API + NO\(_3\) LIM + OH LIM + NO\(_3\) | oxidation deposition aerosol hydrolysis photolysis      | 0.85            |
| second generation monoterpe nitrate | HONIT      | MONITU + OH MONITS + OH           | aerosol hydrolysis deposition photolysis oxidation       | 1.7             |

\(^a\) Model results are averaged over Southeast US surface air sampled along the SEAC\(^4\)RS flight tracks.

\(^b\) Primary precursor(s) and associated oxidant(s). The related peroxy radicals and their oxidants can be seen in Figs. 1 and 2.

\(^c\) Removal processes for each species are ordered by their contribution to total loss during SEAC\(^4\)RS. Losses due to oxidation, photolysis, and aerosol uptake are calculated along the SEAC\(^4\)RS flight tracks. Deposition includes both dry and wet scavenging and is calculated from regional means over all Southeast US grid boxes. Wet deposition in the model is calculated for lumped species ISOPNB+ISOPND, MVKN+MACRN, and MONITU+MONITS and individually for all others. For this table, we assume partitioning of 90% ISOPNB (10% ISOPND) based on the initial formation yields and a 50:50 split for the other lumped species. Wet scavenging is only a small contribution to total RONO\(_2\) deposition, and this assumption has minimal impact on these values.

\(^d\) Lifetimes are the combined lifetimes against deposition as calculated over all grid boxes and against oxidation, photolysis, and aerosol hydrolysis as calculated along the flight tracks, with further details in note c. These are representative of daytime conditions only, as determined by the timing of the SEAC\(^4\)RS flights.

\(^e\) INPN is not treated as a transported species, so diagnostics needed to calculate removal rates and lifetime are not available.
