Abstract

It is not hard to write a first order formula which is true for a given graph \( G \) but is false for any graph not isomorphic to \( G \). The smallest number \( D(G) \) of nested quantifiers in a such formula can serve as a measure for the “first order complexity” of \( G \).

Here, this parameter is studied for random graphs. We determine it asymptotically when the edge probability \( p \) is constant; in fact, \( D(G) \) is of order \( \log n \) then. For very sparse graphs its magnitude is \( \Theta(n) \). On the other hand, for certain (carefully chosen) values of \( p \) the parameter \( D(G) \) can drop down to the very slow growing function \( \log^* n \), the inverse of the TOWER-function. The general picture, however, is still a mystery.

1 Introduction

In this paper we shall deal with sentences about graphs expressible in first order logic. Namely, the vocabulary consists of the following symbols:

- *variables* \( x, y, y_1, \text{etc} \);
- the relations $=$ (equality) and $\sim$ (the graph adjacency);
- the quantifiers $\forall$ (universality) and $\exists$ (existence);
- the usual Boolean connectives ($\lor$, $\land$, $\neg$, $\leftrightarrow$, and $\Rightarrow$).

These can be combined into first order formulas accordingly to the standard rules. A sentence is a formula without free variables. On the intuitive level it is perfectly clear what we mean when we say that a sentence is true on a graph $G$. This is denoted by $G \models A$; we write $G \not\models A$ for its negation ($A$ is false on $G$). We do not formalize these notions; a more detailed discussion can be found in e.g. [20, Section 1].

Please note that the variables represent vertices so the quantifiers apply to vertices only, i.e. we cannot express sentences like “There is a set $X$ having a given property”. (In fact, the language lacks any symbols to represent sets or functions.) We do not allow infinite sentences. As we do not go beyond first order logic, the standalone term “sentence” means a “first order sentence.”

From a logician’s point of view, the first order properties of graphs form a natural class of properties to study. For example, the so-called zero-one laws for random graphs have been extensively studied: see e.g. [10, 8, 12, 13, 6, 19, 14, 18, 20].

Of course, if $G \models A$ and $H \cong G$ (i.e. $H$ is isomorphic to $G$), then $H \models A$. On the other hand, for any graph $G$ it is possible to find a first order sentence $A$ which defines $G$, that is, $G \models A$ while $H \not\models A$ for any $H \not\cong G$. Indeed, let $V(G) = \{v_1, \ldots, v_n\}$. The required sentence $A$ could read:

“There are vertices $x_1, \ldots, x_n$, all distinct, such that any vertex $x_{n+1}$ is equal to one of these and $x_i \sim x_j$ iff $\{v_i, v_j\} \in E(G)$, $1 \leq i < j \leq n$.”

However, this sentence looks rather wasteful: we have $n + 1$ variables, the $\sim$-relation was used $\binom{n}{2}$ times, etc. Of a number of possible parameters measuring how complex $A$ is, we choose here $D(A)$, the quantifier depth (or simply depth) which is the size of a longest sequence of embedded quantifiers. (In the above example, $D(A) = n + 1$.) This is a natural characteristics which appears, for example, in the analysis of algorithms for checking whether $G \models A$. Also, the depth function can be studied by using the so-called Ehrenfeucht game [7] (see Section 2 here). Following Pikhurko, Veith and Verbitsky [16] (see also [17]) we let $D(G)$ be the smallest depth of a sentence defining $G$. It is a measure of how difficult it is to describe the graph $G$ in first order logic.

A word of warning: the function $D(G)$ does not correlate very well with our everyday intuition of how complex the graph $G$ is. Such are the limitations of the first order language that, for example, $D(K_n) = D(\overline{K}_n) = n + 1$ is the largest among all order-$n$ graphs but what can be simpler than the complete or empty graph?!

Perhaps, this is just an unlucky example? This approach seems only partially helpful: it is shown in [16] that, certain exceptions aside, $D(G)$ can be bounded by $\frac{v(G)+5}{2}$; however, the situation seems to get messy when we try to describe all graphs with $D(G) \geq (\frac{1}{2} - \varepsilon)v(G)$. Besides a large homogeneous set, there are other obstacles which may push the depth up: Cai, F¨urer, and Immerman [5] constructed graphs $G$ to define which we need $\Omega(v(G))$ nested quantifiers even if we add counting to first order logic. This is a rather drastic addition: for example, we need only two nested quantifiers to define $K_n$ with counting, namely,

“There are precisely $n$ vertices and every two of them are connected.”
The opposite approach was taken by Pikhurko, Spencer and Verbitsky [15]: what is \( g(n) \), the minimum \( D(G) \) over all graphs \( G \) of order \( n \)? It turned out that \( g(n) \) can be arbitrarily small in the following sense: for any recursive function \( f : \mathbb{N} \to \mathbb{N} \) there is \( n \) such that \( f(g(n)) < n \). If we try to “smoothen” \( g(n) \) by defining \( \gamma(n) = \max_{i \leq n} g(i) \), then \( \gamma(n) = \Theta(\log^* n) \). Here, the log-star \( \log^* n \) is the inverse to the TOWER-function, that is, the number of times we have to take the binary logarithm before we get below one:

\[
\log^* n = \min\{i \in \mathbb{N} : \log_2(i/n) < 1\}.
\]

Such a behavior is surprising and intriguing. Having studied the two extreme cases, we concentrate now on what happens in a typical graph. More generally, we consider the standard Erdős-Rényi model \( G \in \mathcal{G}(n, p) \), where \( p \) denotes the edge probability. Of course, we are interested in events occurring whp (with high probability, that is, with probability \( 1 - o(1) \) as \( n \to \infty \)). While a zero-one law studies the probability that a fixed sentence holds, we take a random graph and ask what the ‘simplest’ sentence defining it is.

As \( D(G) = D(G) \), we can assume without loss of generality that \( p \leq \frac{1}{2} \).

In Section 3 we study the case when \( 0 < p \leq \frac{1}{2} \) is a constant and show that whp

\[
D(G) = \log_{1/p} n + O(\ln \ln n). \tag{1}
\]

The case \( p = \frac{1}{2} \) is always of particular interest: \( G \in \mathcal{G}(n, \frac{1}{2}) \) is uniformly distributed among all graphs of order \( n \). In Section 4, we have found a different line of argument (as far as the upper bound is concerned), which allowed us to pinpoint \( D(G) \) down to at most 5 distinct values for infinitely many \( n \). Unfortunately, this approach does not seem to work for \( p \neq \frac{1}{2} \).

In Section 5 we show that for \( p < \frac{1.10}{n} \), \( D(G) \) is determined by the number of isolated vertices and therefore is of order \( \Theta(n) \). We believe (cf. Conjecture 20) that the giant component, which appears around \( p = \frac{1}{n} \), has negligible effect on \( D(G) \) as long as \( p = O(n^{-1}) \) but we were not able to prove this.

Rather surprisingly, for some carefully selected \( p = p(n) \) the function \( D(G) \) can be as small as \( O(\log^* n) \). The reason is that the integer arithmetics can be modeled over the obtained random graphs while integers can be defined by first order sentences of very small depth. We do not present an exhaustive general theorem but give an example demonstrating this phenomenon when \( p = n^{-1/4} \). On the other hand, the upper bound \( O(\log^* n) \) is sharp, up to a multiplicative constant, cf. Theorem 21.

The first order complexity of \( G \in \mathcal{G}(n, p) \) for the general \( p \) remains a mystery. Open problems and conjectures are scattered throughout the text. See also Section 7 for some concluding remarks.

2 The Ehrenfeucht Game

For non-isomorphic graphs \( G \) and \( G' \) let \( D(G, G') \) be the smallest quantifier depth of a first order sentence \( A \) distinguishing \( G \) from \( G' \) (that is, \( G \models A \) while \( G' \not\models A \)). As the negation sign does not affect the depth, we have \( D(G, G') = D(G', G) \).
The converse inequality is trivial. ■

In the remainder of this section, we describe the Ehrenfeucht game which is a very useful combinatorial tool for studying \( D(G, G') \). It was introduced by Ehrenfeucht [7]. Earlier, Fraïssé [9] suggested an essentially equivalent way to compute \( D(G, G') \) in terms of partial isomorphisms between \( G \) and \( G' \). A detailed discussion of the game can be found in [20, Section 2].

Let \( G \) and \( G' \) be two graphs. By replacing \( G' \) with an isomorphic graph, we can assume that \( V(G) \cap V(G') = \emptyset \). The Ehrenfeucht game \( \text{EHR}_k(G, G') \) is played by two players, called Spoiler and Duplicator and consists of \( k \) rounds. For brevity, let us refer to Spoiler as ‘him’ and to Duplicator as ‘her’. In the \( i \)-th round, \( i = 1, \ldots, k \), Spoiler selects one of the graphs \( G \) and \( G' \) and marks some its vertex by \( i \); Duplicator must put the same label \( i \) on a vertex in the other graph. (A vertex may receive more than one mark.) At the end of the game (i.e. after \( k \) rounds) let \( x_1, \ldots, x_k \) be the vertices of \( G \) marked \( 1, \ldots, k \) respectively, regardless of who put the label there; let \( x_1', \ldots, x_k' \) be the corresponding vertices in \( G' \). Duplicator wins if the correspondence \( x_i \leftrightarrow x_i' \) is a partial isomorphism, that is, we require that \( \{x_i, x_j\} \in E(G) \) iff \( \{x_i', x_j'\} \in E(G') \) as well as that \( x_i = x_j \) iff \( x_i' = x_j' \). Otherwise, Spoiler wins.

The crucial relation is that for any non-isomorphic \( G \) and \( G' \) the smallest \( r \) such that Spoiler has a winning strategy in \( \text{EHR}_r(G, G') \) is equal to \( D(G, G') \). In fact, an explicit winning strategy for Spoiler gives us an explicit sentence distinguishing \( G \) from \( G' \).

If Spoiler can win the game, alternating between the graphs \( G \) and \( G' \) at most \( r \) times, then the corresponding sentence has the alternation number at most \( r \), that is, any chain of nested quantifiers has at most \( r \) changes between \( \exists \) and \( \forall \). (To make this well-defined, we assume that no quantifier is within the range of a negation sign.) Let \( D_r(G) \) be the smallest depth of a sentence which defines \( G \) and has the alternation number at most \( r \). Clearly, \( D_r(G, G') = \max \{ D_r(G, G'): G' \not\equiv G \} \), where \( D_r(G, G') \) may be defined as the smallest \( k \) such that Spoiler can win \( \text{EHR}_k(G, G') \) with at most \( r \) alternations.

For small \( r \), this is a considerable restriction, giving a qualitative strengthening of the obtained results. Therefore, we make the extra effort of computing the alternation number given by our strategies if the obtained \( r \) is really small.

Finally, let us make a few remarks on our terminology. When a player marks a vertex, we may also say that the player selects (or claims) the vertex. Duplicator loses after \( i \) rounds if the correspondence between \( \{x_1, \ldots, x_i\} \) and \( \{x_1', \ldots, x_i'\} \) is not a partial isomorphism. (Of course, there is no point in continuing the game in this situation.)
3 Constant Edge Probability

As $D(G) = D(\overline{G})$, we can assume without loss of generality that $p \leq \frac{1}{2}$. For brevity let us denote $q = 1 - p$. In this section we prove the following result.

**Theorem 2** Let $p$ be a constant, $0 < p \leq \frac{1}{2}$. Let $G \in \mathcal{G}(n, p)$. Then whp

$$-O(1) \leq D(G) - \log_{1/p} n + 2 \log_{1/p} \ln n \leq (2 + o(1)) \frac{\ln \ln n}{-p \ln p - q \ln q}$$

The lower bound follows by observing that if for any disjoint $A, B \subset G$ with $|A| + |B| \leq k$, there is a vertex $y$ connected to everything in $A$ but to nothing in $B$ (this is called the $k$-extension property or the $k$-Alice Restaurant property), then $D(G) \geq k + 2$. The upper bound is obtained by some kind of recursion, where for every $x \in G$ we write a sentence $A_x$ describing its neighborhood $\Gamma(x)$. Whp no two neighborhoods are isomorphic so $A_x$ “defines” $x$ and the final sentence $A$ stipulates that the (unique) vertices satisfying $A_x$ and $A_y$ are connected if and only if $x, y \in G$ are. As each recursive step reduces the order by a factor of about $1/p$, the obtained sentence has depth around $\log_{1/p} n$. There are some technicalities to overcome. However, the combinatorial setting of the Ehrenfeucht games makes the proof more transparent and accessible.

Unfortunately, we have hardly any control on the alternation number in Theorem 2. The following result fills this gap by providing the defining sentences of a very restrictive form: no alternation at all. This, however, comes at the expense of increasing the depth by a constant factor.

**Theorem 3** Let $p$ be a constant, $0 < p < 1$. Let $G \in \mathcal{G}(n, p)$. Then whp

$$D_0(G) \leq (2 + o(1)) \frac{\ln n}{-\ln(p^2 + q^2)}.$$  

**Remark.** If we are happy to bound $D_1$ only, then the constant in (4) can be improved: in the proof (Section 3.3) we have to use Lemma 8 instead of Lemma 10.

3.1 The Lower Bound

To prove the lower bound in (3) we use the following lemma.

**Lemma 4** If $G$ has the $k$-extension property, then $D(G) \geq k + 2$.

**Proof.** Let $G' \not\cong G$ be another graph which has the $k$-extension property. (For example, we can take a random graph of large order.) Consider $EHR_k(G, G')$. Duplicator’s strategy is straightforward. If in the $i$-th round Spoiler selects a previously marked vertex, Duplicator does the same in the other graph. Otherwise, she matches the adjacencies between $x_i$ and $\{x_1, \ldots, x_{i-1}\}$ to those between $x'_i$ and $\{x'_1, \ldots, x'_{i-1}\}$ by the $k$-extension property.
It is easy to show that whp $G \in \mathcal{G}(n, p)$, for constant $p \in (0, \frac{1}{2}]$, has the $[r]$-extension property with
\[
    r = \log_{1/p} n - 2\log_{1/p} \ln n + \log_{1/p} \ln(1/p) - o(1),
\]
which gives us the required lower bound by Lemma 4. Indeed, for $k < r - \Theta(1)$, the expected number of ‘bad’ $A, B \subset V(G)$ with $|A| + |B| = k$ can be bounded by
\[
    \left(\begin{array}{c} n \\ k \end{array}\right) 2^k (1 - p^k)^{n-k} = e^{k \ln n - p^k n + o((\ln 2 n)^2)} = o(1).
\]

3.2 The Upper Bound

Let $G = (V, E)$ be a graph. Let $V_i$ consist of all ordered sequences of $i$ pairwise distinct vertices of $G$. For $x = (x_1, \ldots, x_i) \in V_i$ define
\[
    V_x = \{ y \in V \setminus \{x_1, \ldots, x_i\} : \forall j \in [i] \{y, x_j\} \in E\},
\]
and $G_x = G[V_x]$. We abbreviate $G_{x_1, \ldots, x_i} = G(x_1, \ldots, x_i)$, etc. Let us agree that $V_{-1} = \emptyset$, $V_0 = \{(\)\}$ consists of the empty sequence, and $G_{()} = G$.

The following lemma specifies our global line of attack.

**Lemma 5** Suppose that a graph $G$, numbers $l \geq 0$ and $l_0 \geq 3$ satisfy all of the following conditions.

1. For any $x \in V_{l-1} \cup V_l$ we have $D(G_x) \leq l_0$.

2. For any $i \leq l-1$, $x \in V_i$, and distinct $y, z \in V_x$, the following two conditions hold. Let $U = V_{x,y,z}$.
   a. Any injection $f : U \to V_{x,y}$ which embeds $G_{x,y,z}$ as an induced subgraph into $G_{x,y}$ is the identity mapping. (In particular, $G_{x,y,z}$ admits no non-trivial automorphism.)
   b. There is a vertex $v \in V_{x,y} \setminus U$ such that for any vertex $w \in V_{x,z} \setminus U$ we have $\Gamma(v) \cap U \neq \Gamma(w) \cap U$, where $\Gamma$ denotes the neighborhood of a vertex.

3. For any $i \leq l-1$, $x \in V_i$, and distinct $y, z, w \in V_x$, $G_{x,y,z}$ is not isomorphic to an induced subgraph of $G_{x,w}$.

Then $D(G) \leq l + l_0$.

**Proof.** Let us observe first that Condition (2.) (or Condition (3.)) implies that
\[
    G_{x_1, \ldots, x_i, y} \not\cong G_{x_1, \ldots, x_i, z}, \quad \text{for any } i \leq l-1, (x_1, \ldots, x_i) \in V_i, \text{ and distinct } y, z \in V_{x_1, \ldots, x_i}. \quad (6)
\]

We prove the lemma by induction on $l$. If $l$ is 0 or 1, then Condition (1.) alone implies the claim. So, let $l \geq 2$. Let $G' = (V', E')$ be any graph which is not isomorphic to $G$. 6
**Case 1** Suppose that there is \( x \in V \) such that \( G_x \not\cong G'_{y'} \) for any \( y \in V' \). Spoiler selects this \( x \). Let \( x' \) be the Duplicator’s reply. The graph \( G_x \) satisfies all the assumptions of Lemma 5 with \( l \) decreased by 1. Spoiler will always play inside one of \( G_x \) or \( G'_{y'} \). We can assume that Duplicator does the same for otherwise the adjacencies to \( x \) and \( x' \) do not correspond. As \( G_x \not\cong G'_{x'} \), Spoiler can use the induction to win the \( (G_x, G'_{x'}) \)-game in at most \( l + l_0 - 1 \) moves, as required. 

The same argument works if there is \( x \in V' \) such that \( G'_x \not\cong G_y \) for any \( y \in V \).

**Case 2** Suppose now that there are \( x \in V \) and distinct \( y', z' \in V' \) such that

\[
G_x \cong G'_{y'} \cong G'_{z'}.
\]

(7)

Spoiler selects \( y' \in V' \). Assume that Duplicator replies with \( y = x \), for otherwise \( G_y \not\cong G'_{y'} \) by (6) and Spoiler proceeds as in Case 1. Now, Spoiler selects \( z' \); let \( z \in V \) be the Duplicator’s reply. We can assume that

\[
G_{y,z} \cong G'_{y',z'},
\]

(8)

for otherwise Spoiler applies the inductive strategy to the \( (G_{y,z}, G'_{y',z'}) \)-game, where \( l \) is reduced by 2.

We show that Spoiler can win in at most 3 extra moves now. Let \( U = V_{y,z} \) and \( U' = V'_{y',z'} \). Spoiler selects the vertex \( v \in V_y \setminus U \) given by Condition (2b.). Let \( v' \in V'_{y'} \setminus U' \) be the Duplicator’s reply. By Condition (2a.) and (7)–(8) there is a bijection \( g : V'_{y'} \rightarrow V'_{z'} \) which is the identity on \( U' \) and induces an isomorphism of \( G'_{y'} \) onto \( G'_{z'} \). Spoiler selects \( u' = g(v') \). Whatever the reply \( w \in G_x \setminus U \) of Duplicator is, \( \Gamma(v) \cap U \neq \Gamma(w) \cap U \). But in \( G' \) we have \( \Gamma(v') \cap U' = \Gamma(w') \cap U' \). Spoiler can point this difference with one more move into \( U \). The total number of moves is \( 5 \leq l + l_0 \), as required.

By (6), the only remaining case is the following.

**Case 3** Suppose that there is a bijection \( g : V \rightarrow V' \) such that for any \( x \in V \) we have \( G_x \cong G_{g(x)} \).

As \( G \not\cong G' \), there are \( y, z \in V \) such that \( g \) does not preserve the adjacency between \( y \) and \( z \). Spoiler selects \( y \). We can assume that Duplicator replies with \( y' = g(y) \) for otherwise Spoiler proceeds as in Case 1. Now, Spoiler selects \( z \) to which Duplicator is forced to reply with \( z' \neq g(z) \). Assume that \( G_{y,z} \cong G'_{y',z'} \) for otherwise Spoiler applies the inductive strategy for \( l - 2 \) to these graphs. But then \( G_{y,z} \) is an induced subgraph of \( G_w \), where \( w = g^{-1}(z') \), contradicting Condition (3.). 

In order to finish the proof of Theorem 2 we apply Lemma 5 to a random graph \( G \in \mathcal{G}(n, p) \). Let \( l = \log_{1/p} n - C' \log_{1/p} \ln n - 1 \) and \( l_0 = C_0 \ln \ln n \) where \( C \) and \( C_0 \) are constants such that \( C > 2 \) and \( C_0(p \ln p - q \ln q) > C \). Let \( m = np^{l+1} = \ln^C n \). Let \( \varepsilon > 0 \) be a small constant. Let \( n \) be sufficiently large.

Let \( \mathcal{V} = \bigcup_{i=0}^{l+1} \mathcal{V}_i \). Observe that \( |\mathcal{V}| \leq e^{(1+\varepsilon) \log_{1/p} n \ln n} = e^{O(\ln^2 n)} \).

**Lemma 6** Whp for any \( i \leq l + 1 \) and \( x \in \mathcal{V}_i \) we have

\[
| |V_x| - p^n | \leq \varepsilon p^n.
\]

(9)
Proof. Fix some $x \in \mathcal{V}_i$. The size of $V_x$ has the binomial distribution with parameters $(n - i, p')$. By Chernoff’s bound ([1, Appendix A]), the probability $p'$ that this $x$ violates (9) is

$$p' \leq 2e^{-\varepsilon^2np'/3} \leq 2e^{-\varepsilon^2m/3} = o(|\mathcal{V}|^{-1}).$$

(10)

Thus the expected number of ‘bad’ $x$’s is $o(1)$, giving the required.\[\square\]

Lemma 7 Whp Condition (2.) holds.

Proof. Fix $i \leq l - 1$, $x \in \mathcal{V}_i$, and $y, z \in V_x$. Let $U = V_{x,y,z}, W = V_{x,y}, u = |U|$, and $w = |W|$. First we deal with Condition (2a.). Take $j \in [1, u]$. Let $g$ be any injection from $U$ into $W$ such that $|U_g| = j$, where $U_g = \{v \in U : g(v) \neq v\}$ consists of the elements moved by $g$. Let the same symbol $g$ denote also the induced action on edges. Let $E_g$ consist of those $e \in {U \choose 2}$ such that $g(e) \neq e$. It is not hard to see that

$$|E_g| \geq \binom{j}{2} + j(u - j) - \frac{j}{2} = j(u - j/2 - 1).$$

We can find a set $D \subset E_g$ of size at least $|E_g|/3$ such that $D \cap g(D) = \emptyset$. We do so greedily: choose any $e \in E_g$, move $e$ to $D$, and remove $g(e), g^{-1}(e)$ from $E_g$ (if they belong there). The probability that, for all $e \in D$, the 2-sets $e$ and $g(e)$ are simultaneously edges or non-edges is $(p^2 + q^2)^{|D|}$ because these events are independent. This gives an upper bound on the probability that $g$ induces an isomorphism.

Given $j$, there are at most $\binom{u}{j}w^j$ choices of $g$. The sequence $(x, y)$ (or $(x, y, z)$) violates (9) with probability at most $p'$, where $p'$ is as in (10). Thus we can bound the probability that $x, y, z$ violate Condition (2a.) by

$$2p' + \sum_{j=1}^{u} \binom{u}{j}w^j(p^2 + q^2)^{j(u - j/2 - 1)/3} < 2p' + (p^2 + q^2)^{(\frac{1}{3} - \varepsilon)m}.$$

Hence, the expected number of bad witnesses $x, y, z$ is at most

$$\mathcal{V} \left(2p' + (p^2 + q^2)^{(\frac{1}{3} - \varepsilon)m}\right) = o(1),$$

giving the required by Markov’s inequality.

To estimate the probability that (2b.) fails, fix some $v \in W \setminus U$. The probability that some vertex of $V_{x,z} \setminus U$ has the same neighborhood in $U$ as $v$ is at most $(p^2 + q^2)^u$. We have $u > (1 - \varepsilon)m$ with probability at least $1 - p'$. Hence, $v$ does not satisfy Condition (2b.) with probability at most

$$\mathcal{V}_{x,z} \left(p' + (p^2 + q^2)^{(1 - \varepsilon)m}\right) = o(|\mathcal{V}|),$$

finishing the proof.\[\square\]

Condition (3.) is verified similarly to the argument of Lemma 7. (The proof is, in a way, even easier because $|V_{x,y,z} \setminus V_\mathcal{V}| = \Omega(m)$ whp.) All that remains to check is Condition (1.). To deal with it, we need another strategic lemma. For a subset $X$ of vertices of $G = (V, E)$, define the
equivalence relation \( \equiv_X \) on \( V \), called the \( X \)-similarity, by \( x \equiv_X y \) iff \( x = y \) or \( x, y \in V \setminus X \) satisfy \( \Gamma(x) \cap X = \Gamma(y) \cap X \). This is an equivalence relation. Let

\[
S(X) = \{ x \in V : \forall y \in V \ (y \neq x \Rightarrow y \not\equiv_X x) \} \subseteq X.
\]

The vertices in \( S(X) \) are sifted out by \( X \) (that is, are uniquely determined by their adjacencies to \( X \)). We call \( X \) a sieve if \( S(X) = V \).

**Lemma 8** Let \( X \subseteq V \). Define \( Y = S(X) \). If \( S(Y) = V \), then \( D_1(G) \leq |X| + 3 \).

**Proof.** Let \( G' \neq G \). First, Spoiler selects all of \( X \). Let \( X' \subseteq V' \) be the Duplicator’s reply. Assume that Duplicator has not lost yet. For the notational simplicity let us identify \( X \) and \( X' \) so that \( V \cap V' = X = X' \) and our both graphs coincide on \( X \). Let \( Y' = S_{G'}(X) \).

It is not hard to see that Spoiler wins in at most two extra moves unless the following holds. For any \( y \in Y \setminus X \) there is a \( y' \in Y' \setminus X \) (and vice versa) such that \( \Gamma(y) \cap X = \Gamma(y') \cap X \). Moreover, this bijective correspondence between \( Y \) and \( Y' \) induces an isomorphism between \( G[Y] \) and \( G'[Y'] \).

Clearly, if Duplicator does not respect this correspondence, she loses immediately. Therefore, we may identify \( Y \) with \( Y' \). Let \( Z = V \setminus Y \) and \( Z' = V' \setminus Y \). Let \( z \in Z \) and define

\[
W_z = \{ z' \in Z' : \Gamma(z') \cap Y = \Gamma(z) \cap Y \}
\]

If \( W_z = \emptyset \), Spoiler wins in at most two moves. First, he selects \( z \). Let Duplicator reply with \( z' \in Z' \). As the neighborhoods of \( z, z' \) in \( Y \) differ, Spoiler can highlight this by picking a vertex of \( Y \). If \( |W_z| \geq 2 \), then Spoiler selects some two vertices of \( W_z \) and wins with at most one more move, as required.

Hence, we can assume that for any \( z \) we have \( W_z = \{ f(z) \} \) for some \( f(z) \in Z' \). It is easy to see that \( f : Z \rightarrow Z' \) is in fact a bijection (otherwise Spoiler wins in two moves). As \( G \neq G' \), the mapping \( f \) does not preserve the adjacency relation between some \( y, z \in Z \). Now, Spoiler selects both \( y \) and \( z \). Duplicator cannot respond with \( f(y) \) and \( f(z) \); by the definition of \( f \) Spoiler can win in one extra move. \( \blacksquare \)

By Lemma 8, to complete the proof of Theorem 2 it suffices to verify that whp for any \( x \in V_{l-1} \cup \mathcal{V}_l \) there is an \((l_0 - 3)\)-set \( X \subseteq V_x \) such that, with respect to \( H = G_x \), \( S(Y) = U \), where \( Y = S(X) \) and \( U = V_x \). Let \( k = l_0 - 3 \) and \( u = |U| \). Fix any \( X \in \binom{V}{k} \). With probability at least \( 1 - p' \) we have \( up^2 \leq (1 + \varepsilon)m \). Conditioned on this, \( G_x \) is still constructed by choosing its edges independently. The probability that a vertex \( y \in U \setminus X \) belongs to \( Y \) is

\[
\sum_{i=0}^{k} \binom{k}{i} p'^iq^{k-i} \left( 1 - p'q^{k-i} \right)^{u-k-1} \tag{11}
\]

We want to bound this probability from below. Let, for example, \( i_0 = pk - k^{1/2} \ln k \). For \( i_0 \leq i \leq k \) we have \((1 - p'q^{k-i})u \geq 1 - \varepsilon \) by the definition of \( C_0 \). Chernoff’s bound implies that \( \sum_{i=i_0}^{k} \binom{k}{i} p'^iq^{k-i} > 1 - \varepsilon \) as this sum corresponds to the Binomial distribution with parameters \((k', p)\). Hence, the expression (11) is at least \((1 - \varepsilon)^2 > 1 - 2\varepsilon \) and the expectation

\[
E[|Y|] > (1 - 2\varepsilon)u.
\]
We construct the martingale \( Y_0, \ldots, Y_{u-k} \), where we expose the vertices of \( U \setminus X \) one by one and \( Y_i \) is the expectation of \( |Y| \) after \( i \) vertices have been exposed. Changing edges incident to a vertex, we cannot decrease or increase \( |Y| \) more than by two. By Azuma’s inequality ([1, Theorem 7.2.1]), the probability that \( |Y| \) drops, say, below \((1 - 3\varepsilon)u\) is at most \( e^{-\Omega(m)} = o(|V|) \). Whp each \( Y \) has at least \((1 - 3\varepsilon)u\) elements. The following simple lemma completes our quest.

**Lemma 9** Let \( \varepsilon = \varepsilon(p) > 0 \) be sufficiently small. Whp for any \( x \in \mathcal{V}_{l-1} \cup \mathcal{V}_l \), every set \( Y \subset V_x \) of size at least \((1 - 3\varepsilon)u\), \( u = |V_x| \), is a sieve in \( G_x \).

**Proof.** Let \( x \) satisfy (9). The expected number of bad triples \((Y, y, z)\) (that is, the distinct vertices \( y, z \in V \setminus Y \) have the same neighborhood in a set \( Y \) of size at least \((1 - 3\varepsilon)u\)) is

\[
\sum_{i \leq 3\varepsilon u} \binom{u}{i} u^2 (p^2 + q^2)^{u-i} = o(|V|).
\]

The claim follows from (10). \( \square \)

### 3.3 Games with no Alternations

Following our standard scheme, we first specify a graph property which ensures the desired bound on \( D(G) \) and then show that a random graph satisfies this property whp.

**Lemma 10** Assume that in a graph \( G = (V, E) \) we can find \( X \subset V \) such that

1. \( X \) is a sieve;
2. \( G[X] \) has no nontrivial automorphism;
3. \( G \) has no other induced subgraph isomorphic to \( G[X] \).

Then \( D_0(G) \leq |X| + 2 \).

**Proof.** Let \( G' \) be an arbitrary graph non-isomorphic to \( G \). For some \( G' \) Spoiler plays all the time in \( G \), for others he plays all the time in \( G' \).

We first describe the strategy when Spoiler plays in \( G \). Spoiler selects all vertices in \( X \). Suppose that Duplicator managed to establish \( \phi : X \to X' \), a partial isomorphism from \( G \) to \( G' \), where \( X' \subset V' \) is the set of Duplicator’s responses. Denote \( Z = V(G) \setminus X \) and \( Z' = V(G') \setminus X' \). We call two vertices, \( v \in Z \) and \( v' \in Z' \) \( \phi \)-similar if the extension of \( \phi \) which takes \( v \) to \( v' \) is a partial isomorphism from \( G \) to \( G' \). Four cases are possible:

**Case 1** The \( \phi \)-similarity is a one-to-one correspondence between \( Z \) and \( Z' \).

**Case 2** There is \( v \in Z \) without a \( \phi \)-similar counterpart in \( Z' \).
Case 3 There is $v' \in Z'$ without a $\phi$-similar counterpart in $Z$.

Case 4 There are $v'_1, v'_2 \in Z'$ with the same $\phi$-similar counterpart in $Z$.

In Case 1 there are $v_1, v_2 \in Z$ with adjacency different from the adjacency between their $\phi$-similar counterparts in $Z'$. Spoiler selects $v_1$ and $v_2$ and wins. In Case 2 Spoiler wins by selecting the vertex $v$. In Cases 3 and 4 Spoiler fails in this way but plays differently from the very beginning.

Namely, if there exist $X'$ and a partial isomorphism $\phi : X \rightarrow X'$ such that Cases 3 or 4 occur, Spoiler begins with selecting all vertices in $X'$. Duplicator is forced to reply in accordance with $\phi$ due to the conditions assumed for $X$. Then Spoiler selects the vertex $v'$ in Case 3 or $v'_1$ and $v'_2$ in Case 4 and wins.

**Lemma 11** Let $\varepsilon > 0$ and $0 < p < 1$ be fixed. Let $G \in \mathcal{G}(n, p)$ and let $X \subset V$ be any set of size $t \geq (2 + \varepsilon) \log_{1/r} n$, where $r = p^2 + q^2$. Then whp Conditions (1.)–(3.) of Lemma 11 hold.

**Proof.** The expected number of vertices with the same neighborhood in $X$ is at most $n^2 r^t = o(1)$, implying (1.). Conditions (2.) and (3.) follow from the following claim.

**Claim 1** Whp no injective $g : X \rightarrow V$, with the exception of the identity mapping, preserves the adjacency relation. **Proof of Claim.** Fix $g$. Let $k = |K|$ and $l = |L|$, where

$$
K = \{x \in X : g(x) \notin X\}, \quad L = \{x \in X : g(x) \in X \setminus \{x\}\}.
$$

As in the proof of Lemma 7 we can find a set $D \subset \binom{X \setminus K}{2}$ of size at least $l \frac{t-k-l/2-1}{3}$ such that $D \cap g(D) = \emptyset$. The latter property still holds if we enlarge $D$ by the set of all elements of $\binom{X}{2}$ incident to $K$. Hence, the total probability of failure is at most

$$
\sum_{0<k+l\leq t} \binom{t}{k} \binom{t-k}{l} n^k l^l r^{l-k+\left(k+\frac{l}{2}-1\right)+k(t-1)-(\frac{k}{2})} = o(1),
$$

completing the proof of the claim and the lemma.

**4 Edge Probability $1/2$**

Here is the main result of this section.

**Theorem 12** Let $G \in \mathcal{G}(n, \frac{1}{2})$. For infinitely many values of $n$ we have whp

$$
D_2(G) \leq \log_2 n - 2 \log_2 \ln n + \log_2 \ln 2 + 6 + o(1). \tag{12}
$$

**Remark.** The lower bound given by Lemma 4 and the case $p = \frac{1}{2}$ of (5) is by at most $5 + o(1)$ smaller than the upper bound in (12). This implies that $D(G)$ and $D_2(G)$ are concentrated on
at most 6 different valued for such $n$. In Section 4.3 we will show that whp we have only 5 possible values.

Before we start proving Theorem 12, let us observe that for $p = \frac{1}{2}$ and an arbitrary $n$ the upper bound (3) can be improved by using Lemma 8 to

$$D_1(G) \leq \log_2 n - \log_2 \ln n + O(\ln \ln \ln n).$$

(Details are left to the interested Reader.)

4.1 Spoiler’s Strategy

Before we can specify the plan of our attack on Theorem 12, we have to give a few definitions. Let $G = (V, E)$, $W \subset V$, and $u \in \mathbb{N}$. Building upon the notions defined before Lemma 8, let

$$S_u(W) = \bigcup_{U \subset V \setminus W } \left( S(U \cup W) \setminus (U \cup W) \right).$$

In other words, a vertex $y \notin W$ belongs to $S_u(W)$ iff there is a $u$-set $U \subset V \setminus \{W \cup \{y\}\}$ such that $U \cup W$ sifts out $y$. Note that $S(W) = S_0(W) \cup W$.

Lemma 13 Let $Y = S_u(W)$. Suppose that $Y \cup W$ is a sieve in $G$ and that no two vertices of $Y$ have the same neighborhood in $W$. Then $D_2(G) \leq u + w + 4$, where $w = |W|$.

Proof. Let $G' = (V', E')$ be a graph non-isomorphic to $G$. We describe a strategy allowing Spoiler to win the game $EHR_{u+w+4}(G, G')$.

Spoiler first claims $W$. Let Duplicator reply with $W' \subset V'$. Assume that she does not lose in this phase, establishing a partial isomorphism $f : W \rightarrow W'$. Recall that we call two vertices $v \in V$ and $v' \in V'$ $f$-similar if the extension of $f$ taking $v$ to $v'$ is still a partial isomorphism from $G$ to $G'$. Let $Y' = S_u(W')$.

Claim 1 As soon as Spoiler moves inside $Y \cup Y'$ but Duplicator replies outside $Y \cup Y'$, Spoiler is able to win in the next $u + 1$ moves with 1 alternation between the graphs.

Proof of Claim. Assume for example that, while Spoiler selects $y \in Y$, Duplicator replies with $y' \notin Y'$. Spoiler selects some $u$-set $U$ with $y$ sifted out by $U \cup W$. Let the reply to it be $U'$. By the assumption on $y'$, there is another vertex $z'$ with the same adjacencies to $U' \cup W'$. Spoiler selects $z'$ and wins. 

Claim 2 If $Y'$ contains two vertices with the same adjacencies to $W'$, then Spoiler is able to win the game in $w + u + 3$ moves with at most 2 alternations.

Proof of Claim. Assume that $y'$ and $z'$ are both in $Y'$ and have the same adjacencies to $W'$. Spoiler selects these two vertices. In order not to lose immediately, Duplicator is forced to reply at least once outside $Y$. Spoiler wins in the next $u + 1$ moves according to Claim 1. 

Assume therefore that all vertices in $Y'$ have pairwise distinct neighborhoods in $W'$. This assumption and Claim 1 imply that either the $f$-similarity determines a one-to-one correspondence between $Y$ and $Y'$ or Spoiler is able to win the game in $w + u + 3$ moves with at most 2 alternations. We will assume the first alternative. Extend $f$ to a map from $W \cup Y$ onto $W' \cup Y'$ accordingly to the $f$-similarity correspondence between $Y$ and $Y'$.

**Claim 3** Suppose that Duplicator failed to respect the bijection $f$ after a Spoiler’s move into $Y \cup Y'$. Then Spoiler can win in at most $u + 1$ extra moves, during which he alternates at most once.

**Proof of Claim.** Suppose that the previous move $x$ of Spoiler was in $G$, for example. Clearly, the Duplicator’s response $x'$ cannot belong to $Y'$ because $f(x)$ is the only vertex in $Y'$ with the required $W'$-adjacencies. Spoiler applies the strategy of Claim 1. ■

**Claim 4** If $f : W \cup Y \rightarrow W' \cup Y'$ is not a partial isomorphism from $G$ to $G'$, then Spoiler is able to win the game in $w + u + 3$ moves with 1 alternation.

**Proof of Claim.** Assume, for example, that $(y_1, y_2) \in {Y \choose 2}$ is an edge while $(f(y_1), f(y_2))$ is not. Spoiler picks $y_1$ and $y_2$. Duplicator cannot reply with $f(y_1)$ and $f(y_2)$ so Spoiler wins in at most $w + 2 + (u + 1) = w + u + 3$ moves by Claim 3. ■

Assume therefore that $f : W \cup Y \rightarrow W' \cup Y'$ is a partial isomorphism. Denote $R = V \setminus (W \cup Y)$ and $R' = V' \setminus (W' \cup Y')$.

**Claim 5** As soon as Spoiler moves inside $R \cup R'$ but Duplicator fails to reply with an $f$-similar vertex in $R \cup R'$ (in the other graph), Spoiler can win in at most $u + 2$ extra moves, during which he alternates at most once.

**Proof of Claim.** If Duplicator replies with a vertex $x \in Y \cup Y'$, in the next move Spoiler marks the $f$-mate of $x$ and then applies the strategy of Claim 3. If she replies in $R \cup R'$ but not with an $f$-similar vertex, Spoiler highlights this in one more move and again uses Claim 3. ■

**Claim 6** If $W' \cup Y'$ is not a sieve in $G'$, then Spoiler is able to win the game in $w + u + 4$ moves with 2 alternations.

**Proof of Claim.** Spoiler picks two witnesses $z_1', z_2' \in R'$ with the same adjacencies to $W' \cup Y'$. If at least one of the corresponding replies $z_1, z_2$ is not in $R$, Spoiler applies the strategy of Claim 5. Otherwise $z_1$ and $z_2$ belong to different $W \cup Y$-similarity classes and there is a vertex $x \in W \cup Y$ adjacent to exactly one of $z_1$ and $z_2$. If $x \in W$, Spoiler wins immediately. If $x \in Y$, Spoiler picks $f(x) \in Y'$. Duplicator cannot respond with $x$. Now Spoiler wins the game in at most $u + 1$ extra moves by Claim 3. ■

In the rest of the proof we suppose that $W' \cup Y'$ is a sieve. This assumption and Claim 5 imply that either the $f$-similarity determines a one-to-one correspondence between $R$ and $R'$ or Spoiler is able to win the game in $w + u + 3$ moves with 2 alternations. Let us assume the first alternative. Extend $f$ to the whole of $V$ accordingly to the $f$-similarity correspondence between $R$ and $R'$. Thus $f$ is a bijection between $V$ and $V'$ now. As $G$ and $G'$ are not isomorphic, $f$ does not preserve the adjacency for some $(y_1, y_2) \in {Y \choose 2}$. Spoiler selects $y_1$ and $y_2$. If Duplicator replies with $f(y_1)$ and $f(y_2)$, she loses immediately. Otherwise, Spoiler applies the strategy of Claim 5 and wins, having made totally at most $u + w + 4$ moves and 1 alternation. ■
4.2 The Probabilistic Part

Let \( k \) be given. For simplicity let us assume that \( k \) is even. Define

\[
f(n, k) = \left(\frac{n - \frac{k}{2}}{k/2}\right) (n-k)(1-2^{-k})^{n-k-1}.
\]

Basic asymptotics show that for \( n = \Theta(k^2 2^k) \) we have \( \frac{f(n+1,k)}{f(n,k)} \approx 1 \) and thus we can find \( n = (\frac{ln2}{2} + o(1)) k^2 2^k \) such that

\[
f(n, k) = (10 + o(1)) \log_2 n.
\]

We fix this \( n \). Routine calculations show that

\[
k \leq \log_2 n - 2 \log_2 \ln n + \log_2 \ln 2 + 1 + o(1). \tag{13}
\]

Let \( A \) be a fixed \( \frac{k}{2} \)-subset of \( G \in G(n, \frac{1}{2}) \). Let \( U \) consist of pairs \((U, y)\), where \( U \) is a \( k \)-set containing \( A \) and \( y \in V \setminus U \). For \((U, y) \in U\), let \( I(U, y) \) denote the indicator random variable for the event \( y \in S(U) \). We define

\[
X = \sum_{(U,y) \in U} I(U, y),
\]

\[
M = |U| = \left(\frac{n - k/2}{k/2}\right)(n-k),
\]

\[
p = E[I(U, y)] = (1-2^{-k})^{n-k-1},
\]

We further set

\[
\mu = E[X] = Mp = f(n, k) = (10 + o(1)) \log_2 n. \tag{14}
\]

The idea behind these definitions is that we try to apply Lemma 13 for \( W = A \) and \( u = \frac{k}{2} \). Then \( \mu \) is the expected number of ways to construct a vertex of \( S_u(W) \). Our proof works only if \( \mu \) is neither too big nor too small, that is, for some special values of \( n \) only. We do not know if \( D(G) \) can pinned down to \( O(1) \) distinct values for an arbitrary \( n \).

As \( k \approx \log_2 n \) we have

\[
M \approx \frac{n^{\frac{k}{2}+1}}{(k/2)!} = n^{\frac{k}{2} + (1+o(1))}.
\]

As \( \mu = n^{o(1)} \) we further have

\[
p \approx e^{-n^{2-k}} = n^{-\frac{k}{2} + (1+o(1))}. \tag{15}
\]

Lemma 14 For distinct \((U_1, y_1), (U_2, y_2) \in U\),

\[
E[I(U_1, y_1) I(U_2, y_2)] < n^{-\frac{3k}{10} + (1+o(1))}. \tag{16}
\]

When \( |U_1 \cap U_2| < \frac{9k}{10} \)

\[
E[I(U_1, y_1) I(U_2, y_2)] < E[I(U_1, y_1)] E[I(U_2, y_2)] (1 + O(n^{-\frac{1}{10}(1+o(1))})). \tag{17}
\]
Proof. Condition on the adjacency patterns of \( y_1, y_2 \) to \( U_1, U_2 \) respectively. Let \( z \) be any vertex not in \( U_1 \cup U_2 \cup \{y_1, y_2\} \). Suppose (the main case) \( U_1 \neq U_2 \). Then

\[
\Pr[\{z \equiv U_1, y_1\} \land \{z \equiv U_2, y_2\}] \leq 2^{-k-1}
\]  
(18)
as the adjacency pattern of \( z \) to \( U_1 \cup U_2 \) is then determined. When \( U_1 = U_2 \) the adjacency patterns of \( y_1, y_2 \) to \( U_1 \) must be different as otherwise \( I(U_1, y_1) = I(U_2, y_2) = 0 \). Then it would be impossible to have \( z \equiv U_1, y_1 \) and \( z \equiv U_2, y_2 \) so (18) still holds. By inclusion-exclusion

\[
\Pr[\{z \equiv U_1, y_1\} \lor \{z \equiv U_2, y_2\}] \geq 2 \cdot 2^{-k} - 2^{-k-1} = 3 \cdot 2^{-k-1}.
\]

If \( I(U_1, y_1) I(U_2, y_2) = 1 \) then this fails for all such \( z \). But these events are mutually independent. Thus, by (15)

\[
E[I(U_1, y_1) I(U_2, y_2)] \leq (1 - 3 \cdot 2^{-k-1})^{n-2k-2} = n^{-\frac{3k}{2}} (1 + o(1)),
\]  
(19)
giving the required.

Suppose further that \( |U_1 \cap U_2| < \frac{9k}{10} \). Again let \( z \) be any vertex not in \( U_1 \cup U_2 \cup \{y_1, y_2\} \) and condition on the adjacency patterns of \( y_1, y_2 \) to \( U_1, U_2 \) respectively. Now

\[
\Pr[\{z \equiv U_1, y_1\} \land \{z \equiv U_2, y_2\}] \leq 2^{-\frac{11k}{10}}
\]
as this event requires \( z \) to have a given adjacency pattern to \( U_1 \cup U_2 \). Again by inclusion-exclusion

\[
\Pr[\{z \equiv U_1, y_1\} \lor \{z \equiv U_2, y_2\}] \geq 2 \cdot 2^{-k} - 2^{-\frac{11k}{10}}.
\]

As with (19) we deduce

\[
E[I(U_1, y_1) I(U_2, y_2)] \leq \left(1 - 2 \cdot 2^{-k} + 2^{-\frac{11k}{10}}\right)^{n-2k-2}.
\]

Now we want to compare this to \( E[I(U_1, y_1)] E[I(U_2, y_2)] \). We have

\[
(1 - 2 \cdot 2^{-k} + 2^{-\frac{11k}{10}})^{n-2k-2} = \left((1 - 2^{-k})^{n-k-1}\right)^2 (1 + O(n 2^{-\frac{11k}{10}})),
\]
yielding (17).

Lemma 15

\[
\text{Var}[X] = O(E[X]).
\]  
(20)

Proof. As \( X = \sum I(U, y) \), the sum of indicator random variables, we employ the general bound

\[
\text{Var}[X] \leq E[X] + \sum \text{Cov}[I(U_1, y_1), I(U_2, y_2)],
\]  
(21)
the sum over distinct \((U_1, y_1), (U_2, y_2) \in \mathcal{U}\). The first term is \( \mu \). Consider the sum of the covariances satisfying \(|U_1 \cap U_2| > \frac{9k}{10}\). There are \( M \) choices for \((U_1, y_1)\). For a given \( U_1 \) there are \( n^{-\frac{3k}{2}} (1 + o(1)) \) choices for \((U_2, y_2)\) and

\[
\sum E[I(U_1, y_1) I(U_2, y_2)] \leq M n^{-\frac{3k}{2}} (1 + o(1)) n^{-\frac{3k}{2}} (1 + o(1)) = o(1).
\]  
(22)
As the covariance of indicator random variables is at most the expectation of the product,
\[
\sum \text{Cov}[I(U_1, y_1), I(U_2, y_2)] = o(1),
\]
where in (22)-(23) the sum is restricted to \( |U_1 \cap U_2| > \frac{9k}{10} \). When \( |U_1 \cap U_2| \leq \frac{9k}{10} \) we have from (17) that
\[
\text{Cov}[I(U_1, y_1), I(U_2, y_2)] = O \left( E[I(U_1, y_1)] E[I(U_2, y_2)] n^{-\frac{k}{2n}}(1+o(1)) \right).
\]
Hence (the sum over \( |U_1 \cap U_2| \leq \frac{9k}{10} \))
\[
\sum \text{Cov}[I(U_1, y_1), I(U_2, y_2)] = O \left( n^{-\frac{k}{2n}}(1+o(1)) \right) \sum E[I(U_1, y_1)] E[I(U_2, y_2)]
\]
But \( \sum E[I(U_1, y_1)] E[I(U_2, y_2)] \) over all \( (U_1, y_1), (U_2, y_2) \in \mathcal{U} \) is precisely \( \mu^2 = O(\ln^2 n) \). This becomes absorbed in the \( n^{-\frac{k}{2n}} \) term and (the sum again over \( |U_1 \cap U_2| \leq \frac{9k}{10} \))
\[
\sum \text{Cov}[I(U_1, y_1), I(U_2, y_2)] = O(n^{-\frac{k}{2n}}(1+o(1))).
\]
In particular, all covariances in (21) together add up to \( o(1) \) and so we actually have the stronger result \( \text{Var}[X] \leq E[X] + o(1). \)

**Lemma 16** Whp every pair \((U_1, y_1) \neq (U_2, y_2)\) from \( \mathcal{U} \) with \( I(U_1, y_1) = I(U_2, y_2) = 1 \) satisfies

1. \( U_1 \cap U_2 = A; \)
2. \( y_2 \notin U_1; \)
3. \( y_1 \neq y_2; \)
4. \( y_1 \neq A y_2; \)
5. For \( u_1, u_2 \in U_1 \) with \( u_1 \neq u_2, u_1 \neq A u_2; \)
6. For \( u_1 \in U_1, u_2 \in U_2, u_1 \neq A u_2. \)

**Proof.** From (22) the expected number of pairs \((U_1, y_1) \neq (U_2, y_2)\) with \( I(U_1, y_1) = I(U_2, y_2) = 1 \) and \( |U_1 \cap U_2| > \frac{9k}{10} \) is \( o(1) \). The total number of pairs \((U_1, y_1) \neq (U_2, y_2)\) with \((U_1 \cap U_2) \setminus A \neq \emptyset\) is less than \( M^2 k^2 \). For each with \( |U_1 \cap U_2| \leq \frac{9k}{10} \) a weak form of (17) gives that \( E[I(U_1, y_1) I(U_2, y_2)] \leq 2p^2 \). Hence the expected number of such pairs with \( I(U_1, y_1) = I(U_2, y_2) = 1 \) is bounded from above by \( M^2 k^2(2p^2) = O((\ln^4 n)/n) = o(1). \) Hence the probability that (1.) fails is \( o(1). \)

For (2.) we first employ (1.) and restrict attention to \( U_1 \cap U_2 = A. \) The number of \((U_1, y_1), (U_2, y_2)\) with \( y_2 \in U_1 \) is less than \( M^2 \frac{k}{n-k} \) and for each \( E[I(U_1, y_1) I(U_2, y_2)] \approx p^2 \) so the expected number with \( I(U_1, y_1) I(U_2, y_2) = 1 \) is less than \( \approx (Mp)^2 \frac{k}{n} \) which is \( O((\ln^3 n)/n) = o(1). \)
For (3.) we first employ (1.) and restrict attention to \( U_1 \cap U_2 = A \). The number of such \((U_1, y_1), (U_2, y_2)\) with \( y_1 = y_2 \) is about \( M^2n^{-1} \) and for each such \( \Pr[I(U_1, y_1) = I(U_2, y_2) = 1] \approx p^2 \) so the expected number of violations of (3.) is around \((Mp)^2n^{-1} = \mu^2n^{-1} = o(1)\).

For (4.) we first employ (1.)–(3.) and restrict attention to pairs satisfying those conditions. The number of such pairs is \( \approx M^2 \). For each such \( \Pr[I(U_1, y_1) = I(U_2, y_2) = 1] \approx p^2 \) and, conditioned on this, \( \Pr[y_1 \equiv_A y_2] \approx 2^{-k/2} \). Hence the expected number of pairs violating (4.) is \( \approx (Mp)^22^{-k/2} = \mu^22^{-k/2} \) which is again \( o(1) \).

For (5.) there are \( M \) choices of \( U_1, y_1 \) and \( O(k^2) \) choices for \( u_1, u_2 \). For each \( \Pr[I(U_1, y_1) = 1] = p \), \( \Pr[u_1 \equiv_A u_2] = 2^{-k/2} \) and these events are independent so the expected number of violations of (5.) is \( O(Mp^2k^22^{-k/2}) \) which is \( o(1) \).

For (6.) we restrict attention to those cases satisfying (1.)–(4.). There are less than \( M^2 \) choices of \( U_1, y_1, U_2, y_2 \) and \( O(k^2) \) choices for \( u_1, u_2 \). For each \( \Pr[I(U_1, y_1) = I(U_2, y_2) = 1] \approx p^2 \), \( \Pr[u_1 \equiv_A u_2] = 2^{-k/2} \) and these events are independent so the expected number of violations of (6.) is \( O(M^2p^2k^22^{-k/2}) \) which is \( o(1) \).

Lemma 17 Let \( G \in G(n, \frac{k}{n}) \) and \( A \) be a fixed subset of \( \frac{k}{n} \) vertices, as above. Let \( Z \) denote the union of all sets \( U - A \) where some \( I(U, y) = 1 \) and let \( S = S_{k/2}(A) \) denote the set of all such vertices \( y \). Let \( R = V \setminus (A \cup Z \cup S) \). Then whp

1. All \( y_1, y_2 \in S \) have \( y_1 \not\equiv_A y_2 \).
2. All \( u_1, u_2 \in Z \) have \( u_1 \not\equiv_A u_2 \).
3. There are no distinct \( z_1, z_2, z_3, z_4 \in R \) with \( z_1 \equiv_S z_2 \) and \( z_3 \equiv_S z_4 \).
4. There are no distinct \( z_1, z_2, z_3 \in R \) with \( z_1 \equiv_S z_2 \equiv_S z_3 \)

Proof. The first two statements are the conclusions (4.)–(6.) of Lemma 16. We concentrate on showing (3.) as (4.) is similar. Set

\[
l = \mu - \mu^{0.6} \tag{25}
\]

Let \( Y \) denote the number of \( l \)-sets \( \{(U_i, y_i) : 1 \leq i \leq l\} \) (counting permutations of the \( (U_i, y_i) \) as the same) and \( z_1, z_2, z_3, z_4 \) satisfying

- \( I(U_i, y_i) = 1 \) for \( 1 \leq i \leq l \).
- The \( U_i - A \) are disjoint, the \( y_i \) are distinct, and no \( y_i \in U_j \).
- \( z_1, z_2, z_3, z_4 \in R \) where \( R \) denotes all vertices except the \( U_i \) and the \( y_i \)
- \( z_1 \equiv_S z_2 \) and \( z_3 \equiv_S z_4 \) where we set \( S = \{y_1, \ldots, y_l\} \).

We bound \( E[Y] \). There are less than \( M^l/l! \) choices for the \( (U_i, y_i) \) and \( n^4 \) choices for the \( z_1, z_2, z_3, z_4 \). Fix those choices. Set \( R^- = R \setminus \{z_1, z_2, z_3, z_4\} \) and let \( z \in R^- \). For each \( 1 \leq i \leq l \)

\[
\Pr[z \equiv_{U_i} y_i] = 2^{-k}.
\]

17
For each \(1 \leq i, j \leq l\), as \(|U_i \cap U_j| = \frac{k}{2}\),
\[
\Pr[(z \equiv U_i, y_i) \land (z \equiv U_j, y_j)] \leq 2^{-\frac{3k}{2}}.
\]
We apply the Bonferroni inequality, in the form that the probability of a disjunction is at least the sum of the probabilities minus the sum of the pairwise probabilities:
\[
\Pr[\bigvee_{i=1}^l z \equiv U_i, y_i] \geq l 2^{-k} - \binom{l}{2} 2^{-\frac{3k}{2}}.
\]
These events are independent over the \(z \in R^-\) as they involve different adjacencies. Let OK denote the event that no \(z \equiv U_i, y_i\) for any \(z \in R^-\) and \(1 \leq i \leq l\). The independence gives:
\[
\Pr[\text{OK}] \leq \left(1 - l 2^{-k} + \binom{l}{2} 2^{-\frac{3k}{2}}\right) n^{-l(1+\frac{k}{2})-\frac{k}{2}}.
\]
We bound
\[
1 - l 2^{-k} + \binom{l}{2} 2^{-\frac{3k}{2}} \leq (1 - 2^{-k})^l (1 + n^{-1.1})
\]
and
\[
n - l \left(1 + \frac{k}{2}\right) - \frac{k}{2} \leq n - k - 1
\]
so that
\[
\Pr[\text{OK}] \leq p^l (1 + n^{-1.1})^n \leq p^l (1 + o(1))
\]
Our saving comes from
\[
\Pr[z_1 \equiv_S z_2] = \Pr[z_3 \equiv_S z_4] = 2^{-l}.
\]
The adjacencies on the \(z_i\) to \(S\) are independent of the event OK. But
\[
\land_{i=1}^l I(U_i, y_i) = 1 \Rightarrow \text{OK}.
\]
Thus
\[
\Pr\left[\left(\land_{i=1}^l I(U_i, y_i)\right) \land (z_1 \equiv_S z_2) \land (z_3 \equiv_S z_4)\right] \leq p^l 2^{-2l} (1 + o(1)).
\]
Putting this together
\[
E[Y] \leq \frac{M^l}{l!} n^4 p^l 2^{-2l} (1 + o(1)).
\]
Recall that \(Mp = \mu \approx 10 \log_2 n\). The function \(\mu^x/x!\) hits a maximum at \(x = \mu\) where it is less than \(e^\mu\). Thus
\[
\frac{(Mp)^l}{l!} \leq e^\mu.
\]
Hence
\[
E[Y] \leq e^\mu n^4 2^{-2l}.
\]
We have selected \(l \approx \mu\) so that
\[
e^\mu 2^{-2l} = (e/4)^{\mu (1+o(1))} = n^{-K(1+o(1))},
\]
where \(K = -10 \log_2 (e/4) > 4\). We deduce
\[
E[Y] = o(1)
\]
so that almost surely there is no such \( l \)-tuple. Recall that \( X \) was the total number of \((U, y)\) with \( I(U, y) = 1 \). As \( E[X] = \mu \) and, from (20), \( \Var[X] = O(\mu) \) with probability \( 1 - o(1) \) we have \( X \geq l \). Further, Lemmas 14 and 16 give that whp the extensions have properties (1.)–(2.). Thus whp there exists a family of \((U_i, y_i)\) of size \( l \) which satisfies (1.)–(2.). But also whp any such family of size \( l \) will satisfy (3.) and (4.). So whp there is such a family. The expansion of the family to all \((U, y)\) with \( I(U, y) = 1 \) retains the properties (3.)–(4.) as the set \( S \) is just getting larger. So the theorem is proved. \( \blacksquare \)

4.3 Putting All Together

We can now finish the proof of Theorem 12. By Lemma 17 we have whp that all \( A \cup S_{k/2}(A) \)-similarity classes are singletons except possibly one 2-element class \( \{x, y\} \). If we let \( W = A \cup \{x\} \) and \( u = \frac{k}{2} \), then clearly \( G \) satisfies all the assumptions of Lemma 13, which implies that \( D_2(G) \leq k + 5 \), giving the required by (13).

Finally, let us justify the Remark after Theorem 12. Recall that given \( k \) we have chosen \( n \) so that \( f(n, k) \approx 10 \log_2 n \) and deduced that \( D_2(G) \leq k + 5 \) whp. The probability that the \((k - 1)\)-extension property fails for \( G \) is at most

\[
\left( \frac{n}{k - 1} \right) \left( 1 - 2^{-k+1} \right)^{n-k} = e^k \ln n - 2^{-k+1} n^{1+\Theta(1)} k \ln k = f(n, k) e^{-\Theta(1)} n^{\frac{k}{2} - \Theta(1)} k \ln k = o(1).
\]

By Lemma 4, \( k + 1 \leq D(G) \). Thus, \( D(G) \) and \( D_2(G) \) are concentrated on at most 5 different values.

5 Sparse Random Graphs

The following lemma helps us to deal with very sparse random graphs. Let \( t_k = t_k(G) \) be the number of components of \( G \) which are order-\( k \) trees. (Thus \( t_1(G) \) is the number of isolated vertices.) For a graph \( F \), let \( c_F(G) \) be the number of components isomorphic to \( F \).

**Lemma 18** Suppose that for any connectivity component \( F \) of a graph \( G \) we have

\[
c_F(G) + v(F) \leq t_1(G) + 1. \tag{26}
\]

Then \( D(G) = D_1(G) = t_1(G) + 2 \) unless \( G \) is an empty graph (when \( D(G) = D_0(G) = v(G) + 1 \)).

**Proof.** Assume that \( e(G) \neq 0 \).

The lower bound on \( D(G) \) follows by considering \( G' \) which is obtained from \( G \) by adding an isolated vertex. The graphs \( G \) and \( G' \) are isomorphic as far as non-isolated vertices are concerned. The best strategy for Spoiler is to pick \( t_1(G) + 1 \) isolated vertices in \( G' \) and, by making one more move in \( G \), to show that at least one of the Duplicator’s responses is not an isolated vertex.

On the other hand, let \( G' \neq G \). There must be a connected graph \( F \) such that \( c_F(G) \neq c_F(G') \), say \( c_F(G) < c_F(G') \). Spoiler picks one vertex from some \( c_F(G) + 1 \) \( F \)-components of \( G' \). If a
move $x$ of Duplicator falls into the same component of $G$ as some her previous move $y$, then
Spoiler switches to $G$ and begins claiming a contiguous path from $x$ to $y$; he wins in at most
$v(F)$ moves by either connecting $x$ to $y$ or by claiming a path of length $v(F) + 1$.

Otherwise, Duplicator must have selected a vertex inside a component $C$ of $G$ which is not
isomorphic to $F$. As soon as this happens, Spoiler wins by growing a connected set inside the
larger component of the two, in at most $v(F)$ moves.

The total number of moves does not exceed $(c_F(G) + 1) + v(F) \leq t_1(G) + 2$ (while we have only
one alternation), as required. ■

---

**Theorem 19** Let $\varepsilon > 0$ be fixed. Let $p = p(n) \leq (\alpha - \varepsilon)n^{-1}$, where $\alpha = 1.1918...$ is the (unique)
positive root of the equation
\[
e^{-\alpha + \alpha e^{-\alpha}} + 1 = e^{\alpha e^{-\alpha}}
\]
Then whp $G \in \mathcal{G}(n, p)$ satisfies the condition (26).

In this range, whp $D(G) = D_1(G) = (e^{-pn} + o(1))n$.

**Proof.** It is easy to compute the expectation of $t_k(G)$ for $G \in \mathcal{G}(n, p)$:
\[
\lambda_k = E[t_k] = \binom{n}{k} k^{-2} p^{k-1} q^{(n-k)+(k)-k+1}.
\]

Let $c = pn$. For a fixed $k$ we have $\lambda_k = (f_k + o(1))n$, where $f_k := \frac{e^{-k-2}}{k!e^k}$. We have
\[
\frac{f_{k+1}}{f_k} = ce^{-c} \times (1 + 1/k)^{k-2}.
\]

The first factor $ce^{-c}$ is at most $1/e$ (maximized for $c = 1$). Unexciting algebraic calculations
show that the second factor is monotone increasing for $k \geq 1$ and approaches $e$ in the limit.
This implies that the sequence $f_k$ is decreasing in $k$. (In particular, $f_1$ is strictly bigger than
any other $f_i$, $i \geq 2$.)

Also, $f_1 = e^{-c} > 0.3$ for $0 \leq c \leq \alpha$.

Theorem 5.7 in Bollobás [4] describes the structure of a typical $G$ for $p = O(n^{-1})$. In particular,
it implies that there is a constant $K$ such that whp at least $0.9n$ vertices of $G$ belong either
to tree components of orders at most $K$ or to the giant component. The giant component (for
$c > 1$) has order $(1 - \frac{c}{e} + o(1))n$, where $s$ is the only solution of $se^{-s} = ce^{-c}$ in the range
$0 < s \leq 1$. It is routine to see that $f_1 > 1 - \frac{c}{e}$. (In fact, $c = \alpha$ is the root of $f_1 = \frac{c}{e}$; this is
where $\alpha$ comes from.)

A theorem of Barbour [3] (Theorem 5.6 in [4]) implies that, for any $k \leq K$, we have whp
\[
|t_k(G) - \lambda_k| \leq o(n).
\]

Now, we have all the ingredients we need to check (26). Let $F \subset G$ be any connectivity
component. If $F$ is the giant component of $G$, then $c_F(G) = 1$ but, as we have seen, $v(F) \leq t_1(G)$
so (26) holds. So we can assume that $v(F) = o(n)$. If $v(F) > K$, then $c_F(G) + v(F) \leq \frac{0.1n}{K} + K <
On the other hand, the distribution of $t_1(G)$ if $F$ is a tree with $k \in [2, K]$ vertices, then (27) and the inequality $f_1 > f_k$ imply the required. Finally, it remains to assume that the component $F$ of order at most $K$ contains a cycle. But the expected number of such components is at most $\sum_{i=2}^{K} \binom{n}{i} p^i i^{-1} \binom{i}{2} = O(1)$. Markov’s inequality implies that whp no such $F$ violates (26).

Of course, the value of $t_1(G)$ can be estimated more precisely for some $p$ than we did in Theorem 19. Without going into much details, let us describe some of the cases here. Let $\omega$ be any function of $n$ which (arbitrarily slowly) tends to the infinity with $n$.

If $n^2 p \to 0$, then whp we have isolated vertices and edges only. The distribution of $t_2(G) = e(G)$ approaches the Poisson distribution $\mathcal{P}_\lambda_2$. Hence, we have whp that $n - \omega < D(G) \leq n + 1$.

Suppose that $n^2 p \not\to 0$ but $pn \to 0$. The expected number of vertices in components of order at least 3 is at most $n \binom{n}{2} 3p^2 = o(\lambda_2)$. By Markov’s inequality, whp we have $o(\lambda_2)$ such vertices.

On the other hand, the distribution of $t_2(G)$ is $o(1)$-close to $\mathcal{P}_\lambda_2$ (Theorem 5.1 in [4]). Hence,

$$\left| D(G) - n + \frac{\lambda_2}{2} \right| \leq o(\lambda_2) + \omega.$$ 

Observe that there is no phase transition in the behavior of $D(G)$ at $p \approx \frac{1}{n}$. This should not be surprising: $D(G)$ is determined by $t_1(G)$ in this range. We believe (but were not able to prove) that whp $D(G) = t_1(G) + 2$ for $p = O(n^{-1})$. To show this it is enough to define the giant component by a sentence of depth $o(n)$. In fact, we conjecture that a far stronger claim is true.

**Conjecture 20** Let $\frac{1+\epsilon}{n} < p = O(n^{-1})$. Then whp $D(F) = O(\ln n)$, where $F$ is the giant component of $G \in \mathcal{G}(n, p)$.

### 6 Modeling Arithmetics on Graphs

In this section we consider $D(G)$ for the random graph $G \in \mathcal{G}(n, p)$ where $p = n^{-1/4}$. We expect that our results would hold for $p = n^{-\alpha}$ for any rational $\alpha \in (0, 1)$, but this would require considerable technical work so we are content with this one case. In [20, Section 8] it was shown, for $\alpha = \frac{1}{3}$, that there was an arithmetization of certain sets that led to non-convergence and non-separability results. Our methods here will be similar.

**Theorem 21** Let $p = n^{-1/4}$ and $G \in \mathcal{G}(n, p)$. Then whp

$$D(G) = \Theta(\log^* n).$$

The lower bound is very general. We use only the trivial fact that any particular graph is the value of the random graph with probability $O(n^{-1})$. (Indeed, the value is exponentially small.) Let $F(k)$ be the number of first order sentences of depth at most $k$. Then $\Pr[D(G) \leq k] = O(F(k)n^{-1})$ as there are at most $F(k)$ such graphs. From general principles [20, Section 2.2] $F(k)$ is bounded effectively by the tower function so that if $k = c\log^* n$ with $c$ appropriately small $F(k) = o(n)$ and $\Pr[D(G) \leq k] = o(1)$. 

21
Now we turn to the main part, bounding \( D(G) \) from above. For any set \( W \) of vertices let \( N(W) \) denote the set of common neighbors of \( W \). When \( |W| = 4 \), \( \Pr[N(W) = \emptyset] = (1 - p^4)n^{-4} \approx e^{-1} \). We are guided by the idea that \( N(W) = \emptyset \) is like a random symmetric 4-ary predicate with probability \( e^{-1} \), which is bounded away from both zero and one.

Let \( W \) be a set of four vertices. Dependent only on \( W \) we define

- \( A = N(W) \), the common neighbors of \( W \);
- \( B \), consisting of those \( z \notin W \cup A \) such that \( z \) is adjacent to precisely four vertices of \( A \) and no other \( z' \notin W \cup A \) has exactly the same adjacencies to \( A \).

For \( w \notin W \cup A \) let \( H_w(A) \) denote the 3-regular hypergraph on \( A \) consisting of those triples \( T \) so that there is no \( z \notin W \cup A \) adjacent to \( T \cup \{w\} \). (The condition that \( z \notin W \cup A \) is a technical convenience that does not asymptotically affect the \( H_w(A) \).) If, further, \( a \in A \) we let \( H_{w,a}(A) \) denote the 2-regular hypergraph (i.e. graph) of pairs \( T \) with \( T \cup \{a\} \in H_w(A) \). Further, for distinct \( a, b \in A \) we let \( H_{w,a,b}(A) \) denote the 1-regular hypergraph (i.e. set) of elements \( y \) with \( \{a, b, y\} \in H_w(A) \). For \( w \notin W \cup A \cup B \) let \( H_w(B) \) denote the 3-regular hypergraph on \( B \) consisting of those triples \( T \) so that there is no \( z \notin W \cup A \cup B \) adjacent to \( T \cup \{w\} \). (Again, the condition \( z \notin W \cup A \cup B \) is a technical convenience.) Informally, the idea is that the \( H_w(A), H_w(B) \) act like random objects with probability \( e^{-1} \).

Call \( A \) universal if the \( H_v(A), v \notin W \cup A \), range over all 3-regular hypergraphs on \( A \). Call \( B \) splitting if the \( H_v(B), v \notin W \cup A \cup B \), are all different. As there are \( 2^{O(m^3)} \) 3-regular hypergraphs over an \( m \)-set a simple counting argument gives that if \( A \) is universal we must have \( |A| = O(\ln^{1/3} n) \) while if \( B \) is splitting we must have \( |B| = \Omega(\ln^{1/3} n) \).

Our argument splits into two lemmas.

**Lemma 22** Whp there exists a 4-set \( W \) such that, with \( A, B \) as defined above,

1. \( A \) is universal;
2. \( B \) is splitting.

**Lemma 23** Any graph \( G \) on \( n \) vertices with the property of Lemma 22 has \( D(G) = O(\log^* n) \).

Note that the proof of Lemma 22 is a random graph argument while the proof of Lemma 23 is a logic argument involving no probability.

**Proof of Lemma 22.** Set \( u = \lfloor \ln^{0.3} n \rfloor \). For any set \( W \) of four vertices

\[
\Pr[|N(W)| = u] = \Pr[\text{Bin}(n - 4, p^4) = u] \approx e^{-1}/u!.
\]

Thus the expected number \( \mu \) of such \( W \) has \( \mu \approx \frac{\binom{n}{4}}{4!}e^{-1}/u! \) which approaches infinity. An elementary second moment calculation gives that the number of such \( W \) is \((1 + o(1))\mu \) whp. Hence it suffices to show that the expected number of \( W \) with \( A \) having size \( u \) but \( A, B \) failing the conditions of Lemma 22 is \( o(\mu) \). Fix \( W \) and \( A \) of size \( u \). It suffices to show that \( A, B \) satisfy
Lemma 22 whp. The conditioning is only on the adjacencies involving a vertex of $W$, all other adjacencies remain random.

First we show that $A$ is universal. Let $Z$ be those vertices adjacent to four or more vertices of $A$. Let $Z'$ consist of vertices with at least one neighbor in $Z$. Whp every four vertices in the graph have $O(\ln n)$ common neighbors so $|Z|$ is polylog while $|Z'| = n^{3/4 + o(1)}$.

For each 3-set $Y \subset A$ let $N^-(Y)$ denote those $v \notin W \cup A \cup Z$ which are adjacent to all vertices of $Y$. The $|N^-(Y)|$ are independent, each with Binomial distribution Bin($n-o(n)$, $(1+o(1))n^{-3/4}$). The probability that $|N^-(Y)| > 2n^{1/4}$ or $|N^-(Y)| < \frac{1}{2^n}n^{1/4}$ is then less than $\exp(-cn^{1/4})$ for a constant $c$ by Chernoff bounds. We only need that this probability is $o(n^{-3})$. Thus with high probability for every 3-set $Y \subset A$ we have $|N^-(Y)| \in [\frac{1}{2^n}n^{1/4}, 2n^{1/4}]$. Condition on these $N^-(Y)$ satisfying these conditions. Let $R$ be the (remaining) vertices, not in $W, A, Z, Z'$ nor any of the $N^-(Y)$. For $z \in R$ the adjacencies to the $N^-(Y)$ are still random. For such $z$ we have $Y \in H_z(A)$ if and only if $z$ is adjacent to no vertex in $N^-(Y)$, (Note that $z$ does not send any edges to $Z$.) As $|N^-(Y)| \leq 2n^{1/4}$ the probability that $z$ is adjacent to no vertex of $N^-(Y)$ is at least $e^{-2}$. As $|N^-(Y)| \geq \frac{1}{2^n}n^{1/4}$ the probability that $z$ is adjacent to some vertex of $N^-(Y)$ is at least $1 - e^{-1/2}$. Set $\gamma = \min(e^{-2}, 1 - e^{-1/2})$. Then for any hypergraph $H$ on $A$ we have $\Pr[H_z(A) = H] \geq \gamma^{\binom{n}{3}}$. But these events are now independent over the $(1-o(1))n$ values $z \in R$ so that the probability that no $H_z(A) = H$ is less than $(1-\gamma^{\binom{n}{3}})^n$. Here because $u^3 = o(\ln n)$ this quantity is less than, say, $\exp(-n^{0.99})$. There are fewer than $2u^3$ hypergraphs $H$ on $A$. Hence the probability that any such $H$ is not one of the $H_z(A)$ is less than $2u^3\exp(-n^{0.99})$. The $2u^3$ term is basically negligible and the probability that $A$ is not universal is less than $\exp(-n^{0.98})$ and certainly $o(1)$. We note that $A$ being universal will not be fully needed in Lemma 23, we shall need only seven particular values of $H_z(A)$.

Now we look at the size of $B$. For each $z \notin A \cup W$ the probability that $z$ is adjacent to precisely four elements of $A$ is $\binom{n}{4} p^4 (1-p)^{u-4} \approx u^4 n^{-1}/24$ and given this the probability that no other $z'$ has the same adjacencies is approximately $(1-p^4)^n \approx e^{-1}$ so $B$ has expected size $\mu \approx u^4/24e$. A second moment calculation gives that whp $|B| \approx \mu = \Theta(\ln^{1.2} n)$.

Finally we show that $B$ is splitting. At this stage $W, A, B$ are fixed and all of the adjacencies that do not have at least one vertex from $W \cup A$ are random. Whp no $z \notin W \cup A \cup B$ is adjacent to five (or more) vertices of $B$. Let $Z$ be those $z \notin W \cup A \cup B$ adjacent to four vertices of $B$. Whp $|Z|$ is polylog.

For each 3-set $Y \subset B$ we let $N^*(Y)$ denote those $v \notin W \cup A \cup B$ which are adjacent to all vertices of $Y$ and $N^-(Y) = N^*(Y) - Z$. As before, whp all $|N^*(Y)|$ have size between $\frac{1}{2^n}n^{1/4}$ and $2n^{1/4}$ and so the same, asymptotically, holds for the $|N^-(Y)|$. As before we fix the $N^*(Y)$ and their adjacencies to $Y$. Consider distinct $u, u' \notin W \cup A \cup B$. The probability that either $u$ or $u'$ is adjacent to nine (or more) vertices of $Z$ is $o(n^{-2})$. Call a 3-set $Y \subset B$ exceptional if $u$ or $u'$ is adjacent to some $z \in Z$ which is adjacent to all of $Y$. With probability $1 - o(n^{-2})$ there are at most $2 \cdot 8 \cdot 4 = 64$ exceptional $Y$. Hence the number of nonexceptional $Y$ is $\approx \binom{B}{3}/9$. For the nonexceptional $Y$ we have $Y \in H_u(B)$ if and only if $u$ is adjacent to no vertex in $N^-(Y)$ and similarly for $Y \in H_w(B)$. Thus $\Pr[Y \in H_u(B)] \in [\gamma, 1 - \gamma]$ with $\gamma$ as previously defined. Further these events are independent over different nonexceptional $Y$. Set $\gamma^* = \gamma^2 + (1-\gamma)^2$. Then $H_u(B), H_w(B)$ agree on a nonexceptional $Y$ with probability at most $\gamma^*$. Independence gives that they agree on all nonexceptional $Y$ with probability at most $\gamma^*$ to the $\approx \binom{B}{3}$ power. As this power is $\gg \ln n$ the probability is certainly $o(n^{-2})$. There are $O(n^2)$ choices of $u, u'$ so whp no $H_u(B) = H_w(B)$.\[\square\]
Proof of Lemma 23. The main portion of the argument consists of placing an arithmetic structure on $A$ in such a way that any vertex in $A$ can be described with quantifier depth $O(\log^* |A|) = O(\log^* n)$. For convenience we assume $|A| = 3s + 2$. (Otherwise we would give the one or two extra elements of $A$ which would increase the depth by at most two.) Label the elements of $A$ by $a, b, x_1, \ldots, x_s, y_1, \ldots, y_s, z_1, \ldots, z_s$ in an arbitrary way. Now we, effectively, model arithmetic on $A$. From the universality there exist $w_1, \ldots, w_7$ (witnesses) such that

1. $H_{w_1}$ consists of the triples $\{x_i, y_i, z_i\}$
2. $H_{w_2,a,b}$ consists of the elements $x_i$
3. $H_{w_3,a,b}$ consists of the elements $y_i$
4. $H_{w_4,a}$ consists of all pairs $\{x_i, y_j\}$ with $i \leq j$
5. $H_{w_5}$ consists of all triples $\{x_i, y_j, z_{i+j}\}$ with $1 \leq i, j, i + j \leq s$
6. $H_{w_6}$ consists of all triples $\{x_i, y_j, z_{i-j}\}$ with $1 \leq i, j, i \cdot j \leq s$.
7. $H_{w_7,a}$ consists of all pairs $\{x_i, y_2i\}$ with $1 \leq i \leq s$ and $2^i \leq s$.

We give a first order expression in terms of the $v_1, v_2, v_3, v_4$ which define $A$ and the special elements $a, b \in A$ and the witnesses $w_1, \ldots, w_7$ which forces $A$ to have this form. Note that membership in $A$ is given by a first order statement and membership in an $H_w$ or $H_{w,a}$ or $H_{w,a,b}$ is given by a first order statement in terms of the variables. Let $A^- = A - \{a, b\}$ for convenience. Now we express the following six properties.

1. (1-Factor) $H_{w_1}$ consists of vertex disjoint triples and every element of $A^-$, and only those elements, are in such a triple.
2. (Splitting the 1-Factor) For each triple in $H_{w_1}$ exactly one of the elements is in $H_{w_2,a,b}$ and exactly one (a different one) is in $H_{w_3,a,b}$. Now let (for convenience) $X$ denote those $x \in A^-$ with $x \in H_{w_2,a,b}$ and let $Y$ denote those $y \in A^-$ with $y \in H_{w_3,a,b}$ and $Z$ the other elements of $A^-$. Henceforth the use of the letter $x, y, z$ shall tacitly assume that the element is in the respective set $X, Y, Z$. We write $x \sim y$ or $x \sim z$ or $y \sim z$ if the two elements are in a common triple in $H_{w_1}$.
3. (Creating $\leq$) Here adjacency is in $H_{w_4,a}$. We require that all adjacencies be between an $x$ and a $y$. Let $N(x)$ denote the $y$ adjacent to $x$. We require that for every $x, x'$ either $N(x) \subseteq N(x')$ or $N(x') \subseteq N(x)$ with equality only when $x = x'$. We require that when $y \sim x$ then $y \in N(x)$. This forces the $N(x)$ to form a chain and so the $x$ and $y$ can be renumbered to fit the condition. We now define $x \leq x'$ by $N(x') \subseteq N(x)$. The relations $\geq, >, \prec$ have their natural Boolean meaning in terms of $\leq$. We define $y \leq y'$ and $z \leq z'$ by $x \leq x'$ where $x \sim y \sim z$ and $x' \sim y' \sim z'$. We let $x_1, y_1, z_1$ denote the first elements under $\leq$ and $x_s, y_s, z_s$ the last elements. The notions of successor $x^+$ and predecessor $x^-$ are naturally defined (when they exist) in terms of $\leq$. We let $z_2$ denote the successor of $z_1$.
4. (Creating addition) Addition is generated from the formulas $\alpha + 1 = \alpha^+$ and $\alpha + \beta^+ = (\alpha + \beta)^+$, though we need some care as addition in this model is not always defined. For every $x \in X, y \in Y$ there is at most one $z \in Z$ with $\{x, y, z\} \in H_{w_5}, \{x_1, y_1, z_2\} \in H_{w_5}$.

24
For \( x \neq x_0 \), \( \{x, y_1, z\} \in H_{w_5} \) where \( z \sim x^+ \). If \( \{x, y, z\} \in H_{w_5} \) and \( y, z \) have successors then \( \{x, y^+, z^+\} \in H_{w_5} \). If \( \{x, y, z\} \in H_{w_5} \) and \( y, z \) have predecessors then \( \{x, y^-, z^-\} \in H_{w_5} \). We let \( x + x' = x^* \) denote that \( \{x, y^*, z^*\} \in H_{w_5} \) where \( y^* \sim x' \) and \( y^* \sim x^* \). Let \( x + z = z' \) mean that when \( z, z' \) are replaced by their \( \sim \) elements in \( x \) that we then have the equality, and similarly for other forms like \( y + y' = z \).

5. (Creating multiplication) Multiplication is generated from the formulas \( \alpha \cdot 1 = \alpha \) and \( \alpha \cdot \beta^+ = (\alpha \cdot \beta) + \beta \), though we need some care as addition in this model is not always defined. For every \( x \in X, y \in Y \) there is at most one \( z \in Z \) with \( \{x, y, z\} \in H_{w_5} \). \( \{x, y_1, z\} \in H_{w_5} \) precisely when \( x \sim z \). If \( \{x, y, z\} \in H_{w_5} \) and \( y \) has a successor then \( \{x, y^+, z^\prime\} \in H_{w_6} \) if and only if \( z^\prime = x + z \).

6. (Creating exponentiation) Base two exponentiation is defined by \( 2^1 = 2 \) and \( 2^{a^+} = 2^a + 2^a \), though we need some care as addition in this model is not always defined. For every \( x \in X \) there is at most one \( y \in Y \) with \( \{x, y\} \in H_{w_7, a} \). \( \{x_1, y_2\} \in H_{w_7, a} \). If \( \{x, y\} \in H_{w_7, a} \) then \( \{x^+, y^\prime\} \in H_{w_7, a} \) if and only if \( y = y' \). We write \( x' = 2^x \) if \( \{x, y'\} \in H_{w_7, a} \) and \( x' \sim y' \).

We can give the \( d \)-th binary digit of \( x \) (we count the first digit as the first on the right, zero if and only if \( x \) is even) for all \( x \in X \). The 1-st digit of \( x \) is zero if and only if \( x = x' + x' \) for some \( x' \). Otherwise the \( d \)-th digit is zero if and only if there exist \( q, r, x = q \cdot 2^d + r \) with \( r < 2^{d-1} \) or if \( x = q \cdot 2^d \) or if \( x < 2^{d-1} \). (This technical complication is caused by leaving zero out of the model.) This is first order as we already have multiplication, exponentiation, less than and addition.

Now any \( x \leq s \) is described with quantifier depth \( \Theta(\log^* s) \). Let \( x \) have \( m \) digits. We say that \( x \leq 2^m \) and the disjunction over \( d \leq m \) of the statements that the \( d \)-th binary digit is what it is. For each such \( d \) (and for \( m \)) we have to describe \( d \). But now we are describing numbers up to \( \log_2 s \) and so by an induction the total depth will be \( \Theta(\log^* s) \). This also includes describing the last element \( x_s \) so that we determine \( s \) with depth \( \Theta(\log^* s) \).

Now the elements \( v \) of \( B \) are described with depth \( \Theta(\log^* s) \) by describing the four vertices of \( A \) that \( v \) is adjacent to and saying that \( v \) is adjacent to no other vertices of \( A \) and that no other \( w \notin W \cup A \) has just those adjacencies to \( A \).

Finally any \( v \notin W \cup A \cup B \) is described in depth \( O(\log^* s) \) by listing the edges of \( H_v(B) \) and stating that no other \( v' \) produces the same hypergraph. The assumption \( B \) splitting means that we have described all the vertices.

7 Concluding Remarks

Our Theorem 2 has a strong link with the zero-one law which was discovered independently by Glebskii et al [10] and Fagin [8] and says that \( G \in \mathcal{G}(n, \frac{1}{2}) \) satisfies any fixed first order sentence with probability approaching either 0 or 1. Given \( \epsilon \in (0, 1) \), define \( T_\epsilon(n) \) to be the maximum \( k \) such that, if \( n_1, n_2 \geq n \), then \( D(G, H) > k \) with probability at least \( 1 - \epsilon \) for independent \( G \in \mathcal{G}(n_1, p) \) and \( H \in \mathcal{G}(n_2, p) \). The Bridge Theorem [20, Theorem 2.5.1] says that, in a rather general setting, a zero-one law is obeyed iff, for each \( \epsilon, T_\epsilon(n) \) tends to the infinity as \( n \) increases. Spencer and St. John [21] call \( T_\epsilon(n) \) the tenacity function and suggest it as a quantitative measure for observation of a zero-one law. While in [21] the tenacity function
is studied for words, here we are able to find its asymptotics in the case of graphs. Since the lower bound based on the $k$-extension property goes through for $D(G,H)$ with both $G$ and $H$ random, we have $T_\epsilon(n) = \log_{1/p} n + O(\ln \ln n)$, irrespective of the constant $\epsilon$.

Another interesting first order parameter of a graph $G$ is $I(G)$, the smallest depth of a sentence distinguishing $G$ from any non-isomorphic graph of the same order as $G$. Of course, $I(G) \leq D(G)$, so all upper bounds we have proved apply to $I(G)$ as well. All our lower bounds also apply to $I(G)$ with the exceptions of Theorem 19. Its $I(G)$-analogue would say that, for $G \in \mathcal{G}(n, \frac{c}{n})$ with $c < c_0$, where $c_0 = 1.034...$, we have

$$I(G) = (1 + o(1)) t_2(G) = (ce^{-2c}/2 + o(1)) n,$$

where $t_2(G)$ denotes the number of isolated edges. The reason is that if $G \not\cong G'$ but $v(G) = v(G')$, then the multiplicities of at least two non-isomorphic components must differ while the two most frequent components in $G$ are isolated vertices and edges. (And the order of the giant component catches up with $t_2(G)$ at $p \approx \frac{c_0}{n}$.)

We make the following general conjecture.

**Conjecture 24** Let $\epsilon > 0$ be fixed and $n^{-1+\epsilon} \leq p \leq \frac{1}{2}$. Then whp $D(G) = O(\ln n)$.

One can also ask about $D_\#$, the analog of $D(G)$ when we add counting to first order logic. Here, the situation is strikingly different. A result of Babai and Kučera [2] (combined with Immerman and Lander’s [11] logical characterization of the vertex refinement step in [2]) implies that whp $G \in \mathcal{G}(n, \frac{1}{3})$ can be defined by a first order sentence with counting of quantifier depth at most 4.
