Brief Report

An automated DIY framework for experimental evolution of *Pseudomonas putida*

Summary

Adaptive laboratory evolution (ALE) is a general and effective strategy for optimizing the design of engineered genetic circuits and upgrading metabolic phenotypes. However, the specific characteristics of each microorganism typically ask for exclusive conditions that need to be adjusted to the biological chassis at stake. In this work, we have adopted a do-it-yourself (DIY) approach to implement a flexible and automated framework for performing ALE experiments with the environmental bacterium and metabolic engineering platform *Pseudomonas putida*. The setup includes a dual-chamber semi-continuous log-phase bioreactor design combined with an anti-biofilm layout to manage specific traits of this bacterium in long-term cultivation experiments. As a way of validation, the prototype was instrumental for selecting fast-growing variants of a *P. putida* strain engineered to metabolize D-xylose as sole carbon and energy source after running an automated 42 days protocol of iterative regrowth. Several genomic changes were identified in the evolved population that pinpointed the role of RNA polymerase in controlling overall physiological conditions during metabolism of the new carbon source.

Introduction

The development of do-it-yourself (DIY) technical solutions (Moe-Behrens *et al.*, 2013; de Lorenzo and Schmidt, 2017) for performing adaptive laboratory evolution (ALE) experiments (Portnoy *et al.*, 2011; Dragosits and Mattanovich, 2013; LaCroix *et al.*, 2017) is expanding the capabilities of researchers to integrate this attractive technique in their regular laboratory workflows. Some examples include the development of automatic microbial cultivation platforms operating mini-chemostats (Amanullah *et al.*, 2010; Bergenholm *et al.*, 2019), turbidostats (Marlière *et al.*, 2011; Wong *et al.*, 2018; McGeechey *et al.*, 2019) or segregostats (Sassi *et al.*, 2019). Yet, in any circumstance ALE experiments have to be designed taking into account the biological constraints of the evolving microbe and the target to achieve. One of such microorganisms of interest is the soil bacterium *Pseudomonas putida* (in particular strain KT2440) which, because of its distinct management of oxidative stress, has emerged as a prime host of engineered redox reactions (Nikel *et al.*, 2014, 2016; Nikel and de Lorenzo, 2018). On this background, we set out to design and implement a DIY framework specifically developed for applying flexible ALE protocols to this bacterium for the sake of increasing its performance as whole-cell catalyst.

The construction details and every step of the implementation of the evolutionary device are fully disclosed in the Supplementary Information (Materials, Equipment and other procedural features: see Figs S1–S25 and Tables S1–S3). The reader is encouraged to access such accompanying particulars for a more complete comprehension of the technical solution hereby presented. The experimental setup was inspired in the turbidostat scheme proposed by Marlière *et al.* (2011) but was redesigned considering a number of constrains...
linked to the intrinsic biological features of the KT2440 strain of *P. putida*. One first consideration is that the specimen of interest belongs to a bacterial species that naturally sticks to surfaces and builds considerable amounts of biofilms (Auerbach et al., 2000; Espinosa-Urgel et al., 2000; Tolkner-Nielsen et al., 2000; Espeso et al., 2018). Biofilm formation is operationally problematic, because it clogs culture conduits and selects for surface super-sticker variants. A second constraint is that *P. putida* KT2440 is strictly aerobic (Nikel and de Lorenzo, 2013; Kampers et al., 2019), and proper aeration is required to ensure culture viability and vitality during the long-term experiment. Furthermore, the evolutionary platform must ensure isolation of the manipulated culture to avoid contamination by microorganisms that may displace the template strain. Finally, growth media quality should be secured at all times for maximizing cell division and foster DNA replication – thereby increasing chances of mutations.

With these criteria in mind, an experimental setup was designed and assembled to execute a basic protocol for sustaining bacterial growth for long periods of time. Figure 1A shows the thereby implemented workflow process as a block diagram. The sketch illustrates a recurrent cycle in which a semi-continuous incubation of a culture is executed by a period of time defined by the user. The protocol included a control loop in the reactor incubation step (blue box) where the workflow was stalled in a periodic subroutine of incubation steps followed by optical density measurements at regular intervals (t_{sampling}). Such a recurrent sequence ended when an upper threshold OD_{600} value was reached, allowing the workflow in this manner to keep advancing. Figure 1B shows the fluidic layout implemented for succeeding with this protocol. The basic setup includes (i) a bioreactor coupled to a photodetector to obtain OD_{600} readings, (ii) an auxiliary chamber to allow biofilm cleaning with NaOH and H_{2}O, (iii) a rack of pumps to deliver the different chemicals and (iv) a group of valves to set the logic of the liquid transport through the circuit. The tubing is connected in a circular fashion with two independent waste outputs and venting connections to ensure an uninterrupted cell culture with sufficient aeration. The design was complemented with electronic and control layers, consistently designed to make possible the synchronized actuation of all these devices (Figs S1–S15). Additionally, this basic arrangement was complemented with the manufacturing of 3D-printed supports to spatially arrange pumps and valves (Figs S16–S18) and the assembly of an online optical density chamber to gather OD_{600} lectures (Figs. S19–S25).

To test the efficacy of the thereby constructed DIY platform, we used a derivative of *P. putida* KT2440 that had been engineered to grow on D-xylose, a pentose abundant in hydrolysates of lignocellulosic materials (Chen et al., 2017). The construct at stake (named *P. putida* mk-1, Table S3) bears a large number of genomic modifications for increasing stability, raising the intracellular levels of ATP and NAD(P)H (Martínez-García et al., 2014a,b) and avoiding misrouting of intermediates during D-xylose metabolism. Specifically, *P. putida* mk-1 lacks flagella and other energy-draining cellular devices and has a deletion of *gcd* (thereby lacking glucose dehydrogenase). In addition, the strain bears a chromosomal implant of a synthetic xylABE operon encoding XylA (xylose isomerase), XylB (xylulokinase) and XylE (xylose-proton symporter) from *Escherichia coli* (Dvorák and de Lorenzo, 2018). To this end, the DNA segment bearing xylABE was assembled in a mini-Tn5 transposon vector (Martínez-García et al., 2014a,b) as described in the Supplementary information. During the construction of the test strain, the mobile element mini-Tn5 Sm::[PEM7 \rightarrow xylABE] was randomly inserted throughout the genome of strain *P. putida* EM42 Δgcd (Table S3). The organization of the mini-Tn5 transposon was such that the xylABE operon could be expressed from the synthetic PEM7 promoter engineered in the mobile element as well as from readthrough transcription of nearby promoters close to the site of insertion.

Selection of the best grower clone on D-xylose as sole carbon source yielded the aforementioned strain *P. putida* mk-1 with the business DNA segment inserted in the midst of the locus PP_2260 (a putative glycerol-phosphate ABC transporter ATP-binding protein; Fig. 2C). Whether there was a benefit in the interruption of that ORF is unknown, but insertion of the DNA segment with [PEM7 \rightarrow xylABE] in the chromosome secured the stable inheritance of the knocked-in trait during the course of the bioreactor experiment (Fig. 2A).

Next, strain *P. putida* mk-1 was inoculated in an intermediate reactor chamber with an operative volume of 20 ml and containing around 10^9 cultivated cells with an OD_{600} bounded within the range [0.1–0.5]. During a 45 days period, cells were recurrently incubated and diluted (Fig 2A) using M9 minimal medium supplemented with 0.2% (w/v) D-xylose and 60 μg ml^{-1} streptomycin. Under these simple conditions, the setup selects for faster growers which – in case of appearance – should bear mutations that increase overall physiological fitness and/or improve nesting of the implanted metabolic segment in the background biochemical network of *P. putida*. The progress of the experiment is shown in Figure 2A. At the end of the corresponding period of time, an increase in growth rate of the population present in the culture became clearly noticeable, same as the fact that beneficial changes occurred probably mainly during the initial phase of the experiment (Fig. 2A, Fig. S26). To examine the basis of such a change,
samples were collected from the reactor and further inspected. First, the evolved sample (hereafter called mk-2) was verified as an authentic descendant of the original strain. For this, the mk-2 sample was plated on LB and M9 + 0.2% (w/v) citrate agar dishes and cells were streaked out to discard any contamination. Strain clonal identity was confirmed through PCR of the genome with primers 5ʹCTTCAGCTCTTCGCTGTACA3ʹ and 5ʹGCGTGCGCTACAACCTTAC3ʹ that amplify the region surrounding the deletion of the glucose dehydrogenase gene (PP_1444) present in the template strain and which acted as a diagnostic signature. Second, the growth rate of the evolved culture on D-xylose as the only C source was re-assessed in respect to the precursor strain performing independent growth curve assays in Erlenmeyer flasks. Regression slopes comparing the two (Fig. 2B) indicated that the evolved specimen grew a 60% faster than template strain. Finally, the genomes of the original P. putida mk-1 strain and the evolved counterpart mk-2 were sequenced to find mutations that could account for the observed shift in the growth phenotype.

While no modifications became apparent in the bacteria of reference, the faster-growing derivative bore 3 conspicuous changes in its chromosome. The first modification of the evolved genome was found in the rpoC gene of P. putida, which encodes the β subunit of RNA polymerase. The rpoC gene of mk-2 had a point mutation C → T in codon 51 (cCt → cTt) causing a quite drastic change Pro51Leu. The emergence of this modification acted in fact as a descriptor of the efficacy of the evolutionary experiment. This is because a large number of rpoC mutations have been reported in the course of laboratory evolution studies aiming to increase E. coli growth rate (Cheng et al., 2014; Wytock et al., 2018; Kavvas et al., 2020). Therefore, the
Pro51Leu change plausibly reflects a similar adaptation in *P. putida*. The other two mutations were identified in the implanted xylose cluster. One of them involved a single base change G → T in the codon 33 of the *xylE* gene (gGt → gTt) which translates into a Gly33Val amino acid change. The *xylE* product is a xylose-proton symporter of *E. coli* composed by several transmembrane domains connected by periplasmic/cytoplasmic amino acid stretches (Davis and Henderson, 1987), and Gly33 is located in a periplasmic side close to the H⁺ coupling site Asp27 (Madej et al., 2014). While a number of loss-of-function mutations have been reported for *xylE* (Sun et al., 2012), to the best of our knowledge no changes are known to enhance xylose transport. The Gly 33Val observed in mk-2 could be one of them, an issue that deserves further studies. Finally, a 13-bp deletion removing part of the *P*<sub>EM7</sub> box was observed also in the faster-growing culture. As mentioned above, *P*<sub>EM7</sub> sequence features –35 and –10 boxes in high case and underlined text, while deletion found in mk-2 genome appears underlined in red colour. Single nucleotide changes found in *rpoC* and *xylE* appear in brackets: wild type and mutated codon are depicted with mutated site in high case. The amino acid change and position in the polypeptide are also shown below.

The loss of part of the –10 box (Collado-Vides et al., 1991; Meyesman et al., 2014) is expected to reduce the promoter activity in the mk-2 cells. Selective pressure to curb $P_{EM7}$ strength might be related to the fact that overproduction of the XylE transporter is toxic to P. putida cells (unpublished data). The coexistence in mk-2 of mutations anticipated to both decrease xylE transcription and improve XylE efficiency could reflect a solution to the conflict between the negative effects of overproducing a membrane protein and the need to secure a sufficient inflow of the carbon source for a faster growth. Note that – as discussed above – even complete elimination of the $P_{EM7}$ promoter of the genomic implant [$P_{EM7} \rightarrow xyLAE$] could still deliver expression of the operon owing to readthrough transcription from promoter(s) outside the mini-Tn5 insertion (Fig. 2C).

Whether the effects of these three mutations found in the evolved, faster-growing sample are additive, synergistic or altogether independent is beyond the scope of this technical note and will be the subject of subsequent studies. Correspondingly, further rational engineering cuts and ALE with the constructed system are being considered to remove additional metabolic bottleneck(s) that could have prevented achieving even faster growth of P. putida recombinant on the non-native substrate during the evolution experiment (Elmore et al., 2020). Yet, the data presented above accredits the power of the simple and affordable DIY setup described here to generate phenotypes of considerable biotechnological interest in the synthetic biology chassis and metabolic engineering platform Pseudomonas putida. Besides the enhancement of catabolic traits, the authors foresee the use of the bespoke device also for the evolution of biosynthetic pathways in P. putida and other bacterial cell factories. As additional modules, e.g., for absorbance or fluorescence quantification, can be easily integrated into the presented setup, we entertain the use of this framework also for the accelerated evolution of industrially relevant strains equipped with genetically encoded product-responsive biosensors (Mahr et al., 2015).

**Fig. S7.** Switch PCB blueprint. Small pin boxes correspond to actuator KK254 switches, which are connected to 16-pin compacted pin headers host male IDC connectors in charge of linking the board with MOSFET input pins. Real size is 150 x 100 mm. Hole pitch is 2.54 mm. Red and blue lines depict tracks printed in the front and bottom of the PCB, respectively.

**Fig. S8.** Fuse PCB blueprint. Small pin boxes correspond to actuator KK254 switches. Resettable fuse is soldered in the rounded pinholes. PCB size is 35.5 x 12.7 mm. Hole pitch is 2.54 mm. Blue lines depict tracks printed in the bottom of the PCB.

**Fig. S9.** FT232H PCB blueprint. Small pin boxes correspond to actuator KK254 switches. Rounded pinholes are used to solder straight PCB sockets that allow a removable connection with FT232H. D0 and D1 labels define the orientation of the chip. PCB size is 60 x 40 mm. Hole pitch is 2.54 mm. Blue lines depict tracks printed in the bottom of the PCB.

**Fig. S10.** Power board PCB blueprint. Small pin boxes correspond to actuator KK254 switches. Large square labeled as “12V DC IN” is designed to assemble a 4-way MOLEX mini-fit switch used to host 12V ATX terminals (typically found in PC power supplies). Additional through holes are available to add a 47 µF and 100 nF condenser to reduce noise coming from the power supply. PCB size is 50 x 20 mm. Hole pitch for KK254 switches is 2.54 mm, and 4.2 mm for MOLEX mini-fit. Blue lines depict tracks printed in the bottom of the PCB.

**Fig. S11.** Relay board PCB blueprint. Small pin boxes correspond to actuator KK254 switches. Large square labeled is designed to assemble a 12VDC SPDT Relay used to activate or deactivate the air compressor unit, which works at 120/220 VAC. A diode (see arrow) should be used to damp current oscillations when switching ON/OFF the relay. PCB size is 60 x 20 mm. Hole pitch for KK254 switches is 2.54 mm. Blue lines depict tracks printed in the bottom of the PCB.

**Fig. S12.** Images of the assembled device. (A) General overview; (B) Electronic and Control layer; (C) Fluidic layer.

**Fig. S13.** Schematic representation of wiring and connector diagram. Each component of the device is connected with a labeled wire. Each wire has a wire type and two terminals that use different connectors.

**Fig. S14.** Example of coding structuring model used to program the Arduino card. Complex high-level instructions are divided in simpler actions using a cascading decomposition. The codification is then implemented by aggregating these point actions into functions, tested before being used, and then taken as blocks to create more complex routines. This methodology allows minimizing the debugging step and makes easier the code comprehension.

**Fig. S15.** Schematic representation of code structure used to program the Arduino. First an assignation of pins to physical actuators is performed. Next variables used to control the logic of the flow (times to wait, values of OD600, etc.) are included in the code. Then functions in charge of executing operations of increasing complexity to the fluid are defined one by one. Finally, the execution loop calls the highest-level functions to recurrently apply the required physical actions planned in the cyclic operation to be performed.
