TROPICAL REAL HURWITZ NUMBERS

HANNAH MARKWIG AND JOHANNES RAU

ABSTRACT. In this paper, we define tropical analogues of real Hurwitz numbers, i.e. numbers of covers of surfaces with compatible involutions satisfying prescribed ramification properties. We prove a correspondence theorem stating the equality of the tropical numbers with their real counterparts. We apply this theorem to the case of double Hurwitz numbers (which generalizes our result from [GPMR]).

1. INTRODUCTION

1.1. Result. We study tropicalizations of covers of surfaces with compatible orientation-reversing involutions and define tropical analogues of real Hurwitz numbers, i.e. numbers of such covers satisfying fixed ramification data. We prove a correspondence theorem stating the equality of tropical real Hurwitz numbers and real Hurwitz numbers. As in the complex case (i.e. without the extra data of real involutions), the basic idea is that tropical covers can be considered as graphical representations of pair-of-pants decompositions or of the terms in the well-known degeneration formula for Hurwitz numbers (see e.g. [BBM2, C2]).

1.2. Motivation and background. The definition of Hurwitz numbers as numbers of ramified covers of a fixed target curve satisfying prescribed conditions goes back to Hurwitz and has since then provided fruitful connections between various areas of mathematics such as algebraic geometry, representation theory, the theory of random matrices and mathematical physics (see e.g. [ELSV, OP2, OP1]). Real versions of Hurwitz numbers have been considered, e.g. in [C1]. They also appear in the study of topological field theories [AN]. At first glance, they lack an important feature that complex Hurwitz numbers have: they are not invariants of the chosen branch points. In light of the success of tropical methods for the study of real analogues of numbers of plane curves (which is summarized in the next subsection), we believe that the study of tropical methods for real Hurwitz numbers that we initiated in [GPMR] with Guay-Paquet and continue here will be fruitful for the further research in this area.

1.2.1. Welschinger invariants and tropical geometry. Tropical geometry is a powerful tool for the study of enumerative problems [M]. It has particular success in real enumerative geometry and the study of Welschinger invariants [IKS2, S]. The latter can be viewed as analogues of plane Gromov-Witten invariants, i.e. of numbers of (complex) nodal plane curves of some fixed degree and genus satisfying point conditions. More precisely, when counting complex curves the number we obtain does not depend on the particular choice of the point conditions, as long as they are in general position. For real curves this is no longer true. However, when we count each curve with a suitable sign depending on the nodes, we obtain an invariant count, the Welschinger number [W]. Obviously, it is a lower bound for the number of real curves. The tropical approach provides algorithms to determine

2010 Mathematics Subject Classification: Primary 14T05, Secondary 14N10.
Welschinger invariants. It can also be used for interesting statements on the asymptotics when compared to Gromov-Witten invariants (e.g. [IKS1]). We would also like to mention related work of Itenberg and Zvonkine (not yet published) in which the authors define a signed count of real polynomials (i.e. real Hurwitz numbers of genus 0 and with a total ramification point) and show the invariance of the position of the branch points. It will be interesting to study their situation with a tropical perspective.

1.2.2. Tropical Hurwitz numbers. Tropical versions of (complex) double Hurwitz numbers of $\mathbb{P}^1$ have been studied in [CJM1] using an approach via the symmetric group. A more general correspondence theorem obtained with topological methods was proved in [BBM2]. Tropical Hurwitz numbers appear in the tropical computation of genus zero Zeuthen numbers, i.e. numbers of curves satisfying point conditions and tangency conditions to fixed lines [BBM1]. Tropical double Hurwitz numbers are useful to prove statements about the structure of double Hurwitz numbers [CJM2].

In [GPMR], together with Guay-Paquet we define tropical real double Hurwitz numbers with positive branch points and study their combinatorial properties.

In this paper, we generalize the correspondence theorem to arbitrary covers. Our approach is similar to the open Hurwitz numbers approach in [BBM2].

1.3. Organization of this paper. In section 2, we introduce covers of surfaces and numbers of such covers satisfying fixed ramification data. We concentrate on the case of real Hurwitz numbers, i.e. numbers of covers of surfaces with compatible orientation-reversing involutions. In section 3, we introduce tropical curves, covers and real structures which turn out to be natural counterparts of real covers. We also introduce tropical real Hurwitz numbers. In section 4, we prove our correspondence theorem stating the equality of real Hurwitz numbers with their tropical counterparts. In section 5, we focus on the case of covers of $\mathbb{P}^1$ with only real branch points. In this case, we can boil down our general definition of real tropical Hurwitz numbers to a more combinatorial recipe. We also recover the correspondence theorem of [GPMR] dealing with double Hurwitz numbers with positive real simple branch points.

1.4. Acknowledgements. The first author is supported by DFG-grant MA 4797/1-2 and GIF grant no. 1174-197.6/2011. The second author would like to thank the Université de Genève for the hospitality during his stay. We would like to thank Erwan Brugallé, Ilia Itenberg and Grisha Mikhalkin for helpful discussions.

2. Real covers and Hurwitz numbers

We start by recalling the general definition of (complex) Hurwitz numbers. Fix a genus $g$, a degree $d$ and a collection $\mu = (\mu_1, \ldots, \mu_n)$ of $n$ partitions of $d$. Let $D$ be a connected oriented closed compact topological surface of genus $h$ and fix $n$ points $p_1, \ldots, p_n \in D$. We want to count ramified covers of degree $d$, i.e. maps $f : C \to D$ where $C$ is another connected orientable closed compact topological surface of genus $g$ and $f$ is a continuous map which restricts to a degree $d$ covering over $D \setminus \{p_1, \ldots, p_n\}$ and which has ramification profile $\mu_i$ over $p_i$ (i.e. the multiset of ramification indices of the preimages of $p_i$ equals $\mu_i$). Given two such covers $f : C \to D$ and $f' : C' \to D$, an isomorphism of covers is a homeomorphism $\varphi : C \to C'$ such that $f = f' \circ \varphi$. Moreover, for our purposes it will sometimes be useful to add markings to the ramification points. More precisely, a marking of a cover $f$ is a choice of labellings $q_{i,1}, \ldots, q_{i,l(\mu_i)}$ for the preimage $q_i = f^{-1}(p_i)$ of each branch point $q_{i,j}$ is $\mu_{i,j}$ (we consider $\mu_i$ as a vector here). We require that an isomorphism of marked covers respects the labels, i.e. $\varphi(q_{i,j}) = q'_{i,j}$. 
Definition 2.1
We define the Hurwitz number $H^C_g(D,\mu)$ to be the weighted number of covers $f : C \to D$ up to isomorphism. Each cover is weighted by $\frac{1}{|\text{Aut}(f)|}$. Analogously, we let $H^\text{mark, C}_g(D,\mu)$ be the number of marked covers (with respect to marked iso-/automorphisms).

Remark 2.2
$H^C_g(D,\mu)$ is non-zero only if the prescribed data $g$, $h$ and $\mu$ satisfies the Riemann-Hurwitz formula. We will assume this in the following.

Let $\text{Aut}(\mu) = \prod_{i=1}^n \{\sigma \in S_t(\mu_i) : \mu_i(\sigma(j)) = \mu_i(\sigma(j)) \forall j\}$

the group of automorphisms of $\mu$. Let $f^{\text{mark}}$ be a marked cover and let $f^{\text{unmark}}$ be the corresponding unmarked cover. The action of $\text{Aut}(f^{\text{unmark}})$ on the labels of $f^{\text{mark}}$ gives a group homomorphism

$k : \text{Aut}(f^{\text{unmark}}) \to \text{Aut}(\mu)$.

We have $\ker(k) = \text{Aut}(f^{\text{mark}})$ and $|\text{Aut}(\mu) : \text{Im}(k)| = m$, where $m$ is the number of markings for $f^{\text{unmark}}$ (up to isomorphism). Hence $|\text{Aut}(f^{\text{unmark}})|m = |\text{Aut}(f^{\text{mark}})| |\text{Aut}(\mu)|$ and

$H^\text{mark,C}_g(D,\mu) = |\text{Aut}(\mu)| \cdot H^C_g(D,\mu)$.

Note that $H^C_g(D,\mu)$ does not depend on the choice of the $n$ branch points, nor on the concrete Riemann surface $D$ (as any other choice $(D',p_1',\ldots,p_n')$ is homeomorphic to the given one).

Given a complex structure on $D$, for each $f : C \to D$ there exists a unique complex structure on $C$ such that $F$ is a holomorphic ramified cover. Hence $H^C_g(D,\mu)$ can also be interpreted as the count of (non-constant) holomorphic maps of compact Riemann surfaces with fixed ramification profile. However, we stick to the topological viewpoint as this simplifies the gluing construction later.

We now add the data of an orientation-preserving involution $\iota_D : D \to D$, i.e. $\iota_D \circ \iota_D = \text{id}$. The fixed point set of the involution is called the real locus of $D$. We consider real covers, i.e. triples $(C,f,\iota_C)$ such that $f : C \to D$ is a cover as before, $\iota_C$ is an orientation-reversing involution on $C$ and the compatibility condition $\iota_D \circ f = f \circ \iota_C$ holds. For such covers to exist, we need that $\mathcal{P} = \{p_1,\ldots,p_n\}$ is invariant under $\iota_D$ (not necessarily pointwise), which we assume from now on. An isomorphism of real covers is required to satisfy $\iota_{C'} \circ \varphi = \varphi \circ \iota_C$.

Definition 2.3
The real Hurwitz number $H^R_g((D,\iota_D),\mathcal{P},\mu)$ is defined to be the weighted number of real covers $(C,f,\iota_C)$ up to isomorphism. Each cover is weighted by $\frac{1}{|\text{Aut}(f)|}$. Analogously we define $H^\text{mark,R}_g((D,\iota_D),\mathcal{P},\mu)$ to the number of marked covers (with respect to marked real iso-/automorphisms).

As before, we have

$H^\text{mark,R}_g((D,\iota_D),\mathcal{P},\mu) = |\text{Aut}(\mu)| \cdot H^R_g((D,\iota_D),\mathcal{P},\mu)$.

Remark 2.4
The real Hurwitz number $H^R_g((D,\iota_D),\mathcal{P},\mu)$ is invariant under homeomorphism respecting the involutions and the branch points. More precisely,

$H^R_g((D,\iota_D),\mathcal{P},\mu) = H^R_g((D',\iota_{D'}),\mathcal{P}',\mu)$

(where $\mathcal{P}' = \{p_1',\ldots,p_n'\}$) if there is a homeomorphism $h : D \to D'$ satisfying $h \circ \iota_D = \iota_{D'} \circ h$ and $h(p_i) = p_i'$. 
Instead of ramified covers of closed surfaces, we can as well consider coverings without ramification of surfaces with boundary. The transition is made by removing open discs around each branch point as well as its preimages resp. gluing in discs (with a marked point) to the boundary circles. The ramification index of a point translates to the degree of the map between the corresponding boundary circles. This framework is referred to as open Hurwitz numbers in [BBME2] and is more appropriate to describe the gluing constructions needed in the following. We will therefore adopt this viewpoint from now on. Moreover, we need to define the following refined real Hurwitz numbers for which we also prescribe the behaviour of the involution at the ramification points. Let us be more precise.

Consider the (unramified) cover \( f : C \to D \) of surfaces with boundary and equipped with orientation-reversing involutions such that \( f \circ \iota_C = \iota_D \circ f \). Let \( B = \{B_1, \ldots, B_n\} \) the collection of boundary circles of \( D \) and \( B_{1,1}, \ldots, B_{1,\ell(\mu_i)} \) be the boundary circles of \( C \) mapped to \( B_i \) (hence we fix a marking of the cover). By slight abuse of notation, we denote by \( \iota \) the map between indices such that \( \iota_D(B_i) = B_{i(i)} \) and \( \iota_C(B_{i,j}) = B_{i(i,j)} \). For the refined Hurwitz numbers we are going to define, the data of \( \iota \) is fixed. Moreover, we prescribe the following. Note that on any boundary circle which is invariant under \( \iota \), the involution has exactly two fixed points. If \( B_{i,j} \) is a boundary circle which is invariant under \( \iota_C \) (i.e. \( \iota_C(i,j) = (i,j) \)) then \( B_i \) is \( \iota_D \)-invariant and the preimage of a fixed point of \( B_i \) in \( B_{i,j} \) is a \( \iota_C \)-invariant set. Hence it consists exactly one fixed point of \( B_{i,j} \) if \( \mu_{i,j} \) is odd and two or no fixed points if \( \mu_{i,j} \) is even. In particular, if \( \mu_{i,j} \) is even, both fixed points of \( B_{i,j} \) are mapped to the same fixed point in \( B_i \). This gives rise to a map

\[
F : \{(i,j) : \mu_{i,j} \equiv 0 \mod 2\} \to \text{Fix}(\iota_D) \cap (B_1 \cup \ldots \cup B_n).
\]

\[
\begin{array}{c}
\text{Fix}(\iota_C) \\
B_{i,j}
\end{array}
\rightarrow
\begin{array}{c}
\text{Fix}(\iota_D) \\
B_i
\end{array}
\]

Even-to-one

\[
\begin{array}{c}
\text{Fix}(\iota_C) \\
B_{i,j}
\end{array}
\rightarrow
\begin{array}{c}
\text{Fix}(\iota_D) \\
B_i
\end{array}
\]

Odd-to-one

**Definition 2.5**

As before, fix \( g, d, \mu \). Fix \( \iota \) as above with \( \mu_{i(i,j)} = \mu_{(i,j)} \). Let \( D \) be a surface of genus \( h \) with \( n \) boundary circles \( B_1, \ldots, B_n \) and with orientation-reversing involution \( \iota_D \) such that \( \iota_D(B_i) = B_{i(i)} \). Finally, fix a map

\[
F : \{(i,j) \in \text{Fix}(\iota) : \mu_{i,j} \equiv 0 \mod 2\} \to \text{Fix}(\iota_D) \cap (B_1 \cup \ldots \cup B_n)
\]

with \( F(i,j) \in B_i \). We define the **refined real Hurwitz number** \( H^\text{ref,R}_g(D, \iota_D, \mu, \iota, F) \) to be the weighted number of marked (unramified) real covers \( f : C \to D \) of given genus and ramification profile and such that

- \( \iota_C(B_{i,j}) = B_{i(i,j)} \),
- \( F(\text{Fix}(\iota_C \cap B_{i,j})) = F(i,j) \) (if \( \mu_{i,j} \) is even).

Each cover is weighted by one over the number of automorphisms (of marked real covers).

The independence statement of the representative in a homeomorphism class (respecting involutions and boundary circles) analogous to remark 2.4 also holds here.
3. TROPICAL CURVES, REAL STRUCTURES AND COVERS

A tropical curve can be thought of as the metrization of the dual graph of a marked nodal stable curve. More precisely, a tropical curve is a weighted metric graph, that is a connected compact 1-dimensional topological space $C$ which locally around each point $p$ is homeomorphic to a star with $r$ branches whose preimages in $C$ we call the flags of $C$ at $p$. The number $r$ is called the valence of the point $p$ and denoted by $\text{val}(p)$. We require that there are only finitely many points with $\text{val}(p) > 2$. The weighting is a function $g : C \to \mathbb{N}$ which is non-zero at finitely many points. We think of the number $g(p)$ as the genus at $p$. We refer to the points with $\text{val}(p) > 2$ or $g(p) > 0$ as the (inner) vertices of $C$. The points with $\text{val}(p) = 1$ are called leaves. The set of vertices and leaves is denoted by $\text{Vert}(C)$. An edge is a path connecting two elements of $\text{Vert}(C)$ without meeting any other. Each edge contains two flags corresponding to its two adjacent vertices. The set of edges is denoted by $\text{Edge}(C)$. We require that the edges adjacent to leaves (called ends) are infinitely long while all other edges (called internal edges) have a length in $\mathbb{R}$.

In a variant of this definition, we require all ends to have a length in $\mathbb{R}$ just as the internal edges. The resulting object is called an open tropical curve. Of course, we could combine these two definitions and allow partially open tropical curves for which some ends are infinitely long and some ends have a finite length. We avoid this to keep notation simpler.

An automorphism of tropical curves is a homeomorphism respecting the metric data and the genus function.

The genus of a tropical curve $C$ is defined to be the sum of the first Betti number of $C$ as a graph and $\sum_{v \in C} g(v)$.

**Definition 3.1**

Let $C$ be an (open) tropical curve. A prereal structure on $C$ is given by an automorphism $\iota : C \to C$ with $\iota^2 = \text{id}$. A tropical curve with a prereal structure is called a prereal tropical curve.

Given a prereal structure, we denote by $\text{Vert}_{\text{fix}}(C)$ the set of vertices $v$ with $\iota(v) = v$ and by $\text{Edge}_{\text{fix}}(C)$ the set of edges $e$ with $\iota|_e = \text{id}_e$.

In the following, we enhance a prereal tropical curve with more data similar to metrized complexes (see e.g. [AB, ABBR]). For this purpose, we denote by $S_{g,n}$ an oriented topological surface of genus $g$ and with $n$ boundary circles for a given genus $g \in \mathbb{N}$ and a number $n$.

**Definition 3.2**

Let $C$ be a tropical curve with prereal structure $\iota$. A real structure on $C$ is given by the following additional data.

(a) For each $v \in \text{Vert}_{\text{fix}}(C)$ we consider the oriented topological surface $S_v := S_{g(v), \text{val}(v)}$ and fix

- a labelling of the boundary circles of $S_v$ by the flags adjacent to $v$ (we denote the boundary circle corresponding to the flag $f$ by $B_f$),
- a orientation-reversing involution $\iota_v$ on $S_v$, such that labelling and involutions are compatible, i.e. $\iota_v(B_f) = B_{\iota(f)}$ for all flags $f$.

(b) For each edge $e \in \text{Edge}_{\text{fix}}(C)$ given by the two flags $f, f'$ adjacent to $v, v'$, we consider the two fixed points of $\iota_v|_{B_f}$ resp. $\iota_{v'}|_{B_{f'}}$ and choose a identification between them (one of the two possible). We can now speak of the fixed points of $e$ and denote this set (of two elements) by $F_e$.
A tropical curve together with a fixed real structure \((C, \iota_C, (S_v)_{v \in \text{Vert}(C)})\) is called a real tropical curve. By abuse of notation, we sometimes denote a (pre-)real tropical just by \(C\).

**Remark 3.3**

The definition of a real structure on a tropical curve \(C\) is tailored such that we can construct a “global” topological surface with orientation-reversing involution from it. This is done in two steps.

(a) For each vertex \(\text{Vert}(C)\) we take oriented copy of \(S_v := S_{g(v), \text{val}(v)}\) and extend the labellings and real involutions to the case of non-fixed vertices, i.e. for each \(v \notin \text{Vert}_{\text{fix}}(C)\), we also fix a labelling of the boundary circles of \(S_v\) by the flags adjacent to \(v\) and we pick orientation-reversing homeomorphisms \(\iota_v : S_v \to S_v\) with \(\iota_v \circ \iota_v = \text{id}_{S_v}\) and \(\iota_v(B_f) = B_{g(v)}(f)\) for all flags \(f\). Additionally, if \(v\) is a leaf vertex adjacent to an infinitely long edge, we mark the disc \(S_v\) by choosing a point \(p_v \in \text{Int}(S_v)\) such that \(\iota_v(p_v) = p_v\).

(b) For each edge \(e \in \text{Edge}(C)\) given by the two flags \(f, f'\) adjacent to \(v, v'\), we glue the surfaces \(S_v\) and \(S_{v'}\) along the boundary circles \(B_f\) and \(B_{f'}\) via a homeomorphism \(g_f : B_f \to B_{f'}\) such that

- \(g_f\) reverses orientations (in order to make the orientations of the glued surfaces compatible),
- \(g_f\) is compatible with the local real involutions, i.e. the diagram
  \[
  \begin{array}{ccc}
  B_f & \xrightarrow{\iota_v} & B_{g(v)}(f) \\
  g_f \downarrow & & \downarrow g_v(f) \\
  B_{f'} & \xleftarrow{\iota_{v'}} & B_{g(v')}\end{array}
  \]
  (1)

  commutes,

- if \(e \in \text{Edge}_{\text{fix}}(C)\), then the identification of the fixed points chosen in part (b) of definition 3.2 agrees with the one given by \(g_f\) (by the previous condition \(g_f\) maps fixed points to fixed points).

Obviously, homeomorphisms \(g_f\) satisfying these conditions exist. After gluing we obtain a oriented topological surface \(C\) of genus \(g(C)\), with marked points labelled by the leaves of \(C\) (in the case of an open tropical curve, with boundary circles labelled by the leaves of \(C\)). Moreover, the local real involutions can be glued as well and give rise to a global real involution \(\iota_C : C \to C\).

A morphism \(\varphi : C \to D\) of (open) tropical curves is a harmonic map of metric graphs satisfying the local Riemann-Hurwitz condition at each point. More precisely, \(\varphi\) is surjective and piecewise integer affine linear, the slope of \(\varphi\) on a flag or edge \(e\) is called the weight \(\omega(e) \in \mathbb{N}_{>0}\). (The case of contracted edges is not relevant for our purposes.) The harmonicity (also referred to as balancing) states that for each point \(v \in C\), the number \(d_v := \sum_{f \to f'} \omega(f)\) (where \(f'\) is a chosen flag adjacent to \(\varphi(v)\) and the sum goes over all flags \(f\) mapping to \(f')\) does not depend on the choice of \(f'\). This number is called the local degree of \(\varphi\) at \(v\). The local Riemann-Hurwitz condition states that when \(v \mapsto v'\) with local degree \(d\)
\[
2 - 2g(v) = d(2 - 2g(v')) - \sum (\omega(e) - 1),
\]
where the sum goes over all flags \(e\) adjacent to \(v\).

**Definition 3.4**

Let \(\varphi : C \to D\) be a morphism of (open) tropical curves, and assume that both \(C\) and \(D\) contain only one inner vertex \(v\) resp. \(v'\). Then the data specified in 2.1 to define a (complex) Hurwitz number is encoded in the tropical cover: for each flag \(f\) of \(v\), we can define a
vector $\mu_f$ of ramification indices by collecting the weights of the flags of $v$ mapping to $f$. By harmonicity (resp. balancing), the $\mu_f$ are all partitions of the same degree, namely the local degree of $\varphi$ at $v$. The local Riemann-Hurwitz condition at $v$ implies that the Riemann-Hurwitz formula is satisfied for ramified covers matching the data. We denote $H^R(\varphi, v) = H^\text{mark,ref}_g(S_{\varphi}, \mu)$. Let us emphasize that the covers contributing here are marked, where we use the flags of $C$ as labels (as the entries of $\mu$ are labelled by these flags as well).

For a general morphism $\varphi : C \to D$ and a vertex $v$ of $C$, we can cut the edges adjacent to $v$ and also the edges adjacent to $\varphi(v)$ in $D$, thus producing local morphisms of open tropical curves $\varphi_v : C_v \to D_{\varphi(v)}$ satisfying the requirement from above (here, $C_v$ denotes the link of $C$ at $v$, and $\varphi_v$ the restriction of $\varphi$ to this link). We denote the corresponding local Hurwitz number as above by $H^C(\varphi, v)$.

**Definition 3.5**

Let $C$ and $D$ be prereal structures for tropical curves $C$ resp. $D$. We say $\varphi : C \to D$ is a prereal morphism if it satisfies $t_D \circ \varphi = \varphi \circ t_C$.

Let $D$ be a real tropical curve. A real tropical cover of $D$ is a prereal curve $C$ and a prereal morphism $\varphi : C \to D$ together with a map

$$F : \{ e \in \text{Edge}_{\text{in}}(C) : \omega(e) \equiv 0 \mod 2 \} \to \bigcup_{e' \in \text{Edge}_{\text{in}}(D)} F_{e'}$$

such that $F(e) \in F_{\varphi(e)}$. We often denote the cover just by $\varphi$. An isomorphism of real covers $\varphi, \varphi'$ is a prereal isomorphism $\alpha : C \to C'$ such that $\varphi = \varphi' \circ \alpha$ and such that $F(e) = F'(\alpha(e))$ for all even edges $e$.

The analogous definition is made for the case of open tropical curves.

**Definition 3.6**

Fix a real tropical cover $\varphi : C \to D$ of a (open) real tropical curve $D$, and assume that both $C$ and $D$ contain only one inner vertex $v$ resp. $v'$, which are necessarily both fixed vertices for $C$ and $D$. Notice that the data we need to specify to obtain a refined Hurwitz number as in definition 2.5 is encoded in the real tropical cover: The vectors of ramification indices are determined by the weights of $\varphi$, as in definition 3.4. The local Riemann-Hurwitz condition implies that the Riemann-Hurwitz formula is satisfied for a cover matching the ramification data as in definition 2.5, resp. more precisely, for a cover where we add in punctured discs for the boundary circles. The choice of fixed points is given by the map $F$, as the notation suggests. Thus, we can define $H^R(\varphi, v) = H^\text{ref,ref}_g(S_{\varphi}, (t_C, \mu, \alpha, F))$.

Let us emphasize again that the labels used to mark the covers contributing to $H^R(\varphi, v)$ correspond to the flags of $C$.

As in definition 3.4, we define the local Hurwitz number $H^R(\varphi, v)$ of a real tropical cover $\varphi : C \to D$ at a fixed vertex $v$ of $C$ to be the number associated to the open cover that we obtain by cutting the edges adjacent to $v$ and to its image and considering the morphism restricted to the link at $v$, so that we obtain a cover whose source and target both contain only one vertex, as required above.

Note that the numbers $H^R(\varphi, v)$ depend on the real structure we fixed for the tropical curve $D$.

**Definition 3.7**

Let $\varphi : C \to D$ be a real tropical cover. Set $EE := \{ e \in \text{Edge}_{\text{in}}(C) : \omega(e) \text{ even} \}$, let $\text{Edge}_{\text{conj}}(C)$ be the set of unordered pairs $(e, e')$ of edges of $C$ satisfying $t_C(e) = e'$ and $\text{Vert}_{\text{conj}}(C)$ the set of unordered pairs $(v, v')$ of vertices of $C$ satisfying $t_C(v) = v'$. We
define the multiplicity of $\varphi$ to be $m(\varphi) := \frac{2|EE|}{\text{Aut}(\varphi)} \prod_{v \in \text{Vert}_m(C)} H^R(\varphi, v) \prod_{(e,e') \in \text{Edge}_{\text{conj}}(C)} \omega_{\varphi}(e) \prod_{(v,v') \in \text{Vert}_{\text{conj}}(C)} H^C(\varphi, v)$.

Note that this is well-defined: since $\varphi$ is compatible with the involutions, $\omega(e) = \omega(e')$ for a tuple $(e, e') \in \text{Edge}_{\text{conj}}(C)$. This also implies that $H^E(\varphi, v) = H^E(\varphi, v')$ for a tuple $(v, v') \in \text{Vert}_{\text{conj}}(C)$. Note also that the multiplicity depends on the choice of real structure for $D$, since the local Hurwitz numbers depend on $S_v$.

**Definition 3.8**

As before, fix $g, d, \mu$. Let $(D, \iota_D, (S_v)_{v \in \text{Vert}(C)})$ be a real tropical curve with $n$ leaves $l_1, \ldots, l_n$. We define the real tropical Hurwitz number $H^\text{trop}_g((D, \iota_D, (S_v)_{v \in \text{Vert}(C)}), \mu)$ to be the number of marked real tropical covers $\varphi : C \to D$ of given genus, degree and ramification (i.e. the multiset of weights of the leaves of $C$ mapping to $l_i$ is equal to $\mu_i$), counted with multiplicity as defined above.

**Remark 3.9**

In complete analogy to section 2, we can count marked instead of unmarked covers. Here, a marking of tropical cover is a labelling $l_{i,1}, \ldots, l_{i,|\mu_i|}$ of the leaves mapping to $l_i$ such that $\omega(l_{i,j}) = \mu_{i,j}$. The multiplicity of a marked cover is given by the same formula as in definition 3.7, where $\text{Aut}(\varphi)$ denotes the group of automorphisms respecting the marking. Let $H^\text{trop,mark}_g((D, \iota_D, (S_v)_{v \in \text{Vert}(C)}), \mu)$ be the corresponding number. As before we have $H^\text{trop,mark}_g((D, \iota_D, (S_v)_{v \in \text{Vert}(C)}), \mu) = |\text{Aut}(\mu)| \cdot H^\text{trop}_g((D, \iota_D, (S_v)_{v \in \text{Vert}(C)}), \mu)$.

**4. THE CORRESPONDENCE THEOREM**

In this section, we state and prove the correspondence theorem declaring the equality of real Hurwitz numbers as defined in 2.3 to their tropical counterparts defined in the previous section, definition 3.8. The result can easily be generalized to open or partially open Hurwitz numbers, we avoid this here for the sake of simplicity.

**Theorem 4.1**

Let $(D, \iota_D, (S_v)_{v \in \text{Vert}(C)})$ be a real tropical curve. Let $(\mathcal{D}, \iota_D, \mathcal{P})$ be the associated topological surface with real structure and with punctures, according to remark 3.3. Fix a genus $g \geq 0$ and for each leaf $i$ of $D$ a ramification profile $\mu_i$. Then $H^\text{hurw}^R((\mathcal{D}, \iota_D, \mathcal{P}), \mu) = H^\text{trop}_g((D, \iota_D, (S_v)_{v \in \text{Vert}(C)}), \mu)$.

Of course, by our previous remarks the same equality holds for the marked numbers.

**Proof:**

The main strategy of the proof is analogous to [BBM2, Theorem 2.11] and we focus on the necessary generalizations for the real case here. We present the proof in three steps:

1. step:

Let us start with a real ramified cover $\Phi : (\mathcal{C}, i\mathcal{C}) \to (\mathcal{D}, i\mathcal{D})$. The first step of the proof is to construct a tropical real cover $\varphi : C \to D$ associated to $\Phi$. Let us start by constructing the underlying graph of $C$. Remember that $D$ is obtained from gluing simpler surfaces according to the combinatorial structure of $\mathcal{D}$. In particular, $\mathcal{D}$ contains embedded circles $D_e$ labelled by the edges of $D$. If $e$ is adjacent to a leaf $i$, the circle $D_e$ bounds a sphere with one marked point and $\Phi$ is ramified only above these marked points (according to $\mu_i$). For any $e$, $\Phi^{-1}(D_e)$ is a collection of embedded circles in $\mathcal{C}$. We call a component of $\mathcal{C}$
(resp. of \(D\)) the closure of a connected component in the surface minus all the embedded circles. \(C\), as a graph, consists of a vertex for each component of \(C\) and an edge for each embedded circle, connecting the two vertices whose components it is adjacent to.

By our construction, \(\Phi\) maps every component resp. embedded circle of \(C\) to a unique component resp. embedded circle of \(D\). This defines a map \(\varphi : C \to D\) on the level of graphs. To make \(C\) a fully-fledged tropical curve and \(\varphi\) a morphism, it suffices to determine the weights \(\omega_{\varphi}(e)\) for all edges \(e\) of \(C\). Together with the metric structure on \(D\) this determines uniquely the metric/tropical structure on \(C\). The weights, in turn, are given by the formula

\[
\omega_{\varphi}(e) = \deg(\Phi : D_e \to D_{\varphi(e)}),
\]

where the right hand side denotes the degree of the corresponding \(S^1\)-cover.

We now add a prereal structure to \(C\). From the compatibility condition \(\iota_C \circ \Phi = \Phi \circ \iota_D\) it follows that \(\iota_C\) maps components to components and embedded circles to embedded circles (as \(\iota_D\) does the same on \(D\) by construction). This gives an involution \(\iota_C : C \to C\) which turns \(C\) into a prereal curve. Note that

\[
\omega_{\varphi}(e) = \omega_{\varphi}(\iota_C(e)),
\]

hence \(\iota_C\) respects the lengths of the edges of \(C\). Moreover, again by construction it is clear that \(\varphi\) is a prereal morphism satisfying the condition on the weights of the ends as prescribed by the ramification data.

Finally, the last piece of information missing is the map

\[
F : \{ e \in \text{Edge}_{\text{fix}}(C) : \omega(e) \equiv 0 \mod 2 \} \to \bigcap_{e \in \text{Edge}_{\text{fix}}(D)} F_e
\]

As explained before definition 2.5, for each \(e \in \text{Edge}_{\text{fix}}(C)\) with even weight the map \(\Phi : D_e \to D_{\varphi(e)}\) is of even degree and hence maps both fixed points of \(D_e\) to the same fixed point of \(D_{\varphi(e)}\). But remember that we can identify \(F_{\varphi(e)}\) with the two fixed points of \(D_{\varphi(e)}\). We set \(F(e)\) to be the image of the two fixed points of \(D_e\).

2. step:

So far, we constructed a map Trop from the set of all real ramified covers \(\Phi\) of \(D\) to the set of all tropical real covers \(\varphi\) of \(D\). The next step is to analyse the fibres of this map. So let us fix a tropical real cover \(\varphi : C \to D\) and set

\[
\mathfrak{A} := \text{Trop}^{-1}(\varphi).
\]

For each vertex \(v \in \text{Vert}_{\text{fix}}(C)\), let \(\mathfrak{B}(v)\) be the set of covers contributing to the local real Hurwitz number \(H^R(\varphi, v)\). For each pair of conjugated vertices \(v, v'\) of \(C\), let \(\mathfrak{B}(v, v')\) be the set of covers contributing to the local complex Hurwitz number \(H^C(\varphi, v)\). We set

\[
\mathfrak{B} := \prod_{v \in \text{Vert}_{\text{fix}}(D)} \mathfrak{B}(v) \times \prod_{(v, v') \in \text{Vert}_{\text{conj}}(D)} \mathfrak{B}(v, v').
\]

We want to compare \(\mathfrak{A}\) and \(\mathfrak{B}\), which is easier after adding some additional structure. Namely, for each pair of conjugated edges \(e, e'\) of \(C\) let us fix a point \(p(e) \in D_{\varphi(e)}\) (and its conjugate \(p(e') \in D_{\varphi(e')}\)). Now let \(\mathfrak{A}'\) be the fibre of \(\varphi\) under Trop, with the additional choice of a point in \(\Phi^{-1}(p(e))\) for each such pair and with the additional choice of one of the two fixed points in \(\Phi^{-1}(D_{\varphi(e)})\) for each even \(e\) in \(\text{Edge}_{\text{fix}}(C)\). We call these choices a gluing data.
An isomorphism of elements in $\mathfrak{A}'$ is a usual isomorphism which respects the gluing data. The map from $\mathfrak{A}'$ to $\mathfrak{A}$ forgetting the gluing data is essentially $\lambda$-to-1, where
\[ \lambda = 2^{|\mathfrak{E}|} \cdot \prod_{(e,e') \in \text{Edge}_{\text{conj}}(D)} \omega_{\phi}(e). \]
More precisely, after dividing out isomorphisms, we have
\[ |\mathfrak{A}'/\text{isom.}| = \lambda \cdot |\mathfrak{A}/\text{isom.}|, \]
where $|.|$ denotes the weighted cardinality with weights $1/\text{Aut}$. We can add the same gluing data to each factor of $\mathfrak{B}$ and obtain the set $\mathfrak{B}'$ of local covers with gluing data such that
\[ |\mathfrak{B}'/\text{isom.}| = \lambda^2 \cdot |\mathfrak{B}/\text{isom.}|. \]
Here, an isomorphism is given by an isomorphism in each factor.

In a third step, we now show
\[ |\mathfrak{B}'/\text{isom.}| = \text{Aut}(\phi) \cdot |\mathfrak{A}'/\text{isom.}|. \]
This finishes the proof, as the above formulas imply
\[ H_{\eta}^{\text{trop}}((D, t_D, (S_v)_{v \in \text{Vert}(C)}), \mu) = \sum_{\phi} \frac{\lambda}{\text{Aut}(\phi)} \cdot |\mathfrak{A}/\text{isom.}| \]
\[ = \sum_{\phi} |\mathfrak{A}/\text{isom.}| \]
\[ = H_{\eta}^{\mathfrak{B}}((D, t_D), \mathcal{P}, \mu). \]

3. step:
In order to show
\[ |\mathfrak{B}'/\text{isom.}| = \text{Aut}(\phi) \cdot |\mathfrak{A}'/\text{isom.}|, \]
note that the additional structure of gluing data allows us to construct a bijection between $\mathfrak{B}'$ and $\mathfrak{A}'$. An element of $\mathfrak{B}'$ hands us a cover $\Phi_v : S_v \to S_{\phi(v)}$ for each $v \in C$, contributing to the local refined Hurwitz numbers. (For a pair of conjugated vertices $v, v'$, we are only given $\Phi_v$. We then set $S_{v'} := S_v$ (with opposite orientation) and $\Phi_{v'} := \iota_{\phi(v')} \circ \Phi_v$.) We also have an involution on the disjoint union of all the $S_v$ such that $S_v$ is mapped to $S_{\phi(v)}$ and the compatibility with $t_D$ holds. We now glue the boundary circles of the $S_v$ according to the combinatorial structure of $C$. We do this in such a way that the local covers $\Phi_v$ can be extended to a global map $\Phi$ on the glued surface $C$. In order to fix such a gluing, for each edge $e$ and associated pair of boundary circles $B_f$ and $B_{f'}$, we have to choose points $p \in B_f$ and $p' \in B_{f'}$ which are mapped to the same point in $D_{\phi(e)} \subset D$. Additionally, if $e \in \text{Edge}_{\text{fix}}(C)$, in order to extend the involutions $\iota_v$ and $\iota_{v'}$ to the glued surface, the necessary and sufficient condition is that the gluing identifies fixed points of
If \( e \) has odd weight, the above conditions leave us with a unique choice for the gluing (as over each fixed point downstairs there is a unique pair of fixed points upstairs, which hence has to be identified). For an even edge \( e \) in \( \text{Edge}_{\text{fix}}(C) \) resp. a pair of conjugated edges \( e, e' \), we choose the unique gluing which identifies the pairs of points specified in the gluing data (note that in the latter case, the gluing at \( e \) fixes the gluing at \( e' \)).

The image of the marked points in the new circles defines a gluing data for \( \Phi \). As our gluing data was chosen to be invariant under the involution, we can indeed extend the involution to \( C \) and hence, in total, we constructed an element in \( \mathcal{A}' \). The inverse map is given by starting with an element \( \Phi \) in \( \mathcal{A}' \) and cut it into local pieces along the immersed circles (with gluing data induced from the gluing data on \( \Phi \)).

It remains to discuss isomorphisms. Let \( \Phi : C \to D \) be an element in \( \mathcal{A}' \). Let \( \Psi : C \to C \) be a real automorphism of \( \Phi \). The way it maps components (of \( C \)) to components and embedded circles to embedded circles defines a prereal automorphism \( \alpha : C \to C \) of \( \varphi \).

This gives a surjective group homomorphism
\[
\text{Aut}(\Phi) \to \text{Aut}(\varphi).
\]

The kernel of this map consists of automorphisms which keep the components and boundary circles fixed, i.e. which split into local automorphisms on the components. This is exactly the group of automorphisms of the element in \( \mathcal{B}' \) corresponding to \( \Phi \). This proves the claim.

The correspondence theorem for real Hurwitz numbers yields a graphical organization of the covers to be counted, in terms of tropical covers. It can also be viewed as a graphical organization of a degeneration formula for real Hurwitz numbers. In particular, it allows to express arbitrary real Hurwitz numbers in terms of (real) triple Hurwitz numbers of the sphere (i.e. Hurwitz numbers of the sphere with three branch points).

5. Covers of \( \mathbb{P}^1 \) with Real Branch Points

In this section, we focus on the case of real double Hurwitz numbers of \( \mathbb{P}^1 \) with only real branch points. In this case, the triple Hurwitz numbers which are needed as input data for the combinatorial enumeration of covers (in terms of real tropical covers) can be computed explicitly, allowing a completely combinatorial treatment of the counting problem. In the case where all branch points besides 0 and \( \infty \) are real, we recover the combinatorial recipe discussed in [GPMR] using the approach via the symmetric group. We enrich this result by a combinatorial treatment of the arbitrary case, where also negative branch points are allowed.
We need the following input data. We fix two natural numbers $d, g$ and two partitions of $d$, called $\lambda = (\lambda_i)$ and $\nu = (\nu_i)$. We set $r := 2g - 2 + \ell(\lambda) + \ell(\nu)$, this is the number of additional simple branch points a generic cover of $\mathbb{P}^1$ with ramification profiles $\lambda$ at 0 and $\nu$ at $\infty$ has, by the Riemann-Hurwitz formula.

We fix $r$ points in $\mathbb{R}$, say $x_1 < \ldots < x_r$ and equip each of these points with a sign $s(i) = s(x_i) \in \{+, -\}$. To this data we associate the following real tropical curve $L$. Regardless of the real structure, the curve is just (the standard model of) $\mathbb{R} \cup \{\pm \infty\}$ modified at the points $p_i$. Hence $L$ is a caterpillar tree with two special ends labelled by $\pm \infty$ and $r$ ends labelled by $1, \ldots, r$. Moreover, $w_i$ denotes the vertex obtained from modifying at $x_i$. All vertices have genus 0. The real involution on $L$ is just identity, $\iota_L = \text{id}$. Finally, for each vertex $v_i$, let $f_{i, \infty}$ denote the two flags pointing towards $\pm \infty$ and let $f_i$ be the third flag (corresponding to the end $l_i$). The real structure on $S_{v_i} = S_{0,3}$ is induced from the standard real structure on $\mathbb{C}P^1$. Corresponding to $f_{-\infty}, f_{+\infty}$ and $f_i$, we remove open discs around 0, $\infty$ and a third point $p_i \in \mathbb{R} \setminus \{0\} \subseteq \mathbb{R}P^1$ whose sign is equal to $s(i)$. On $B_{f_{\pm \infty}}$ call the two fixed points positive resp. negative, depending on whether they touch the positive or negative part of $\mathbb{R} \setminus \{0\}$. For each edge $e \in L$, we identify the two positive and the two negative fixed points. This gives $L$ the structure of a real tropical curve. Obviously, the real topological surface associated to $L$ is completely determined by the numbers $n^+$ resp. $n^-$ of positive resp. negative signs $s(i)$. Namely, the surface is obtained from $\mathbb{C}P^1$ with standard real structure and punctures at $0, \infty, n^+$ punctures on the positive and $n^-$ punctures on the negative part of $\mathbb{R}P^1 \setminus \{0, \infty\}$.

![Real tropical curve](image)

Our goal is to count real tropical covers of $L$ of genus $g$ and degree $d$ with ramification profiles $\lambda$ resp. $\nu$ at $l_{-\infty}$ resp. $l_{+\infty}$ and simple ramification at all other leaves. That is, we determine the tropical real Hurwitz numbers $H^\text{trop}_{g}((L, \text{id}_{L}, (S_{v_i})_{v \in \text{Vert}(L)}, \mu))$, with the real structure $(S_{v_i})_{v \in \text{Vert}(L)}$ as described above, where

$$\mu = (\lambda, \nu, (2, 1, \ldots, 1), \ldots, (2, 1, \ldots, 1)).$$

In these situations, the count can be simplified in the following way: for each real tropical cover $\varphi : C \to L$ contributing to $H^\text{trop}_{g}((L, \text{id}_{L}, (S_{v_i})_{v \in \text{Vert}(L)}, \mu))$, we contract the ends of $L$ adjacent to the leaves $1, \ldots, r$ and the ends of $C$ adjacent to leaves mapping to these ends. Then we consider covers of $\mathbb{R}P^1$ arising like this. Notice that covers arising like this do not satisfy the Riemann-Hurwitz condition at every vertex, so they are not morphisms in the sense defined above. Nevertheless, their properties can be described easily.

For a harmonic map $\varphi : C \to \mathbb{R}P^1$, a balanced wiener is a set of two edges of the same weight and adjacent to the same two vertices. The set of such pairs is denoted by $W$. A balanced fork is a set of two ends of the same weight adjacent to the same (inner) vertex. The set of balanced winers and forks is denoted by $WF$. 
**Definition 5.1**

A *signed cover* of $\mathbb{T}P^1$ is a harmonic map $\varphi : C \to \mathbb{T}P^1$ with a choice of subset $I \subset WF$ of the set of balanced wieners and forks (we call the elements of $I$ the *conjugated* wieners resp. forks) and a choice of sign $S(e) \in \{+,-\}$ for every internal edge $e$ of even weight which is not contained in a conjugated wiener. (The set of these edges is denoted by $EE$.)

We require that $C$ has $r$ 3-valent vertices $v_1, \ldots, v_r$ such that $\varphi(v_i) = x_i$.

Set $I' = I \cap W$, the set of conjugated wieners. We associate the following *multiplicity* to a signed cover.

$$m(\varphi) := \frac{2|EE|}{2|WF|} \prod_{(e,e') \in I'} \omega(\varphi(e)).$$

We depict conjugated wieners/forks as bold edges, positive edges normal and negative edges dashed. Edges of odd weight which are not in a conjugated wiener/fork are drawn normal.

**Definition 5.2**

A signed cover $(\varphi : C \to \mathbb{T}P^1, I, (S(e))_{e \in EE})$ is called *real* if locally at each vertex $v_i$, the cover equals one of the local pictures shown in the following list, depending on the sign $s(i)$ (or their reflections, with two edges coming from the left and one leaving to the right). If $s(i)$ is negative, the local possible pictures are:

If $s(i)$ is positive, the local possible pictures are:

With the following two lemmata, we classify all possible vertices of real tropical covers contributing to $H^0_y \mathbb{h}op(\mathcal{L}, id_L, (S_v)_{v \in \text{Vert}(L)}, \mu))$. When shrinking ends, these vertices either become 2-valent and disappear (lemma 5.3), or they can be identified with the pictures in definition 5.2 (lemma 5.5).

Let $T$ be an open three-valent line with standard real structure. That is, the involution is the identity, and the surface associated to the vertex of $T$ is $\mathbb{P}^1$ with three boundary circles around punctures in the real part.

We set $\gamma = 0$ and assign the ramification profiles $(d)$, $(d)$ and $(1, \ldots, 1)$ to the three leaves of $T$. It follows from the Riemann-Hurwitz condition that any cover $\varphi : S \to T$ has one
inner vertex $v$ to which all $d + 2$ ends are adjacent. We will now compute all non-zero local Hurwitz numbers $H^R(\varphi, v)$ matching this situation. We use the following notation: Fixing one leaf $l$ of $T$, we denote by $\alpha(\varphi)$ the number of real automorphisms of $\varphi$ which are non-trivial only on $\varphi^{-1}(l)$. Here, we choose $l$ to be the leaf with ramification $(1, \ldots, 1)$, hence $\alpha(\varphi) = |\text{Aut}(\varphi)|$.

**Lemma 5.3**
The only non-zero local Hurwitz numbers $H^R(\varphi, v)$ for a cover $\varphi : S \to T$ of an open three-valent line $T$ with ramification profiles $(d), (d)$ and $(1, \ldots, 1)$ are given in the following list. (Note that the map $F$ (the choice of fixed points for each even edge) is encoded in the following pictures by marking the points in $\text{Im}(F)$ in red.)

- If $d$ is odd then

\[
H^R(\varphi, v) = \alpha(\varphi) = 2 \cdot \frac{d-1}{2} \cdot \frac{d-1}{2} \cdot (\frac{d-1}{2})!
\]

- If $d$ is even: either the two fixed points for the two even fixed edges of $S$ are connected by a real arc, then

\[
H^R(\varphi, v) = \frac{1}{2} \cdot \alpha(\varphi) = 2^{\frac{d}{2}-1} \cdot \left(\frac{d}{2}\right)!
\]

- or the fixed points are endpoints of the two real arcs leading to the boundary circle for which we impose ramification $(1, \ldots, 1)$, then

\[
H^R(\varphi, v) = \frac{1}{2} \cdot \alpha(\varphi) = 2^{\frac{d}{2}-2} \cdot \left(\frac{d}{2}\right)!
\]
Remark 5.4
Note that the lemma just provides a sophisticated way of saying
\[ H^R_0((\mathbb{CP}^1, \text{conj}), \{0, 1, \infty\}, ((d), (d), (1, \ldots, 1))) = 1, \]
where in the even case two covers of weight 1/2 contribute. Remember that in the complex case we have \( H^R_0(\mathbb{CP}^1, \{0, 1, \infty\}, ((d), (d), (1, \ldots, 1))) = 1/d. \)

Proof:
Requiring ramification profile \((1, \ldots, 1)\) over one boundary circle means the map is not ramified there — we may as well fill in the corresponding discs and consider unramified maps between cylinders. We may identify the real structure on the target cylinder as \( g \) automorphisms above. If \( \phi \) is an open three-valent line \( T \) of \( S \) listed below. As before, the surface associated to the vertex of \( T \) we see that these cases correspond to the three real tropical covers shown in the statement. It remains to count the number of markings in each case, i.e. thenumber of ways we can choose of orientation for the target pair of pants or, in other words, to the two possible cyclic orderings of the three branch points on the real locus (after fixing the orientation).

Again, we denote by \( \alpha(\varphi) \) the number of real automorphisms of \( \varphi \) which are non-trivial only on \( \varphi^{-1}(l) \), where now \( l \) is the leaf with simple ramification \((2, 1, \ldots, 1)\). In other words, \( \alpha(\varphi) = |\text{Aut}(\varphi)| \) if \( a \neq b \) and \( \alpha(\varphi) = |\text{Aut}(\varphi)|/2 \) if \( a = b \).

Lemma 5.5
The only non-zero local Hurwitz numbers \( H^R_0(\varphi, v) \) for a cover \( \varphi : S \to T \) of an open three-valent line \( T \) with ramification profiles \((d)\) (over \( \infty \)), \((a, b)\) (over 0) and \((2, 1, \ldots, 1)\) (over \(-1\)) are given in the following list. Again, we encode the map \( F \) by marking the points in \( \text{Im}(F) \) in red (in the third case, where we have two fixed even edges mapping to the right boundary circle, the same fixed point is chosen, indicated by a “2×” in the picture).

- If \( d \) is odd, then
  - \( \alpha(\varphi) = |\text{Aut}(\varphi)| \)
  - \( \alpha(\varphi) = |\text{Aut}(\varphi)|/2 \) if \( a = b \).
• If \( d \) is even and \( a, b \) odd, then

\[
H^R(\varphi, v) = \alpha(\varphi) = 2^{d-3} \left( \frac{d-3}{2} \right)!
\]

• If \( d, a \) and \( b \) are even, then

\[
H^R(\varphi, v) = \alpha(\varphi) = 2^{d-2} \left( \frac{d-2}{2} \right)!
\]

• If \( d \) is even and the involution on \( a = b \) is non-trivial, then

\[
H^R(\varphi, v) = \alpha(\varphi) = 2^{d-2} \left( \frac{d-2}{2} \right)!
\]

Remark 5.6
Again the lemma states in a sophisticated way that

\[
H^R_0((\mathbb{CP}^1, \text{conj}), \{0, 1, \infty\}, ((d), (a, b), (2, 1, \ldots, 1))) = 1,
\]

where in the even case \( a = b \) two covers of weight 1/2 contribute.
Proof:
Let us first show that the four cases in the statement are indeed the only ones with non-zero Hurwitz number. Disregarding the real structures on the source surface, there is a unique homeomorphism type of cover of given ramification which can be described by the map
\[ \varphi': \mathbb{C} \rightarrow \mathbb{C}, \]
with \( \lambda = (-1)^{a-1} \frac{da}{d\varphi} \) (the simple ramification point is at \( z_s = \frac{b-a}{b} \)). This cover has no non-trivial automorphisms, except for \( a = b \), when there is exactly one (given by \( z \mapsto -z \)).

We now have to analyse the possibilities to equip the source Riemann sphere with a real structure \( \iota \) compatible with \( \varphi' \). Let us focus on the fixed point sets for \( \iota \). First note that \( z_s \) must always be a fixed point, since it is the only ramification point over \( -1 \). Near \( z_s \), the preimage \( \varphi'^{-1}(\mathbb{R}P^1) \) looks like the union of two smooth arcs — one of them the standard real line \( \mathbb{R}P^1 \), the other one with tangent direction \( \pm i \). Notice that the cyclic order of the ramification points on the standard real line is \( \infty, -1, z_s, 1 \). The fixed point set of \( \iota \) must be a circle that contains one of these two arcs. In the first case \( \text{Fix}(\iota) = \mathbb{R}P^1 \), we obtain the standard involution \( \text{conj} : z \mapsto \bar{z} \). This corresponds to the first three cases from above.

Let us now consider the second case, i.e. \( \text{Fix}(\iota) \) contains the arc with tangent direction \( \pm i \). Note that this arc, and hence \( \text{Fix}(\iota) \), is invariant under \( \text{conj} \). It follows that \( \text{Fix}(\iota) \) intersects \( \mathbb{R}P^1 \) in exactly one further point, which must be \( \pm 1 \) or \( \infty \). The remaining two ramification points must be exchanged by \( \iota \) since they do not belong to the fixed circle. It follows from the cyclic ordering of the four ramification points on the standard real line that the point of intersection must be \( \infty \) and \( \iota \) must exchange \( \pm 1 \).

This is only possible if \( a = b \). It follows that in this case \( \iota \) must be equal to \( z \mapsto -\bar{z} \). This corresponds to the fourth case in the list of the statement.

So far, we proved that the four cases in the statement are indeed the only non-zero Hurwitz number and in each case their is only one (unmarked) cover that contributes. It remains to calculate the number of markings and automorphisms. Note that when \( a = b \), the choice of marking the two preimages of 0 is cancelled by the (unmarked) automorphism \( z \mapsto -z \). What remains is the number of markings for the preimages of the simple branch point, but this is exactly \( \alpha(\varphi) \).

Construction 5.7
Let \( \varphi: C \rightarrow L \) be a real tropical cover contributing to a Hurwitz number
\[ H^\text{op}_{g}((L, \text{id}_L, (S_v)_{v \in \text{Vert}(L)}), \mu)), \]
where \( L \) is a real tropical line as defined at the beginning of this section.

Shrink the ends adjacent to the leaves marked with \( 1, \ldots, r \) in \( L \). Accordingly shrink the ends of \( C \) mapping to these ends, producing a prereal tropical curve \( C' \) and a harmonic map \( \varphi': C' \rightarrow \mathbb{TP}^1 \). We drop two-valent vertices that appear as a consequence of shrinking ends and merge their adjacent edges to one edge of the appropriate length. Notice that the Riemann-Hurwitz condition implies that we obtain a three-valent curve \( C' \) with \( r \) inner
vertices. The involution of $C$ induces an involution on $C'$, whose non-fixed locus can only consist of wieners and balanced forks. We choose the conjugated edges in the non-fixed locus as the set $I$ of conjugated wieners resp. balanced forks. We choose as sign for the fixed even edges of $C'$ the sign of the chosen fixed point for these edges. Notice that it follows from lemma 5.3 that this is well-defined: if an even fixed edge of $C'$ originally comes subdivided by a 2-valent vertex, then the two adjacent edges of $C$ which are not shrunk have the same fixed point.

In terms of our drawing conventions, this means that we draw the fixed even edges of $C'$ whose chosen fixed point is drawn at the bottom of the circle as dotted lines, and those whose fixed point is drawn at the top of the circle as normal lines. The conjugated edges are drawn bold.

**Proposition 5.8**

The procedure described in construction 5.7 is a bijection between the set of real tropical covers contributing to $H_g^{\text{top}}((L, i\delta_L, (S_v)_{v\in \text{Vert}(L)}), \mu))$ and real signed covers whose weights of ends are given by $\lambda$ and $\nu$. Moreover, the multiplicity of a real tropical cover $\varphi : C \to L$ and $\text{its image } \varphi' : C' \to \TP^1$ are the same.

**Proof:**

We have seen in 5.7 already that we obtain a signed cover $\varphi : C' \to \TP^1$ from $\varphi : C \to L$ by shrinking ends. Applying our drawing conventions, we see that the pictures listed in lemma 5.5 indeed yield the first four pictures of definition 5.2, while the analogous pictures we obtain for the opposite choice of orientation of the target surface yield the second four pictures. So, indeed, we obtain a real signed cover by shrinking ends. Vice versa, we produce a real tropical cover of $L$ by growing ends at the images of three-valent vertices of $C'$ and their preimages. It follows from lemma 5.3 and 5.5 that there is a unique way to grow ends and extend the involution, up to the choice of markings of the newly attached ends.

It remains to prove the statement about the multiplicity. First note that the automorphisms groups of $\varphi$ and $\varphi'$ exactly differ by the automorphisms which exchange the shrunk leaves. To be precise, for each vertex $v$ of $C$ let $\alpha(\varphi, v)$ be the number of automorphisms of $\varphi$ which only exchanges the shrunk leaves adjacent to $v$ (when $v \notin \text{Fix}(\iota_C)$, we consider non-real automorphisms and hence $\alpha(\varphi, v) = d_\varphi(v)!$). Then

$$\left| \text{Aut}(\varphi) \right| = \left| \text{Aut}(\varphi') \right| \prod_{[v] \in \text{Vert}(C)/\iota_C} \alpha(\varphi, v).$$

(2)

Now fix $[v] \in \text{Vert}(C)/\iota_C$, shrink the adjacent leaves and consider the corresponding change of the multiplicity. Let us first consider the case that after shrinking we get a three-valent vertex of $C'$ (in particular, $v \notin \text{Fix}(\iota_C)$). By lemma 5.5, we have $H_B(\varphi, v) = \alpha(\varphi, v)$, which cancels one of the factors in equation (2). Let us now assume after shrinking the vertex is two-valent. Then by lemma 5.5 the local Hurwitz number equals to $\alpha(\varphi, v)$ times a factor 1 resp. $1/2$ if the subdivided edge is a fixed edge of odd resp. even weight and a factor $1/\omega$ if the subdivided edge is a non-fixed edge of weight $\omega$ (as $H^B(\varphi, v) = \omega!/\omega = (\omega - 1)!$, c.f. 5.4). Note that this factor is exactly the inverse of the factor such an edge contributes to $m(\varphi)$, in other words, it cancels with one of the two corresponding factors in $m(\varphi)$. By shrinking all $[v] \in \text{Vert}(C)/\iota_C$ inductively, we get

$$m(\varphi) = \frac{2^{\left| \text{EE}(C') \right|}}{\left| \text{Aut}(\varphi') \right|} \prod_{(e, e') \in \text{Ed}(\text{conj}(C'))} \omega_{e}(e).$$

It remains to note that the automorphisms of $\varphi'$ are generated by exchanging the two edges of a wiener or fork. Hence $|\text{Aut}(\varphi')| = 2^{|W_{\text{wiener}}|}$ and therefore $m(\varphi) = m(\varphi')$ from definition 5.1. \qed
Corollary 5.9
With the above notations, $H_{g}^{\text{top}}((L, \text{id}_{L}, (S_{v})_{v \in \text{Vert}(L)}), \mu))$ equals the number of signed real covers of $\mathbb{T}P^{1}$ whose weights match $\lambda$ and $\nu$, counted with multiplicity.

Now recall the definition of real tropical double Hurwitz number in [GPMR]. Notice that by definition, it counts real signed covers of $\mathbb{T}P^{1}$ for which the signs $s(i)$ of the branch points are all positive. The following corollary follows easily.

Corollary 5.10
If all signs $s(i)$ for branch points are positive, the equality
$$\tilde{H}_{g}(\lambda, \nu) = |\text{Aut}(\lambda)| \cdot |\text{Aut}(\nu)| \cdot H_{g}^{\text{top}}((L, \text{id}_{L}, (S_{v})_{v \in \text{Vert}(L)}), \mu))$$
holds, where $\tilde{H}_{g}(\lambda, \nu)$ denotes the tropical real double Hurwitz number considered in [GPMR].

Example 5.11
In the following example, we demonstrate that the real tropical Hurwitz numbers (and with that, real Hurwitz numbers) depend on the chosen branch points, or, more concretely, on the chosen number of positive and negative branch points. We pick $g = 0$, $\lambda = (5)$ and $\nu = (3, 1, 1)$. First consider two positive branch points. The only cover contributing to this count is depicted below. Its multiplicity is $2/2 = 1$.

Now assume the first branch point is negative and the second positive. Then we obtain the following two pictures with multiplicities $2/2 = 1$ and $2$, respectively. As $1 \neq 3$, the Hurwitz number depends on the chosen signs for the branch points.
