Abstract

We calculate the density shift and broadening of selected dipole transition lines of pionic helium in gaseous helium at low temperatures up to $T = 12$ K and pressure up to a few bar. In the approximation of binary collisions the shift and broadening depend linearly on the density; we evaluate the slope of this linear dependence for a few spectral lines of known experimental interest, and also investigate its temperature dependence. We find a blue shift of the resonance frequencies of the $(n, l) = (16, 15) \rightarrow (16, 14), (17, 16) \rightarrow (17, 15)$, and $(16, 15) \rightarrow (17, 14)$ unfavored transitions, and a red shift for the favored one $(17, 16) \rightarrow (16, 15)$. The results are intended to significantly increase the efficiency of the laser spectroscopy investigations of pionic helium and help the interpretation of the experimental data.

PACS numbers:
I. INTRODUCTION

Pionic helium is a three-body system composed of a helium nucleus, an electron in a ground state and a $\pi^-$ in a highly excited Rydberg state with principal quantum number $n \sim (m^*/m_e)^{1/2}$, where $m^*$ is the reduced mass of $\pi^-$ and the helium nucleus. These states promptly de-excite via Auger transitions to lower lying states which have large overlap with the helium nucleus and subsequently undergo fast nuclear absorption for times less than $10^{-12}$ s. However long-lived $\pi^-$ were observed in bubble-chamber experiments [1]. To explain this anomaly, Condo suggested that metastable atomic states of $\pi^-$ are formed

$$\text{He} + \pi^- \rightarrow [\text{He}^+ \pi^-]_{nl} + e^-$$

(1)

in which $\pi^-$ occupies states with high angular momentum $l \sim n - 1$. These Rydberg states are expected to retain nanosecond-scale lifetimes against nuclear absorption and the electroweak decay $\pi^- \rightarrow \mu^- + \bar{\nu}_\mu$. This is because for nearly circular orbits of $\pi^-$, the overlap with the helium nucleus is minimized, whereas radiative de-excitation and the decay via Auger transitions which lead to fast nuclear absorption are strongly suppressed. This hypothesis has been confirmed at TRIUMF in experiments with $\pi^-$ stopped in liquid helium [2].

A method for laser spectroscopy of metastable pionic helium atoms in gaseous helium has been proposed [3, 4]. When comparing experimental transition frequencies to three-body QED calculations of pionic helium, the $\pi^-$ mass can be determined with a fractional precision better than $10^{-6}$. However systematic effects such as collision-induced shift and broadening (S&B) of the transition lines, as well as the quenching of the metastable states can prevent the experiment from achieving this high precision. Thus reliable theoretical calculation for the density-dependent shift and width is needed for the extrapolation of transition wavelengths at zero target density.

II. COLLISIONAL SHIFT AND BROADENING OF THE TRANSITION LINES

A. Prerequisites: the potential energy surface

The collisional shift and broadening of the laser stimulated transition line $(n, l) \rightarrow (n', l')$ in pionic helium are obtained in the impact approximation of the binary collision theory of
the spectral line shape. This approach has already been applied in the calculations of the density effects on the line shape in antiprotonic helium and produced theoretical results in agreement with experiment; see also and references therein. The success of these calculations was due to the use of a highly accurate three-electron potential energy surface (PES) for the description of the binary interaction of an exotic helium atom with the atoms of the helium gas. The PES had been evaluated with ab initio quantum chemistry methods for nearly 400 configurations of the three heavy constituents of the interacting atoms (two helium nuclei and an antiproton or pion), selected to match the typical interparticle distances in the experimentally interesting metastable states of exotic helium. The configurations were parameterized with the length \( r \) of the vector joining the heavy particles in the antiprotonic/pionic atom, the length \( R \) of the vector joining its center-of-mass with the nucleus of the ordinary helium atom, and the angle \( \theta \) between them. Subsequently, the numerical values of the PES at these \( \sim 400 \) grid points were fitted with smooth functions \( V(r, R, \theta) \). Two such fits, referred to as D47 and HN1, have been widely used in calculations; they have been shown to produce numerical results for the S&B in antiprotonic helium that differ by less than the overall numerical uncertainty. Earlier attempts to use the same PES in the evaluation of the S&B of the spectral lines in pionic helium failed because the typical distances \( r \) between the pion and the helium nucleus in the pionic helium metastable states are outside the range for which the PES has been calculated, and the two fits D47 and HN1 produce wrong values when used for extrapolation of the PES. In the present work we carefully analyzed the behavior of these fits and established that the problem can be resolved by appropriately truncating the integration over \( r \) in the expression for the effective state-dependent interatomic potentials in terms of \( V(r, R, \theta) \) and the pionic helium atom wave function \( \chi_{nl}(r) \)

\[
V_{nl}(R) = \frac{1}{2} \int_0^\infty dr \int d\theta \sin \theta \chi_{nl}^2(r) V(r, R, \theta) \quad \rightarrow \quad V_{nl}(R) = \frac{1}{2} \int_{r_1}^{r_2} dr \int d\theta \sin \theta \chi_{nl}^2(r) V(r, R, \theta)
\]

while keeping under control at each step the induced numerical uncertainties; the optimal values of the truncating parameters were found to be \( r_1 = 0.2 \) a.u., \( r_2 = 1.3 \) a.u. The S&B of the four transition lines in pionic helium of experimental interest were then evaluated by two alternative methods. Similar to the calculation of the S&B in antiprotonic helium, the obtained results differ by up to 30% and should be regarded as boundaries of the
intervals of uncertainty of the theoretical values of the density shift and broadening slopes in pionic helium.

B. Impact approximation

In this approximation, the slope of the density and temperature-dependent collisional broadening $\Gamma_{fi}(T)$ and shift $\omega_{fi}(T)$ are given by

$$\alpha_{fi}(T) = \frac{\partial \Gamma_{fi}(T)}{\partial N} = \left\langle \frac{\pi}{M k} \sum_{L=0}^{\infty} (2L + 1) 2 \sin^2 \eta_{fi,L}(k) \right\rangle_T$$

and

$$\beta_{fi}(T) = \frac{\partial \omega_{fi}(T)}{\partial N} = -\left\langle \frac{\pi}{M k} \sum_{L=0}^{\infty} (2L + 1) \sin 2\eta_{fi,L}(k) \right\rangle_T,$$

respectively, where $N$ denotes the number density of the target gas, the labels $i$ and $f$ stand for the set of quantum numbers of the initial and final pionic atom states $n, l$ and $n', l'$, and $\langle \cdot \rangle_T$ denotes thermal average over the Maxwell distribution. Both $\alpha$ and $\beta$ and expressed in terms of the relative phase shifts

$$\eta_{fi,L}(k) = \delta_{iL}(k) - \delta_{fL}(k)$$

The partial wave phases $\delta_L(k) = \delta_L(k, R \to \infty)$ are obtained from the asymptotic solution of the variable phase equation

$$\frac{d}{dR} \delta_{nL}(k, R) = -\frac{2MV_{nl}(R)}{k} \left[ \cos \delta_{nL}(k, R) j_L(kR) - \sin \delta_{nL}(k, R) n_L(kR) \right]^2,$$

subject to the boundary condition $\delta_{nL}(k, 0) = 0$, where $k = \sqrt{2ME}$ is the wave-number of relative motion for a given total collision energy $E$, $M$ is the reduced mass of the collision system, $\{j_L(z), n_L(z)\}$ are the Riccati-Bessel functions, and $V_{nl}(R)$ is defined in (2).

In Figs. 1(a-b) we show the scattering phase shifts $\eta_L(k)$ for the ”favored” transition $(17, 16) \to (16, 15)$ and for the ”unfavored” one $(16, 15) \to (16, 14)$, respectively. For the unfavored transition in Fig.1(a), the scattering phases are negative and are appreciably more than $-\pi/2$ over the entire range of wave numbers, giving rise to blue shift of the transition frequency. For $k < 0.5$, the scattering of $s, p$ and $d$-waves gives dominant contribution to the dipole transition line shape. A larger number of partial waves is required to converge the line shift and width with the increased wave-number $k$. When $k \geq 1$, $\eta_L(k)$ exhibit linear
dependence on the wave-number, showing that in this regime the effective potentials act as repulsive hard spheres with effective state-dependent radii, all phase shifts would tend to zero in the high energy limit with $k \gg 1$. Since the phase shifts are small $|\eta_L| \ll \pi/2$ over the whole range of wave-numbers, the collisional broadening of the transition line is negligible $\alpha \sim \sum_L (2L+1)\eta_L^2$ as compared to the line shift $\beta \sim -\sum_L (2L+1)\eta_L$. In contrast, scattering phases are positive for the favored transition shown in Fig. 1(b) resulting in red-shift of the line center, because $\eta_L(k) < \pi/2$ for $k > 0.1$ a.u. Since the $s$-wave scattering phase shift $\eta_0 \rightarrow \pi$ near $k \rightarrow 0$, the effective potential in the initial state $V_{17,16}(R)$ supports a single bound state through the Levinson theorem. Since the contribution of $s$-wave scattering becomes dominant towards threshold, this bound state dramatically affects the transition line shape at very low speeds with $k < 0.1$ as the center frequency undergoes a blue shift when $\eta_0 > \pi/2$. However the thermally-averaged shift and width are weakly affected by the low-velocity tail in the Maxwell distribution, for instance at $T = 6K^\circ$, $\beta \approx -7 \times 10^{-21}$ GHz cm$^3$ and $\alpha \geq 1 \times 10^{-21}$ GHz cm$^3$.

The thermally averaged shift and width of the spectral lines for the selected transitions in pionic helium, obtained with the fits HN1 and D47 are given in columns 4 and 5 of Table II respectively. The temperature dependence of the line profile is relatively weak in gaseous helium. At low perturber density $N = 10^{21}$ cm$^{-3}$, we find a blue shift of the resonance frequencies for the $(n,l) = (16,15) \rightarrow (16,14)$, $(17,16) \rightarrow (17,15)$, and $(16,15) \rightarrow (17,14)$ transitions $\beta = 2.5$ GHz, 6 GHz and 18 GHz, respectively. For the favored transition $(17,16) \rightarrow (16,15)$, the line center is red-shifted by 8 GHz. Thus in the absence of shape resonances in the potential scattering, the direction of the shift reflects the sign of the difference potential $\Delta V(R) = V_i(R) - V_f(R)$. The comparison of the corresponding linewidths in Table II makes evident that the spectral line for the unfavored transition $(16,15) \rightarrow (16,14)$ is only weakly affected by collisions since it is broadened by 0.1 GHz, which makes it suitable for spectroscopic measurements in pionic helium.

To further analyze the effect of the interaction energy $V(r, R, \theta)$ in the He$^+\pi^-\text{-He}$ collision system, in Figs. 2(a-b) we plot the effective state-dependent potentials for the transitions $(17,16) \rightarrow (16,15)$ and $(16,15) \rightarrow (16,14)$, respectively, together with the difference potentials $\Delta V(R)$. Figs. 2(c-d) present the corresponding variable phase-functions at thermal collision energy with $T = 6$ K. For both transitions, the elastic scattering of $s$- and $p$-waves gives the dominant contribution to the line shift and width. The $d$-wave scattering is less
efficient, contributions of partial waves with $L \geq 3$ are suppressed due to large centrifugal barrier. Figs. 2(c-d) make evident that a substantial part of the line shift comes from the classically forbidden regions for relative motion with $4 \leq R \leq 5$ a.u. The $s$- and $p$-wave variable phases rise steeply in the classically allowed part of the scattering potentials $R > 5$ a.u., attain maxima near $R \approx 6$ a.u., then slightly fall off and saturate in the asymptotic region with $R > 7$ a.u. Thus the principal part of the line shift and width at thermal collision energies are due to short-range binary encounters, the effect of the long-range van-der-Waals tail $V(R) \sim C_6/R^6$ acts as a weak perturbation.

C. Coupled partial waves

As an independent test of our hypothesis that the dominant contributions to the line shift and width are induced by effective central state-dependent scattering potentials in both initial and final states, we included the effect of the anisotropic part of the interaction energy. The collision-induced shift and broadening of the transition line shapes are evaluated from

$$
\alpha_{fi} + i\beta_{fi} = \sum_{J' LL'} (-1)^{L+L'}(2J+1)(2J'+1) \left\{ \begin{array}{ccc} J' & J & 1 \\ l & l' & L \end{array} \right\} \left\{ \begin{array}{ccc} J' & J & 1 \\ l & l' & L' \end{array} \right\}
\times \left( \frac{\pi}{M_k} \delta_{LL'} - S^I\! S^I_{JL, J'L'}(k) S_{JL, J'L'}^{J',*}(k) \right)_T,
$$

where $J$ and $J'$ are the total angular momenta before and after the absorption of a photon. We obtain the $S$-matrix elements $S^J(k)$ from the asymptotic of the solutions of the coupled equations for the partial waves

$$
\frac{dS^J(k, R)}{dR} = -i\frac{M}{k} [h^{(2)}(kR) + S^I(k, R) \cdot h^{(1)}(kR)] V^J(R) [h^{(2)}(kR) + h^{(1)}(kR) \cdot S^J(k, R)],
S^I(k) = S^I(k, R \rightarrow \infty),
$$

subject to the boundary condition $S^J(k, 0) = I$, where $I$ is the unit matrix, $h^{(1)}(z)$ and $h^{(2)}(z)$ are diagonal matrices of the Riccati-Hankel functions. We approximate the matrix representation of the interaction energy $V(\theta) = \sum_\lambda V_\lambda P_\lambda(\cos \theta)$ by truncating its Fourier expansion over Legendre polynomials at $\lambda = 2$, i.e.

$$
V_{nl,L,nL'}^J(R) \approx V_{nl}(R) \Delta(JIL)\delta_{LL'} + V_{nl}^{(2)}(R) \sqrt{(2l+1)(2L+1)}(-1)^{l+L'+J} C_{Jl, l'}^{0, 20} C_{Ll, l'}^{0, 20} \left\{ \begin{array}{ccc} 2 & L & L' \\ J & l & l' \end{array} \right\},
$$

\[\text{Figure 2}\]
where $C^{\alpha\gamma}_{\alpha_0, \beta_0}$ are the Clebsch-Gordan coefficients, $\Delta(abc)$ imposes the triangle condition and

$$V_{nl}^{(2)}(R) = \frac{5}{2} \int_{r_1}^{r_2} dr' r_1^2 \int d\theta \sin \theta V(r, R, \theta) P_2(\cos \theta). \quad (10)$$

At low-collision energies, the $S$-matrix for the coupled $s$- and $d$-waves can be parameterized in terms of two variable phases $\delta_0^J$ and $\delta_2^J$ and a mixing angle $\varepsilon^J$

$$S^J(k, R) \approx \begin{pmatrix} e^{2i\delta_0^J(k, R)} \cos 2\varepsilon^J(k, R) & ie^{i(\delta_0^J(k, R)+\delta_2^J(k, R))} \sin 2\varepsilon^J(k, R) \\ ie^{i(\delta_0^J(k, R)+\delta_2^J(k, R))} \sin 2\varepsilon^J(k, R) & e^{2i\delta_2^J(k, R)} \cos 2\varepsilon^J(k, R) \end{pmatrix}. \quad (11)$$

In the $\varepsilon^J \to 0$ limit, the $S$-matrix is diagonal and the usual decoupled result is recovered. In Fig.3 we plot the mixing angle $\varepsilon^J$ as a function of the separation $R$ between the colliding atoms at thermal energy with $T = 6$ K.

The principal effect of the weak quadrupole coupling is to facilitate scattering of $d$-waves due to $s$-wave admixture in both initial and final state wave-functions. The enhancement of the $d$-wave elastic scattering is most effective in the classically allowed region for both initial and final state motions, where the colliding atoms experience the attractive part of the scattering potential. The numerical results for the line shape obtained with the HN1 fit are given in column 3 of Table I. As the comparison demonstrates, the anistropic pairwise interaction has minor effect on the line shifts, which justifies our approximation of using central state-dependent potentials to describe the collision. However the line widths for certain transitions are noticeably affected by the quadrupole interaction; for example, the enhancement of $d$-wave scattering causes additional broadening of the transition line $(16, 15) \to (17, 14)$ by 1 GHz at low-temperatures. In contrast the narrow line of the transition $(16, 15) \to (16, 14)$ is insensitive to anisotropic interatomic interactions.

**D. Anderson’s semiclassical method**

The slopes of the shift and broadening of the spectral line of the transition can alternatively be represented in the form

$$\alpha_{fi}(T) = \frac{\partial \Gamma_{fi}}{\partial N} = \Re \Phi, \quad \beta_{fi}(T) = \frac{\partial \omega_{fi}}{\partial N} = \Im \Phi,$$

$$\Phi = \left\langle 2\pi v_T \int dB b \left[ 1 - \exp \left( -i \int dt \left( V_{nl}'[|R(t)|] - V_{nl}[|R(t)|] \right) \right) \right] \right\rangle_T, \quad (12)$$
where $\mathbf{R}(t)$ is the trajectory of the classical relative motion of the pionic and ordinary helium atoms (i.e. the vector joining the positions of the atoms at time $t$), while $b$ and $v_T = \sqrt{2kT/M}$ are the impact parameter and the initial velocity of the relative thermal motion of the colliding atoms outside the interatomic potential range. Eq. (12) in its initial form involving rectilinear trajectories $\mathbf{R}(t) = \mathbf{R}_0 + tv_T$ was proposed by P.W. Anderson [18]; however, it fails to give reasonable estimates of the density effects at low temperature. The substantial modification that makes Eq. (12) applicable in this case is to use instead the curvilinear trajectories determined by the binary interaction potential in the initial state for the transition of interest, $V_{nl}(R)$, as suggested in [8, 9]. The numerical results for the density shift and broadening slopes for the transition lines in pionic helium of experimental interest, obtained with the fits HN1 and D47, are given in columns 6 and 7 of Table I, respectively.

In agreement with the observations in subsection II B, the detailed look at the multiple integral in Eq. (12) reveals that the dominant contribution to $\Phi$ (through the integrals of the difference $V_{nl'}(R(t)) - V_{nl}(R(t))$ along the various classical trajectories) comes from the range $4 \leq R \leq 10$ a.u. For the favored transition up to 95% of the value of $\Phi$ is accumulated in the range $4 \leq R \leq 6$ a.u., while for the unfavored transition the contributions from the domains $4 \leq R \leq 6$ and $6 \leq R \leq 10$ are balanced. This emphasizes once more the importance of using a realistic and accurate PES in the evaluation of the density effects; estimates based on the asymptotic shape of the interaction potentials, valid for $R > 10$ a.u., cannot be reliable.

III. NUMERICAL RESULTS AND DISCUSSION

The cumulative Table I presents the numerical results on the slopes of the density shift and broadening, $\beta_{fi}(T)$ and $\alpha_{fi}(T)$, of four transition lines in pionic helium of declared experimental interest, obtained with the theoretical methods outlined in the preceding section and using two different fits of the PES. We see that in some cases the numerical values differ quite significantly and require further comments.

1. The two different fits HN1 and D47 produce values that differ by up to 20%. As pointed out, this is related to the extrapolation of the fits outside the range of configurations relevant in antiprotonic helium for which the PES was initially evaluated. As long as both fits give close results for antiprotonic helium, we have no reasons to consider...
any of them as preferable; instead, the difference between the two values should be regarded as numerical uncertainty of the results that could only be eliminated with a new calculation of the PES for a wider range of configurations.

2. The two theoretical approaches of subsections II B and II D produce results that differ by only a few percent for the favored transition $^{(17, 16)} \rightarrow ^{(16, 15)}$ and by up to one third for the unfavored ones. The good agreement with experiment of the results for antiprotonic helium based on the use of classical trajectories, is not an argument to consider this approach as more credible in the case of pionic helium. We should therefore refer to these differences as a theoretical uncertainty of the results.

3. Accounting for the contribution of the anisotropic part of the PES only slightly affects the shift slope $\beta_{fi}(T)$ and has a larger impact on the broadening slope $\alpha_{fi}(T)$ which is still much smaller than the theoretical uncertainty.

4. The moderate temperature dependence of the results is uniformly reproduced in all the calculations.

IV. CONCLUSION

We have calculated the density shift and broadening of four dipole transition lines in pionic helium in gaseous helium. At thermal collision energies, we find a blue shift of the line center in the unfavored transitions $(n, l) = (16, 15) \rightarrow (16, 14)$, $(17, 16) \rightarrow (17, 15)$, and $(16, 15) \rightarrow (17, 14)$, while the transition frequency is red-shifted for the favored transition $(17, 16) \rightarrow (16, 15)$. The narrow collisional line width (0.1 GHz) of the laser-induced resonance transition $(n, l) = (16, 15) \rightarrow (16, 14)$ makes it suitable for precision spectroscopy of pionic helium atoms. We demonstrate that the major part of the collisional shift and width of the spectral lines is induced by the short-range part of the interatomic potential. Our result may be helpful in the extrapolation of the transition wavelengths in pionic helium to zero density of the perturbing helium gas. While the significant overall uncertainty of the S&B slopes, discussed above, may not allow for a direct extrapolation of the experimentally observed resonance frequencies of the laser-induced transitions to zero target gas density,
FIG. 1: The relative phase shifts $\eta_{fi,L}$ of Eq. [5] for: (a) the unfavored laser-stimulated dipole transition $(16,15) \rightarrow (16,14)$ in pionic helium in gaseous helium medium, and (b) the favored dipole transition $(17,16) \rightarrow (16,15)$. The different curves are labelled by the orbital momentum $L$.

we expect that knowing the density shift to $\sim 20\%$ fractional accuracy will greatly enhance the efficiency of the precision laser spectroscopy study of pionic helium.

TABLE I: Slope of the density shift and broadening, $\beta_{fi}(T)$ and $\alpha_{fi}(T)$, for selected transition lines in pionic helium and temperatures $T$ in the range $4 - 12$ K, in units $10^{-21}$ GHz cm$^3$. Listed are the numerical values obtained with Baranger’s method with account of the anisotropic part of the potential energy surface (Eq. (7)) and in the approximation of central interatomic potentials (Eqs. (3,4)), as well as with Anderson’s method (Eq. (12)), using either fit HN1 and D47 of the potential energy surface. The favored transition $(17,16) \rightarrow (16,15)$ is red-shifted, while all the unfavored transitions undergo a blue density-dependent shift.

| Transition          | T, K | Eq. (7) | Eqs. (3,4) | Eq. (12) |
