(Dated: March 6, 2022)

The recent study of $^{77}$Se nuclear magnetic resonance (NMR) in a $\beta$-FeSe single crystal proposed that ferro-orbital order breaks the $90^\circ C_4$ rotational symmetry, driving nematic ordering. Here, we report an NMR study of the impact of small strains generated by gluing on nematic state and spin fluctuations. We observe that the local strains strongly affect the nematic transition, considerably enhancing its onset temperature. On the contrary, no effect on low-energy spin fluctuations was found. Furthermore we investigate the interplay of the nematic phase and superconductivity. Our study demonstrates that the twinned nematic domains respond unequivalently to superconductivity, evidencing the twofold $C_2$ symmetry of superconductivity in this material. The obtained results are well understood in terms of the proposed ferro-orbital order.

Many experiments have established the existence of nematic order — a state that spontaneously breaks the rotational symmetry while time-reversal invariance is preserved — in Fe-based superconductors (FeSCs) [1,2]. Although whether spin or orbital degrees of freedom drive the nematic order is still under debate [3–13], it is widely believed that a nematic instability is an important characteristic of the normal state from which superconductivity emerges. Therefore establishing the mechanism of the nematic order will help to elucidate the Cooper pair formation of superconductivity in this material.

In most FeSCs, the nematic state arises in the vicinity of a spin-density wave state. The temperature ($T$) interval separating them is small. As a result the strong interaction of various degrees of freedom hides the nature of the nematic order. The only exception is $\beta$-FeSe which has a PbO-type crystal structure. The nematic order occurs at $T_{\text{nem}} \approx$ 91 K and at a lower temperature of $T_c \approx$ 9 K SC sets in. The absence of static magnetism in the whole interval of temperature together with its simple structure [16] make $\beta$-FeSe the primary object for investigation of nematicity and its interplay with SC [14,17–26]. To other spectacular properties of $\beta$-FeSe belongs the dramatic increase in $T_c$ under pressure [27,28] or by growing mono layer films on substrates [29,31]. The band structure of $\beta$-FeSe is typical for FeSC [32,33]. The low energy is given by two hole bands around the $\Gamma$ point and two electron bands around the $M$ point. The nesting between the electron and the hole bands advocates strong spin fluctuations (SFs) at low $T$ which indeed were observed in nuclear magnetic resonance (NMR) and neutron studies at $T \ll T_{\text{nem}}$. However no enhancement of SFs was found close to the nematic transition. It led to the suggestion that nematic state in $\beta$-FeSe is driven by orbital degrees of freedom [34,35].

In this Rapid Communication, we report the investigations of nematic order in the normal and superconducting states of $\beta$-FeSe. We show that gluing the sample introduces random local strains (defects) and significantly smears out the otherwise sharp nematic transition resulting in the enhanced onset of nematic ordering. In contrast, it appears that low-energy SFs are essentially unaffected by the strain. Furthermore, we demonstrate that the twofold $C_2$ symmetry of SC in this material is the consequence of the interplay between orbital and superconducting order parameters.

The $^{77}$Se NMR measurements were carried out in a $\beta$-FeSe single crystal from the same batch as the one measured in the previous study [35] at an external field ($\mu_0 H$) of 9 T and in the $T$ range of 4.2 – 180 K. The sample was mounted to a single-axis goniometer for the exact alignment along $H$ within the $a$-$c$ plane of the crystal. The $^{77}$Se NMR spectra were obtained by a standard spin-echo technique, and the $^{77}$Se spin-lattice relaxation rate $T_1^{-1}$ was measured using a saturation method by fitting the recovery of the nuclear magnetization $M(t)$ to a single exponential function, $1 - M(t)/M(\infty) = A \exp(-t/T_1)$, where $A$ is a fitting parameter that is ideally unity. In this Rapid Communication, we glued the sample inside the NMR coil using a small amount of diluted GE varnish not only for the better and stable alignment of the sample, but also for examining a possible effect of gluing on nematicity. The motivation is that while using a glue on samples is unavoidable in many bulk measurements, it is unknown whether there are nontrivial effects of random strains that could be introduced by gluing.

Figure 1 (a) shows $^{77}$Se NMR spectra as a function of $T$ at $\mu_0 H =$ 9 T applied along the crystallographic $a$ axis. The $^{77}$Se line splits into the two lines $\ell_{1,2}$ below $T_{\text{nem}} \sim$ 91 K, which is consistent with the previous results [32]. In Ref. [35], it was established that the splitting of the $^{77}$Se line is much larger than one could expect from the small orthorhombic distortion. In order to further demonstrate that the split $^{77}$Se NMR lines truly...
FIG. 1. (a) The $^{77}\text{Se}$ NMR spectra for a β-FeSe single crystal measured at $\mu_0 H = 9$ T applied along the a axis as a function of $T$. The splitting of the $^{77}\text{Se}$ line into two (labeled $\ell_1$ and $\ell_2$) was observed near $T_{nem} \sim 91$ K. (b) A $^{77}\text{Se}$ spectrum measured at 60 K as a function of angle $\theta$ between the $\text{H}$ and the c directions. (c) Knight shifts of $\ell_1-\ell_2$ lines and $\Delta K_{||a}$ (see the inset) as a function of $\theta$ follow a simple cosine function (solid lines) as expected for a nematic order parameter.

represent the nematic order parameter, we measured the $^{77}\text{Se}$ spectrum at a fixed $T$ of 60 K as a function of angle $\theta$ between the $\text{H}$ and the c directions by rotating the sample with respect to $\text{H}$ from a toward c on the a-c plane. The resultant angle dependence of the $\ell_1-\ell_2$ spectrum and their Knight shifts $K$ are shown in Figs. 1(b) and 1(c), respectively. $K$‘s of both $\ell_1$ and $\ell_2$ decrease with decreasing $\theta$ following a cosine function of $\theta$, and smoothly merge into a single line when $H \parallel c$. As a result, the difference of the Knight shifts $\Delta K_{||a}$ [see the inset of Fig.1(c)] is perfectly described by a cosine function of $\theta$ (solid line). This unambiguously verifies that $\Delta K_{||a}$ indeed reflects the nematic order parameter, which is anticipated to obey such a sinusoidal angle dependence.

Although the $T$ evolution of the $^{77}\text{Se}$ NMR spectrum is very similar to the results obtained in the sample that was not glued [32], it turns out that the full width at half maximum of NMR lines are two to three times broader. Since both the current and the previous NMR studies have been carried out on the crystals from the same batch under the identical experimental setup and conditions, the inhomogeneous NMR line broadening is attributed to local strains introduced by gluing the sample. In addition to the inhomogeneous broadening of the $^{77}\text{Se}$ lines, we find that the nematic transition is not as sharp as in the previous study. Namely, the line splitting does not disappear immediately above the nematic transition temperature $T_{nem} = 91$ K but persists up to higher $T$. Indeed, Figs. 2 (a) and 2(b) indicate that the $\ell_1$ and $\ell_2$ lines start to split at $T^* \sim 120$ K that is significantly higher than $T_{nem}$. In this regard, we refer to the sample that was not glued as strain free. Since in the range of $T_{nem} < T < T^*$ the material remains in the tetragonal symmetry in bulk, the persisting NMR line splitting above $T_{nem}$ indicates that the 90° rotational symmetry should be broken only near local strains. The reason may be the emergence of the local nematic order $\psi(r)$, which exists only locally as a form of small domains without affecting the bulk tetragonal phase of the crystal, by coupling to the local uniaxial strains caused by the gluing. In this case, the broad NMR line between $T_{nem} \leq T \leq T^*$, which is not well resolved, may consist of three lines: the split $\ell_1-\ell_2$ lines from the regions near strains and the unsplit line from the tetragonal region away from strains.

A description of the $T$ dependence of the nematic order parameter $\psi$ can be done in the frame of the Landau theory. The free energy in the presence of an external uniaxial stress $\sigma$ has the following form:

$$\Delta F = \alpha(T-T_{nem})\psi^2 + \frac{b}{2}\psi^4 - \lambda \sigma \psi.$$  \hspace{1cm} (1)

For simplicity we neglect the spatial variation of the nematic order parameter assuming that the size of the domains is large. The effective coupling constant $\lambda$ is a $T$ independent function of the shear modulus $C_{66,0}$ that can be obtained by integrating out the structural degree of freedom from the Landau functional [38]. The linear coupling of $\psi$ to $\sigma$ leads to the induced nematicity seen in the range of $T_{nem} \leq T \leq T^*$. For $T < T_{nem}$, the contribution of $\sigma$ to $\Delta F$ is negligible. Therefore the $T$ dependence of $\psi$ is not affected by local strains due to gluing, as shown in Fig. 2(b). The solution $\psi(T)$ minimizing the Landau functional Eq. (1) is continuous. In the case of a structure with two types of domains with strain and without strain, the splitting seen for $T > T_{nem}$ is mainly given by the domains with strain, whereas for $T < T_{nem}$ both cases give the same NMR line splitting. The solutions of Eq. (1) are given as the solid and dashed curves in Fig. 2(b), where the values of the parameters are the same for both cases, but the solid curve corresponds to 20% of the sample volume being under the stress. It is interesting to note that in BaFe$_2$(As$_{1-x}$P$_x$)$_2$ a similar nematic onset was observed in magnetic torque measurements by Kasahara et al. [32]. For β-FeSe we have the advantage to be able to compare strained and unstrained samples and observe that at a higher $T$ the onset of the nematic ordering is absent in pristine, strain-free crystals, see Fig. 2(b), and only present in glued crystals, which are affected by strain. In β-FeSe the transition at 91 K is therefore of nematic nature and does not share the meta-nematic origin that has been assigned to it in BaFe$_2$(As$_{1-x}$P$_x$)$_2$. Having established that the local strains significantly enhance local nematicity, the question arises whether an-
As one can see, the average of the Knight shifts and the $\ell_1-\ell_2$ splitting $\Delta K_{||a}$, respectively. The comparison with the results in Ref. \[35\] which were rescaled by 1.15 reveals that the actual splitting occurs at $T^* \sim 120$ K significantly higher than $T_{nem} = 91$ K. $\Delta K_{||a}$ becomes proportional to $\sqrt{T_{nem} - T}$ below $T_{nem}$ indicating that $T_{nem}$ is the true nematic transition temperature. The solid and dashed curves in (b) are theoretical calculations (see the text). The inset in (a) shows an enlargement of the region denoted by the red rectangle to compare with the sharp splitting observed in a “strain-free” sample \[35\]. The raw $^{77}$Se spectra from the current Rapid Communication (left) and those from Ref. \[35\] (right) in selected temperatures near $T_{nem}$ are compared in the inset of (b). (c) $T$ dependence of the spin-lattice relaxation rate divided by $T$ $(T/T)^{-1}$ near $T_{nem}$. The asterisk (*) and cross (×) symbols in gray represent the data of $\ell_1$ and $\ell_2$, respectively, measured without gluing the sample \[35\].

FIG. 2. (a) and (b) Temperature dependence of the $^{77}$Se NMR Knight shift $K$ and the $\ell_1-\ell_2$ splitting $\Delta K_{||a}$, respectively. The comparison with the results in Ref. \[35\] which were rescaled by 1.15 reveals that the actual splitting occurs at $T^* \sim 120$ K significantly higher than $T_{nem} = 91$ K. $\Delta K_{||a}$ becomes proportional to $\sqrt{T_{nem} - T}$ below $T_{nem}$ indicating that $T_{nem}$ is the true nematic transition temperature. The solid and dashed curves in (b) are theoretical calculations (see the text). The inset in (a) shows an enlargement of the region denoted by the red rectangle to compare with the sharp splitting observed in a “strain-free” sample \[35\]. The raw $^{77}$Se spectra from the current Rapid Communication (left) and those from Ref. \[35\] (right) in selected temperatures near $T_{nem}$ are compared in the inset of (b).

The low-energy magnetic excitations are hardly affected by the enhanced nematicity. In parallel to the enhanced onset of nematicity, one can notice that the nematic order parameter $\Delta K_{||a}$ as shown in Fig. 2(b) where the previous data were rescaled by 1.15 are enhanced compared to the previous data. A possible origin is a better alignment of $\mathbf{H}$ along the $a$ axis in the present Rapid Communication, but it could be also local strains that enhance the nematicity. Regardless, an important observation is that $\Delta K_{||a}$ reveals an identical $T$ dependence with that in Ref. \[35\]. They form a maximum near 60 K and decrease with decreasing $T$. At the same time the average of the Knight shifts $K_{av} = K_a + K_b$ and $K_{||c}$ show no change with $T$ below 60 K. The increase in the splitting $\Delta K_{||a}$ in the $T$ interval between $T_{nem}$ and 60 K can be certainly attributed to the increase in the anisotropy of hyperfine couplings $A_{xx}^{hf} - A_{yy}^{hf} \propto \psi$ and the spin susceptibilities $(\chi_{xx} - \chi_{yy}) \propto \psi$ as $\Delta K_{||a}$ depends on both of these values $\Delta K_{||a} = 1/2(A_{xx}^{hf} + A_{yy}^{hf})(\chi_{xx} - \chi_{yy}) + 1/2(A_{xx}^{hf} - A_{yy}^{hf})(\chi_{xx} + \chi_{yy})$. The decrease in $\Delta K_{||a}$ with no $T$ change in $K_{||c} = A_{zz}^{hf} \chi_{zz}$ and the average $K_{av} = 1/2(A_{xx}^{hf} + A_{yy}^{hf})(\chi_{xx} + \chi_{yy}) + 1/2(A_{xx}^{hf} - A_{yy}^{hf})(\chi_{xx} - \chi_{yy})$ below 60 K is a more subtle question. It cannot be explained by the nonanalytic contributions to the spin susceptibility in two-dimensional Fermi liquid as they would also give a linear in $T$ contribution to $K_{||c}$ and $K_{av}$. Another interesting observation is that the decrease in $\Delta K_{||a}$ is accompanied by the increase in the low-energy SFs seen in the spin lattice relaxation rate $(T/T)^{-1}$ [see Fig. 2(c)]. This suggests, contrary to the scenario of the spin nematic \[12\], that the increase in SFs results in the suppression of the nematic order. That is, SFs alone may be insufficient to drive nematic order in $\beta$-FeSe.

Now we focus on the NMR data in the superconducting state. In the previous NMR study, we have shown that $\Delta K_{||a}$ abruptly decreases just below $T_c$. A similar anomalous change in $\Delta K_{||a}$ below $T_c$ was also observed, as shown in Fig. 2 (b), but it appears that the drop of $\Delta K_{||a}$ is much less pronounced than in the previous result. This is in line with the consideration that nematicity is strengthened due to gluing, rendering it more robust against the competition of the superconducting order parameter $\Delta K_{||a}$ \[35\]. Clearly one expects that the nematic ordering, which appears at a much higher $T$ than SC, is only marginally affected by SC, but vice versa that SC is much more strongly affected by the presence of already preformed nematic order that breaks the in-plane symmetry. The latter we indeed observe as well and is revealed by measurement of the $T$ dependence of intensities of the $\ell_1$ and $\ell_2$ lines below $T_c$.

The $\ell_1$ and $\ell_2$ lines represent the twinned nematic domains, and their $T$ dependence below $T_c$ is presented in Fig. 2(a). To begin with, it should be noted that $\ell_1$ has a slightly bigger intensity than $\ell_2$ in the normal state above 7.5 K, indicating that one of the twinned nematic domains coincidentally has larger volume than the other. Although the two NMR lines have an unchanged signal intensity with $T$ in the normal state, we observed that just below $T_c$ they lose the signal intensity rapidly with...
Strikingly, Fig. 3(a) reveals that at 5 K \( \ell_1 \) is almost quenched whereas \( \ell_2 \) is visible, in sharp contrast with the fact that \( \ell_1 \) has a bigger intensity than \( \ell_2 \) above \( T_c \). This means that \( \ell_1 \) is losing intensity faster than \( \ell_2 \) with lowering \( T \) in the SC state. Indeed, as shown in Fig. 3(b), the integrated signal intensity as a function of \( T \) reveals the distinctly different \( T \) dependence of \( \ell_1 \) and \( \ell_2 \). Since the split \( \ell_1-\ell_2 \) lines represent the twinned domains whose nematicity are parallel and perpendicular, respectively, to \( \mathbf{H} \), without further analysis, we already conclude that the SC response of the two domains is inequivalent, indicating that \( \lambda_\perp \neq \lambda_\parallel \). Actually in the clean limit at low \( T \) the anisotropy in penetration depth is associated with the anisotropy in the velocities due to the nematic phase as \( \lambda_\perp \neq \lambda_\parallel \rightarrow \langle v_\perp^2 \rangle \neq \langle v_\parallel^2 \rangle \) [11]. This implies that the broken in-plane symmetry of SC is a natural consequence of the elongated Fermi surface caused by orbital ordering.

This tetragonal symmetry breaking of \( \lambda \) is indeed consistent with the highly elongated vortex core along the \( a \) axis observed by scanning tunneling microscopy in FeSe films on a SiC substrate [4]. The twofold symmetry of the vortex core state can be understood by the difference between SC coherence length \( \xi \) along the \( a \) and \( b \) directions, being attributed to the strong impact of the nematic order on SC [12, 13].

In conclusion, we presented a NMR study of a \( \beta \)-FeSe single crystal under small strain generated by gluing. We found that the local strains considerably affect the nematic order, whereas no effect on low-energy SFs was found. These results suggest that nematicity in \( \beta \)-FeSe is not driven by SFs, supporting the orbital ordering picture. The unusual in-plane anisotropy of the penetration depth \( \lambda \) manifests the twofold symmetry breaking of SC due to orbital ordering.
