(Received 24 February 2021; accepted 9 July 2021; published 11 August 2021)

We perform numerical simulations of gravitational waves (GWs) induced by hydrodynamic and hydromagnetic turbulent sources that might have been present at cosmological quantum chromodynamic (QCD) phase transitions. For turbulent energies of about 4% of the radiation energy density, the typical scale of such motions may have been a sizable fraction of the Hubble scale at that time. The resulting GWs are found to have an energy fraction of about $10^{-9}$ of the critical energy density in the nHz range today and may already have been observed by the NANOGrav Collaboration. This is further made possible by our findings of shallower spectra proportional to the square root of the frequency for nonhelical hydromagnetic turbulence. This implies more power at low frequencies than for the steeper spectra previously anticipated. The behavior toward higher frequencies depends strongly on the nature of the turbulence. For vortical hydrodynamic and hydromagnetic turbulence, there is a sharp drop of spectral GW energy by up to five orders of magnitude in the presence of helicity, and somewhat less in the absence of helicity. For acoustic hydrodynamic turbulence, the sharp drop is replaced by a power law decay, albeit with a rather steep slope. Our study supports earlier findings of a quadratic scaling of the GW energy with the magnetic energy of the turbulence and inverse quadratic scaling with the peak frequency, which leads to larger GW energies under QCD conditions.

I. INTRODUCTION

Gravitational wave (GW) astronomy opens a new window to study the physical processes in the early Universe. Relic GWs can be sourced by violent processes such as cosmological phase transitions and after their generation they propagate almost freely throughout the expansion of the Universe that causes the dilution of their strain amplitude and frequency (see Refs. [1–5] for pioneering works and Ref. [6] for a review and references therein). On the other hand, the detection of these relic GWs is a challenging task due to their small amplitudes, the specific range of the characteristic frequencies, and astrophysical foregrounds [7]. Despite tremendous advancements in GW detection techniques, the stochastic GW background of cosmological origin remained unobserved.

Recently, the NANOGrav Collaboration reported strong evidence for a stochastic GW background [8]. In addition to the possibility of GWs induced by astrophysical sources such as supermassive black holes, the NANOGrav data can also be understood as a possible signal from the early universe, such as inflationary GWs [9–14], cosmic strings and domain walls [15–20],1 inhomogeneous neutrino plasma [22,23], phase transitions including the supercooled phase transitions [24], dark phase transitions [25,26], quantum chromodynamic (QCD) with axionic string network, and QCD axion [27–30], and/or magnetic fields [31] and turbulence [32]. In fact, the observed 45 pulsars from the NANOGrav 12.5 year dataset were used to search for cosmological first order phase transitions that occur below the electroweak energy scale [33] and might require physics beyond the standard model. However, since there is a degeneracy with the supermassive black hole signal, distinguishing cosmological sources from the astrophysical

1Some tension between NANOGrav limits and Parkes PTA (PPTA) has been discussed in Ref. [21].
ones is a complex task [7,34] that can be accomplished through different observational data cross correlations [35].

The most promising is astrometric data from current and nearest future missions [36]. Interestingly, the search of GWs through astrometry includes polarization state measurements [37], and correspondingly to constrain nonstandard models of gravity [38].

In this paper we present a self-consistent study of the GWs from turbulent sources possibly present at QCD phase transitions. We extend the work of Ref. [31] by considering a range of typical length scales of the turbulent motions. Such turbulent sources might be driven not just by magnetic fields [39–46], but could include other turbulent sources at the QCD energy scale such as the aforementioned combined effect of QCD axions and magnetic fields [28].

We also investigate the dependence of spectral amplitude and shape on the number of eddies (around 100 at electroweak phase transitions and 5–6 at the QCD phase transitions) within a linear Hubble scale.

As we show, this dependence might be crucial when considering the shape of the GW spectra at low frequencies, as well as the resulting GW energy density strength. Even if primordial fields are not dynamically strong, turbulence can still develop at QCD energy scales [39,47–52]; the latent heat they release still gives rise to pressure gradients resulting in macroscopic plasma motions. Given the very high Reynolds number of the primordial plasma [53], such motions will inevitably decay into turbulence [39,52]. As already alluded to above, particularly important for our work is the earlier finding that the separation and size of nucleation bubbles in a QCD phase transition is a sizeable fraction of the Hubble scale (see Refs. [54,55] for pioneering works and follow-up papers [56–66]). Furthermore, the assumption of turbulence being driven by magnetic fields, allows us to avoid the requirement of first-order QCD phase transitions [52].

The paper is organized as follows. We first review basic properties of relic GWs (Sec. II), discuss then the NANOGrav observations (Sec. III), present our numerical approach (Sec. IV) and results (Sec. V) of our simulations, before concluding in Sec. VI. Throughout the paper, we use natural units with $\hbar = c = k_B = 1$. We also set the permeability of free space to unity, i.e., $\mu_0 = 1$, expressing the electromagnetic quantities in Lorentz-Heaviside units. The Latin indices run $i \in (1,2,3)$ and define the spatial coordinates, and the Greek indices run $\lambda \in (0,1,2,3)$. We choose the metric signature as $(-1,1,1,1)$.

II. THE EARLY-UNIVERSE GRAVITATIONAL WAVE SIGNAL

GWs correspond to the tensor mode of perturbations $\delta \tilde{g}_{\mu \nu}$ above the spatially flat, homogeneous, and isotropic Friedmann-Lemaître-Robertson-Walker (FLRW) background, in the transverse-traceless (TT) gauge defined through the spatial component $h_{ij}^{\text{phys}}$ with $a^2 h_{ij}^{\text{phys}} = \Lambda_{ijlm} \delta g_{lm}$, where $a$ is the scale factor at the physical time $t_{\text{phys}}$. Here and below, super/subscript “phys” denotes physical quantities.

In order to eliminate the expansion-induced dilution from the governing hydromagnetic equations, we use rescaled quantities together with the conformal time $\tau$, defined through $dt = dt_{\text{phys}}/a$, which reduces the metric tensor to the Minkowski form. The background expansion of the Universe during the radiation-dominated epoch is governed by the (dominant) radiation energy density $\varepsilon_{\text{rad}} = \pi^2 g(T)T^4/30$, where $g(T)$ is the effective number of relativistic degrees of freedom at temperature $T$. In the epoch(s) of interest, the expansion of the Universe is fully governed by radiation, and the Hubble parameter $H = a^{-1} da/dt_{\text{phys}} = a^{-2} da/dt$ is given through $H^2(t) = (8\pi G/3)\varepsilon_{\text{rad}}(t)$, where $G$ is Newton’s gravitational constant and $\varepsilon_{\text{rad}}(t)$ denotes the total energy density of radiation (including all relativistic components).

In order to connect physical and comoving variables and to determine the scaling of physical quantities, we compute the ratio of the scale factor today, $a_0 = a(t_0)$ (here and below, “0” denotes the present moment), to that at the time $t_s$ (at the temperature $T_s$ at which the source becomes active and the gravitational signal is generated) corresponding to the start of the simulation. We assume the adiabatic expansion of the Universe, such that $g_s(T)/T^3 a_s(T)$ is constant, where $g_s(T)$ is the number of adiabatic degrees of freedom at temperature $T$. At high enough temperatures ($T > 1$ MeV), we have $g_s(T) = g(T)$ [68]. Note, that our consideration below is valid for any time period during the radiation dominated epoch. However, we will be focused on the time period around the QCD energy scale (150 MeV). We also normalize the scale factor $a_s = a(t_s) = 1$, which differs from the usual convention $a_0 = 1$. Entropy conservation leads to

$$a_0/a_s = 10^{12} \left(g_s(T_s)/15 \right)^{1/3} \left(T_s/150 \text{ MeV}\right),$$

where we have used $T_0 = 2.73$ K and $g_s(T_0) = 3.91$, while at the QCD energy scale we have $g_s(T_s) \approx 15$ [68]. The degrees of freedom at QCD is approximate due to uncertainty in the exact temperature of the QCD transition and knowledge of the standard model (see discussions in

---

2The TT gauge is determined by the TT projection tensor $\Lambda_{ijkl} = P_{ij} P_{kl} - \frac{1}{2} P_{ij} P_{kl}$, where the $P_{ij}$ is a transverse operator $(\partial_i P_{ij} = 0)$, defined as $P_{ij} = \delta_{ij} - \partial_i \partial_j / \nabla^2$, where $\delta_{ij}$ is the Kronecker delta, $\partial_i \equiv \partial / \partial x^i$ denotes the partial derivative in respect of $x^i$ coordinate, and $\nabla$ defines the vector differential operator with the components equal to $\nabla_i \equiv \partial_i$, i.e., $\nabla^2$ is the Laplacian in respect of spatial coordinates; for more details see Chapter 1 (1.2) of [67]).
The GW equation in physical time and space coordinates is given by

\[
(\partial^2_{t_{\text{phys}}} + 3H \partial_{t_{\text{phys}}}) h_{ij}^{\text{phys}} - \nabla^2 h_{ij}^{\text{phys}} = 16\pi G T_{ij}^{\text{TT}} \text{phys},
\]

where the TT superscript denotes the TT projection of the stress-energy tensor such that \(T_{ij}^{\text{TT}} = \Lambda_{ijm} T_{lm}^{\text{phys}}\).

To make the connection with observations, we define the characteristic strain, \(h_c(t)\), which obeys \(h_c^2(t) = \langle (h_{ij}^{\text{phys}}(x,t))^2 \rangle/2\), where angle brackets denote volume averaging in physical space, and the physical energy density \(\varepsilon_{\text{GW}}^{\text{phys}}(t)\) carried by the GWs is given by [67]

\[
\varepsilon_{\text{GW}}^{\text{phys}}(t) = \frac{1}{32\pi G} \langle (\partial_{t_{\text{phys}}} h_{ij}^{\text{phys}}(x,t))^2 \rangle.
\]

It is then expressed in terms of today’s frequency \(f = k/(2\pi a_0)\) that corresponds to the time Fourier transform \(Q(t) = \int_0^\infty df Q(f) e^{-2\pi ift}\) and \(Q(f) = 2\pi \int_0^\infty dt Q(t) e^{-2\pi ift} [67]\).

The relic GW signal strength today is given through the normalized GW energy density parameter \(\varepsilon_\ast\) reduced by the factor \((H_*/H_0)^2(a_*/a_0)^4\), where \(H_*\) is the Hubble parameter at \(t_*\). This accounts for the dilution of the GW energy density parameter with the expansion of the Universe and renormalizes the GW energy density by the critical energy density at the present time, \(\varepsilon_\text{crit} = (3H_0^2)/(8\pi G)\), where \(H_0 = 100h_0\ \text{km s}^{-1}\text{Mpc}^{-1} \approx 3.241 \times 10^{-18} h_0^{-1} \text{s}^{-1}\) is the present value of the Hubble parameter. A frequency of particular interest is the frequency \(f_*\) corresponding to the Hubble horizon scale at \(t_*\)

\[
f_* = \frac{a_* H_*}{a_0} \approx (1.8 \times 10^{-8} \text{ Hz}) \left(\frac{g_*}{15}\right)^{1/6} \left(\frac{T_*}{150 \text{ MeV}}\right).
\]

As discussed above, there are a variety of possible sources of a stochastic GW background in the nHz frequency range, accessible to Pulsar Timing Arrays (PTAs), see Refs. [70,71]; see Sec. III for more details and Ref. [72] for a review and references therein, and these sources include a cosmic population of supermassive black hole binaries (SMBHBs) [72,73], cosmic strings [74–76], inflationary GWs [9,77], any anisotropic stress possibly present in the early universe [81] and phase transitions in the early Universe (around the QCD energy scale) and phase transitions in the early Universe (around the QCD energy scale) for example, see e.g., [3,28,50,82–87]. We also present upper limits on the relic (prior to recombination) GW background strength based on big bang nucleosynthesis (BBN) and the cosmic microwave background (CMB), as well as theoretically estimated strength and characteristic frequencies for different sources (see Sec. V). The estimated characteristic frequency and wave number of GWs are related to each other through \(2\pi f = k\), and can be expressed in terms of the characteristics (length and time scales) of the source. In particular, if we assume that GWs could be sourced by bubble collisions at a phase transition, we expect the frequency of the GWs to be related to the bubble size. We consider that the bubble length scale is the Hubble horizon \(H_*\) at generation divided by the total number of phase transition bubbles \(N_b\). Then, for the QCD phase transitions, the frequency is given by

\[
f_* \approx (1.1 \times 10^{-7} \text{ Hz}) \left(\frac{g_*}{15}\right)^{1/6} \left(\frac{T_*}{150 \text{ MeV}}\right) \left(\frac{N_b}{6}\right),
\]

where we have normalized to six bubbles expected at the QCD phase transition [64]. This argument applies to the case of a first order QCD phase transition. Alternatively, it has been proposed to explain the stochastic GW background from magnetogenesis [88] in low energy scale reheating around the QCD epoch [89]. In addition, through the axion-driven turbulence generation scenario [52], a first-order phase transition is not required and the number of eddies or bubbles (\(N_b\)) defines the size of the largest turbulent eddy that was excited through the axion-driven mechanism. We present our result without specifying the number of bubbles, noticing that more detailed consideration is required to determine the axion-driven turbulence characteristics, which is beyond the scope of the current paper.

### III. NANOGRAV DATA

A pulsar is a highly magnetized and rapidly rotating neutron star that emits a beam of electromagnetic radiation along its magnetic axis [90]. The times of arrival (TOA) of these pulses are extremely regular and can be predicted very accurately over long times [91]. The presence of a GW passing between the observer and pulsar shifts the pulse TOA proportional to the amplitude of the GW [92]. By monitoring the fluctuations in the TOA of radio pulses from millisecond pulsars (see e.g., for a review Ref. [93] and references therein, and for identifying noise sources in PTA see Ref. [94] and references therein) international PTA missions aim to probe a stochastic GW background.

The maximum sensitivity of a PTA experiment is limited by the total observation time. That is, the lowest detectable frequency is on the order of the inverse of the time span of the data (e.g., \(\sim \text{nHz}\) for datasets spanning \(\sim 10\) years) [96]. Furthermore, data sampling (i.e., pulsars are usually observed on the order of weeks [92]) limits the maximum

---

3The quantum mechanical fluctuations during the inflationary epoch induces GWs via parametric resonance [78–80].

---

4The International Pulsar Timing Array (IPTA) is a consortium of consortia, comprised of the European Pulsar Timing Array (EPTA), the North American Nanohertz Observatory for Gravitational Waves (NANOGrav), and the Parkes Pulsar Timing Array (PPTA) [95].
detectable frequency. The NANOGrav 12.5-year data set is sensitive to GW frequencies between approximately 2.5 nHz and 1 μHz [97].

PTA measurements typically characterize a stochastic GW background in terms of its characteristic strain spectrum \( h_c(f) \) fitted with a power-law dependence on frequency \([8]\),
\[
h_c(f) = A_{\text{CP}} \left( \frac{f}{f_{\text{yr}}} \right)^{\alpha_{\text{CP}}},
\]
where the subscript “\( \text{CP} \)” denotes a common-spectrum (CP) process (common to the observed pulsars), the spectral index \( \alpha_{\text{CP}} \) depends on the source of the stochastic GW background, and \( A_{\text{CP}} \) is the strain amplitude at a reference frequency of \( f_{\text{yr}} = 1 \) yr\(^{-1} \). This choice of reference frequency is arbitrary and does not affect the ability to detect a GW signal.

The energy density spectrum of the GW background today expressed in terms of the characteristic strain spectrum is given by \([92]\)
\[
\Omega_{\text{GW}}(f) = \frac{2\pi^2}{3H_0^2} f^2 h_c^2(f) = \Omega_{\text{GW}}^r \left( \frac{f}{f_{\text{yr}}} \right)^{3-\gamma_{\text{CP}}},
\]
where we have used Eq. (6) in the second term on the right-hand side, \( \gamma_{\text{CP}} = 3 - 2\alpha_{\text{CP}} \) and \( \Omega_{\text{GW}}^r = 2\pi^2 A_{\text{CP}}^2 f_{\text{yr}}^2 / (3H_0^2) \). The quantity \( h_0^2\Omega_{\text{GW}}(f) \) is typically considered in order to remove the uncertainty in the value of \( H_0 \).

The NANOGrav Collaboration reports joint \( A_{\text{CP}} - \gamma_{\text{CP}} \) posterior distributions \([8]\). Posteriors for a common-spectrum process (see Ref. [8] Fig. 1) expressed in terms of the GW energy density \( h_0^2\Omega_{\text{GW}}(f) \) and frequency \( f \). This is shown over the NANOGrav 12.5-year sensitivity range of 2.5–100 nHz. The three models used to fit the process include: a) broken power law (blue), 5-frequency power law (orange), and 30-frequency power law (green).

**FIG. 1.** NANOGrav 12.5-year data set 2σ confidence contours for the posteriors of a common-spectrum process (see Ref. [8] Fig. 1) expressed in terms of the GW energy density \( h_0^2\Omega_{\text{GW}}(f) \) and frequency \( f \). This is shown over the NANOGrav 12.5-year sensitivity range of 2.5–100 nHz. The three models used to fit the process include: a) broken power law (blue), 5-frequency power law (orange), and 30-frequency power law (green).

Thus, the 5-frequency power law was fit within the signal-dominated frequency range (approximately \( f \in [2.5 \times 10^{-9}, 1.2 \times 10^{-8}] \) Hz). Figure 1 of Ref. [8] shows the 1σ and 2σ posterior contours for the amplitude \( A_{\text{CP}} \) and spectral slope \( \gamma_{\text{CP}} \).

Figure 1 shows the NANOGrav detection expressed in terms of \( h_0^2\Omega_{\text{GW}}(f) \) as given by Eq. (7). The shaded regions show the 2σ confidence contours of the \( A_{\text{CP}} - \gamma_{\text{CP}} \) parameter space in terms of \( f \) and \( h_0^2\Omega_{\text{GW}}(f) \) for frequencies from 2.5–100 nHz (i.e., the NANOGrav 12.5-year sensitivity range); see Ref. [8] for more detail.

### IV. GRAVITATIONAL WAVE GENERATION

As mentioned in the introduction (see also Ref. [72]), low frequency GWs can originate from various astrophysical foreground sources (white dwarfs, SMBH mergers, etc.), and from relic sources related to inflation and cosmic strings, for example, and in particular, from phase transition-generated turbulence and primordial magnetic fields. We focus here on the latter two. Turbulence and/or magnetic fields would only be generated during a limited amount of time before they would decay. The decay process itself remains highly turbulent and could affect GW production. Let us therefore begin with some general remarks about turbulent decay.

#### A. Gravitational waves from turbulent sources

Using scaled quantities \( h_{ij} = ah_{ij}^{\text{phys}} \) and \( T_{ij}^{\text{TT}} = a^4T_{ij}^{\text{TT,phys}} \), together with \( a(t) \propto t \) in the radiation dominated epoch, the GW equation takes the form
\[
(\partial_t^2 - \nabla^2)h_{ij} = \frac{16\pi G}{a} T_{ij}^{\text{TT}}.
\]

To obtain the GW equation in Fourier (wave number) space, we use the Fourier transforms and the polarization \( r = (+, \times) \) decomposition of the tensor metric perturbations and stress energy tensor projected onto the TT gauge [i.e., \( Q_{ij}(k, t) = \sum_{r=+x} e_{ij}^r(\hat{k})Q_{ij}(k, t), \] where \( e_{ij}^r(\hat{k}) \) and \( e_{ij}^r(\hat{k}) \) are the polarization tensors with \( \hat{k} \) the unit vector, and \( k = ak_{\text{phys}} \) is the rescaled wave number].

---

5We use the spatial Fourier transform convention: \( Q(x, t) = \int d^3k e^{-i\text{k}\cdot\text{x}} Q(k, t) \) and \( Q(k, t) = \int d^3x e^{i\text{k}\cdot\text{x}} Q(x, t) \). The transverse operator \( P_{ij} \) in the Fourier space is given \( P_{ij}(\hat{k}) = \delta_{ij} - \hat{k}_i\hat{k}_j \), and the TT projection operator is \( \Lambda_{ij}^{\text{TT}}(\hat{k}) = P_{ik}(\hat{k})P_{jl}(\hat{k}) - \frac{1}{2} P_{ij}(\hat{k})P_{kl}(\hat{k}) \), correspondingly. The polarization tensors \( e_{ij}^r(\hat{k}) \) and \( e_{ij}^r(\hat{k}) \) can be written as \( e_{ij}^r(\hat{k}) = \hat{e}_i^r\hat{e}_j^r - \hat{e}_i^r\hat{e}_j^r \) and \( e_{ij}^r(\hat{k}) = \hat{e}_i^r\hat{e}_j^r + \hat{e}_i^r\hat{e}_j^r \), where \( \hat{e}_i^r \) and \( \hat{e}_i^r \) are unit vectors that are orthogonal to \( \hat{k} \) and each other; see Chapter 1 (1.2) of Ref. [67], and Ref. [98] for further detail.
As in earlier work [98,99], we use normalized conformal time, \( t = t/t_s \), where \( t_s = H_s^{-1} \) is our starting time, and \( a_s = 1 \) has been chosen. Therefore, \( a = \bar{a} \). We also use the scalar wave vector, \( \vec{k} = k/H_s \), and a scaled normalized stress, \( \tau_{TT}^{+/-} = \tau_{TT}/C_{3}^{2}/\epsilon_{rad}^{TT} \). The GW equation can then be written in the form [98,99]

\[
(\partial_{t}^{2} + \bar{k}^{2}) h_{+/-}(k,t) = \frac{6}{7} \tau_{TT}^{+/-} h_{+/-}(k,t),
\]

(9)

but from now on we omit all overbars.

Throughout this paper, all numerical results will usually be presented as the scaled variables introduced above. In particular, we quote the rms strain, \( h_{rms} = \langle h^{2} \rangle^{1/2} \), where \( h^{2} = h_{+}^{2} + h_{-}^{2} = (h_{ij})^{2}/2 \), and likewise for the scaled GW energy, \( \epsilon_{GW} = \langle \bar{h}^{2} \rangle/6 \), where \( \bar{h}_{+/-} = \partial_{+/-} h \) with \( \bar{h}^{2} \equiv h_{+}^{2} + h_{-}^{2} \) (see Ref. [98,99] for additional subdominant terms that are applied in the calculations). We sometimes also quote the (frequency dependent) characteristic amplitude of the physical strain measured today, \( h_\text{rms}/u_0 \) (see Sec. II).

### B. Turbulent sources

Turbulent flows in the early Universe can be modeled by solving the hydromagnetic equations for the density \( \rho \), the velocity \( \vec{u} \), and the magnetic field \( \vec{B} \) with \( \nabla \cdot \vec{B} = 0 \), adopting an ultrarelativistic equation of state in an expanding universe using conformal time and comoving variables [100,101] with a forcing term \( \mathcal{F} \) in the induction equation for \( \vec{B} \)

\[
\frac{\partial \ln \rho}{\partial t} = -\frac{4}{3} \nabla \cdot \vec{u} + \vec{u} \cdot \nabla \ln \rho + \frac{1}{\rho} [\vec{u} \cdot \delta \mathcal{F}] + \eta J^{2},
\]

\[
\frac{\partial \vec{u}}{\partial t} = -\vec{u} \cdot \nabla \vec{u} + \frac{u}{3} (\nabla \cdot \vec{u}) + \nabla \ln \rho + \frac{2}{\rho} \nabla \cdot (\rho \nu \nabla \vec{u}) - \frac{1}{4} \nabla \ln \rho - \frac{\rho}{\rho} [\vec{u} \cdot \delta \mathcal{F}] + \frac{3}{4\rho} J \times \vec{B},
\]

\[
\frac{\partial \vec{B}}{\partial t} = \nabla \times (\vec{u} \times \vec{B} - \eta J + \mathcal{F}), \quad J = \nabla \times \vec{B}.
\]

We recall that the conformal time \( t \) is normalized to unity at the time \( t_s \) of magnetic field generation, \( \rho \) is in units of the initial value, \( \vec{u} \) is in units of the speed of light, and the magnetic energy density \( \vec{B}^2/2 \) is measured in units of the radiation density at the time of generation. Furthermore, \( \delta_{ij} \vec{v} \cdot \vec{u} \) are the components of the rate of strain tensor with commas denoting partial derivatives, \( \eta \) is the current density, \( \nu \) is the kinematic viscosity, and \( \eta \) is the magnetic diffusivity. The electromotive force, \( \mathcal{F} \), is used to model magnetic field generation with

\[
\mathcal{F}(x,t) = \text{Re}[\mathcal{N} \tilde{f}(k) \exp(i k \cdot x + i \phi)],
\]

(10)

where the wave vector \( k(t) \) and the phase \( \phi(t) \) change randomly from one time step to the next. This forcing function is therefore white noise in time and consists of plane waves with average wave number \( k \) such that \( |k| \) lies in an interval \( k - \delta k/2 \leq |k| < k + \delta k/2 \) of width \( \delta k \). Here, \( \mathcal{N} = f_0/\delta t^{1/2} \) is a normalization factor, where \( \delta t \) is the time step and \( f_0 \) is varied to achieve a certain magnetic field strength after a certain time, and \( \tilde{f}(k) = (k \times e)/|k^2 - (k \cdot e)^2|^{1/2} \), where \( e \) is an arbitrary unit vector that is not aligned with \( k \). Note that \( |f|^2 = 1 \). Following earlier work, the forcing is only enabled during the time interval \( 1 \leq t \leq 2 \). The kinetic and magnetic energy densities are defined as \( \epsilon_{\text{K}}(t) = \langle \rho u^2 \rangle/2 \) and \( \epsilon_{\text{M}}(t) = \langle \vec{B}^2 \rangle/2 \), respectively.

The vigor of turbulence is characterized by the Reynolds number, \( \text{Re} = u_{\text{rms}}/\nu k_t \), where \( u_{\text{rms}} \) is the maximum rms velocity. It can only be determined \textit{a posteriori} from the velocity resulting from the magnetic field through the Lorentz force. For all our runs, we use \( \eta = \nu \).

### C. Turbulent decay laws

Turbulence is known to decay in power-law fashion [102,103] such that the magnetic energy \( \epsilon_{\text{M}}(t) \) decays with time \( t \) like \( \Delta \tau^{-p} \) and the correlation length \( \xi_{\text{M}}(t) \) increases like \( \Delta \rho^{\tau} \), where \( \Delta t = t - t_{\text{off}} \) is the time interval after the forcing has been turned off. The exponents \( p \) and \( q \) are positive and depend on the physical circumstances (magnetically or kinetically dominated turbulence), and whether or not there is magnetic helicity. In helical turbulence, for example, one finds \( p = q = 2/3 \), while for nonhelical magnetically dominated turbulence one finds \( p = 1 \) and \( q = 1/2 \), although other variants are sometimes possible [104,105].

In this paper, we are specifically interested in the dependence of the decay behavior on the forcing wave number \( k_t \) of the turbulence while it was still being driven. The parameter \( k_t \) enters through the prefactor in the decay law.

Furthermore, \( \Delta \tau^{-p} \) would become infinite for \( p > 0 \) and \( \Delta t = 0 \) (when \( t = t_{\text{off}} \)). The singularity of \( \Delta \tau^{-p} \) at \( t = 0 \) is a consequence of a simplified description at the initial time moment. For this reason, it is convenient to express the decay laws as

\[
\epsilon_{\text{M}}(t) = \epsilon_{\text{M}}^{\text{max}} (1 + \Delta t/\tau)^{-p},
\]

(11)

where \( \tau \) is the turnover time, which we will treat as an empirical parameter that we expect to be of the order of \( (\nu_A k_t)^{-1} \), where \( \nu_A = (3 \epsilon_{\text{M}}^{\text{max}}/2)^{1/2} \) is the Alfvén speed, evaluated at the time when \( \epsilon_{\text{M}} \) reaches its maximum value \( \epsilon_{\text{M}}^{\text{max}} \). In some simulations of purely hydrodynamic turbulence, we replace \( \epsilon_{\text{M}} \) by \( \epsilon_{\text{K}} \) in Eq. (11) and use \( \tau = (u_{\text{rms}} k_t)^{-1} \) with \( u_{\text{rms}} = (2 \epsilon_{\text{K}})^{1/2} \) as the nominal turnover.
time. We recall here that we are using nondimensional variables where the radiation energy density is unity.

For all our simulations, we choose \( t_{\text{off}} = 2 \), i.e., turbulence is being driven for one Hubble time during \( 1 \leq t \leq 2 \). In the following, we vary \( k_f \) between 2 and 60. For \( k_f = 60 \), we find that \( \tau \) is shorter than a Hubble time, but in all other cases, it exceeds it by up to factors between ten (in the nonhelical cases) and a hundred (in helical cases).

We arrange the strength of the forcing \( f_0 \) such that \( \mathcal{E}_M \) is similar for different values of \( k_f \). This allows us then to determine the resulting GW energy solely as a function of \( k_f \). For small values of \( k_f \), the turbulence may not be able to reach a statistically steady state by the time \( t_{\text{off}} \), when the driving is turned off.

It is therefore necessary to adjust \( f_0 \) for each value of \( k_f \) separately. Once we have two values of \( c_M^{\text{max}} \) that are close enough to the target strength, we determine the desired forcing strength through linear interpolation. We also consider the case of different values of \( f_0 \) for a fixed value of \( k_f \) (Runs noh5,6 and Runs hel5,6).

V. NUMERICAL SIMULATIONS

We solve the governing equations using the PENCIL CODE [106], where the GW solver has already been implemented [98]. We consider a cubic domain of side length \( 2\pi/k_1 \), where \( k_1 \) is the smallest wave number in the domain. We choose \( k_f = k_1/6 \), so that the scale separation between the initial spectral peak and the lowest wave number in the domain is six. In the following, we discuss the results for different values of \( k_f \). The temporal growth of \( \mathcal{E}_M(t) \) is similar for small values of \( k_f \) [see Figs. 2(a) and 2(b)] where we compare the evolution of \( \mathcal{E}_M \) and \( \mathcal{E}_{GW} \) for the nonhelical and helical cases. The parameters of those runs are listed in Tables I and II (for nonhelical and helical runs). The numerical resolution is \( 512^3 \) mesh points, except for run

| Run  | \( k_f \) | \( k_1 \) | \( f_0 \) | \( p \) | \( \tau \) | \( c_M^{\text{max}} \) | \( \mathcal{E}_{GW}^{\text{max}} \) | \( h_{\text{rms}}^{\text{GW}} \) | \( B \) [\( \mu \text{G} \)] | \( h_0^2\Omega_{GW}(f) \) | \( h_c \) |

In Table I, we have quoted the values of $\sigma_{\text{GW}}$ and $h_{\text{rms}}$, obtained at the end of the simulation. To compute the relic observable $h_0^2\Omega_{\text{GW}}$ at the present time, we have to multiply $\sigma_{\text{GW}}$ by a factor $(H_\gamma/H_0)^2(a_\gamma/a_0)^4$, see Refs. [98,99] for details. Using $g_s = 15$ and $T_s = 150$ MeV, we find $H_\gamma = 1.8 \times 10^4$ s$^{-1}$, and thus this factor is $\approx 3 \times 10^{-5}$. The largest value of $\sigma_{\text{GW}}$ quoted in Table I is $3.5 \times 10^{-4}$ and corresponds therefore to $h_0^2\Omega_{\text{GW}} \approx 10^{-8}$. Likewise, the values of $h_{\text{rms}}$ in Table I have to be multiplied by $a_0^{-1} \approx 10^{-12}$ to obtain the observable $h_c$ at the present time [see Eq. (1)]. Again, the largest value of $h_{\text{rms}} = 5 \times 10^{-2}$ corresponds therefore to the observable $h_c = 5 \times 10^{-14}$.

To simplify the comparisons, we have arranged the forcing amplitude $f_0$ such that $\sigma_{\text{GW}}$ is similar in certain cases. The values of $\gamma_{\text{max}}$ listed in the upper block of Tables I and II (for nonhelical and helical hydromagnetic
noh1, where we use $1024^3$ mesh points. Unless specified otherwise, we use $\nu = \eta = 5 \times 10^{-5}$.

FIG. 3. Similar to Figs. 2(a) and 2(b), but in a double-logarithmic representation for (a) nonhelical and (b) helical cases, where $\gamma_{\text{M}}$ is now plotted versus $\Delta t \equiv t - 2$, the time after which the electromagnetic source is turned off.

FIG. 4. (a) $\gamma_{\text{GW}}$ versus $\gamma_{\text{M}}/k_f$; the straight line shows $\gamma_{\text{GW}} = 5.2 \times 10^{-4}(\gamma_{\text{M}}/k_f)^{1/2}$. (b) Positions of our runs in a diagram showing $\gamma_{\text{GW}}$ versus $\gamma_{\text{M}}$. For orientation the old data points of the Ref. [99] are shown as gray symbols. The open red (filled blue) symbols are for the helical (nonhelical) runs. The green symbols refer to the two hydromagnetic runs of Table III.
turbulence, respectively) are around 0.038 and correspond to 0.8 μG. The growth phase of $E_M(t)$ is similar, but the decay is significantly slower when $k_f$ is smaller. The GW energy saturates at a value $E_{GW}^{\text{sat}}$ some time after $E_M(t)$ has reached its maximum, and is smaller for larger values of $k_f$.

It is important to realize that in all four cases, the decay of the magnetic energy follows an approximate power law decay, as given by Eq. (11). To see this, we plot in Fig. 3 the evolution of $E_M$ versus $t^{-2}$ in a double-logarithmic representation. The parameters $p$ and $\tau$ describe the decay and are also listed in Table I.

Our results confirm that the turbulence decays more slowly for large values of $\tau$, or small values of $k_f$. As already found from earlier simulations [99], the GW energy generally decreases with increasing $k_f$. This is seen more clearly in a diagram of $E_{GW}$ versus $E_M/k_f$; see Fig. 4(a).

For $k_f = 2$, we have performed additional simulations with smaller and larger values $f_0$, both with and without helicity. The resulting values of $E_{GW}^{\text{sat}}$ obey quadratic scaling of the form

$$E_{GW}^{\text{sat}} = (qE_M^{\text{max}}/k_f)^2. \quad (12)$$

with a coefficient $q = 1.1$; see the straight line in Fig. 4(a).

Only the data point for $k_f = 60$ is slightly above the line represented by Eq. (12). This could be an artefact of our Reynolds numbers still not being large enough in our simulations, especially for large values of $k_f$.

To compare with earlier work, we show in Fig. 4(b) the positions of our runs in a $E_{GW}^{\text{sat}}$ versus $E_M^{\text{max}}$ diagram. For orientation, we also show the data points from Ref. [99]. We see that the new data points are well above the older ones of Ref. [99]. This is mainly a consequence of using smaller values of $k_f$ here (2–60, compared to 600 in Ref. [99]). For $k_f = 2$ and $k_f = 0.3$, we show the results for hydrodynamic runs using irrotational and vortical forcings [see the green symbols in Fig. 4(b)]. Those runs

\caption{Comparison of nonhelical magnetic turbulence (mag) with irrotational (irro) and vortical (vort) turbulence.}
\end{table}
are listed in Table III and compared with the nonhelical magnetic turbulence run 'noh1'.

In Fig. 5 we plot the resulting present-day GW energy and strain spectra for our four runs with $k_f = 2$, 6, 20, and 60, both without and with helicity in the driving function $\mathcal{F}$. The first two cases with $k_f = 2$ and 6 lie well within the frequency and amplitude range accessible to NANOGrav. In all cases, the spectra show a sharp drop slightly above the peak frequency. This is a consequence of the rapid temporal growth of the spectra, which leads to a correspondingly large growth at the peak frequency, while at higher frequencies, the spectrum settled at values that were determined by somewhat earlier times when the energy was still weaker.

At frequencies below the peak, we now find a spectrum that is even shallower than the $h_0^2 \Omega_{GW}(f) \propto f$ spectrum found already earlier [99]. A spectrum shallower than proportional to $f$, such as the present $f^{1/2}$ spectrum, could perhaps be explained by the finite size of the computational domain (see Ref. [107]) who found even a $f^{-1/2}$ spectrum for $\Omega_{GW}(f)$. Alternatively, the shallower spectrum might well be physical, or at least significantly extended over a substantial frequency interval below the peak frequency, for example due to inverse cascading in helical [108] and nonhelical [109] cases.

In the absence of sources, a $\Omega_{GW}(f) \propto f^\alpha$ spectrum implies $h_c(f) \propto f^{\alpha/2 - 1}$ for arbitrary spectral indices $\alpha$. For $\alpha = 1/2$, we would thus expect $h_c(f) \propto f^{-3/4}$. However, the observed strain spectrum, $h_c(f) \propto f^{-1/2}$, seems to agree with that found previously from numerical simulations [99]. However, looking more carefully at the strain spectrum for $k_f = 60$, we see a $h_c(f) \propto f^{-3/4}$ spectrum is actually compatible with the simulation; see the corresponding dashed-dotted line in Fig. 5(c). This agreement is probably related to the fact that the turnover time is shorter for the run with $k_f = 60$, compared with those at smaller values (i.e., longer turbulence driving time will allow for more efficient inverse cascading).

In the runs with helicity, we do find $h_0^2 \Omega_{GW}(f) \propto f$, together with a slight enhancement just before reaching a maximum. The subsequent decay for larger values of $f$ is much steeper in the case with helicity than without. Furthermore, in $h_c(f)$ we see a sharper drop to the right of the maximum than in simulations without helicity. These differences in the spectra for helical and nonhelical cases are surprisingly strong and might allow us to infer the presence of magnetic helicity once such a spectrum is detected.

FIG. 6. Magnetic energy spectra for the (a) nonhelical and (b) helical cases.

FIG. 7. Similar to Fig. 5, (a) $h_0^2 \Omega_{GW}(f)$ and (b) $h_c(f)$, but comparing vortical (red) and irrotational turbulence (blue) with MHD turbulence (black).
It is important to note that the $h_0^2\Omega_{GW}\propto f$ spectra in Figs. 4(a) and 4(c) show an increase towards smaller $k_f$. This is to be expected from Eq. (12), but it was not included in the sketch of Ref. [31]; see their Fig. (1). By contrast, in their Eq. (4), an effectively cubic dependence on the magnetic energy was motivated.

The underlying magnetic energy spectrum is shown in Fig. 6(a) for nonhelical and in Fig. 6(b) helical cases where $k_f$ is ranging from 2 to 60. Those are averaged spectra obtained by averaging over the time interval $15 \leq t \leq 20$. In the nonhelical case, the amplitude of the spectrum is smaller for larger values of $k_f$, because here the energy has decayed more rapidly. In the helical case, the spectra have approximately the same height for all values of $k_f$. This is because the height of the spectrum is related to the helicity, which is conserved. For small values of $k_f$, the spectrum has a more extended subinertial range. This is because the turnover time is larger and there was not enough time for the inverse cascade to produce energy and small values of $k$.

Finally, we compare the results for two types of purely hydrodynamic turbulence with vortical and irrotational forcings of Table III. The result is shown in Fig. 7. All these cases are for plane wave forcings. For irrotational forcing, we do not see the sharp drop off of spectral power for frequencies above the peak value as in the vortical case. This suggests that in the inertial range of irrotational turbulence, there is still some power to contribute to GW driving compared with the vortical case, where this is almost not possible at all. However, the spectrum in the irrotational case shows a fairly steep spectrum proportional to $f^{-7}$, so the effect on GW production is here also rather weak. Nevertheless, the spectral form of the peak might give interesting diagnostic clues about the nature of turbulent driving at the time of GW production.

We mention in passing that in earlier work, it was found that irrotational turbulence is much more efficient in driving GWs than vortical turbulence [99]. Remarkably, here this is no longer the case and vortical and irrotational turbulence have rather similar GW energies. This could be related to the small value of $k_f$, possibly combined with a comparatively short time of driving. However, to clarify this further, more targeted numerical experiments would need to be performed.

To put our results into perspective, we compare in Fig. 8 with the contours for possible sources of GWs in the nHz range in terms of $h_0^2\Omega_{GW}$ and $f$. In the upper left, we show

![Image](FIG. 8. Upper left: Runs noh5,6 (yellow) and hel5,6 (magenta), which correspond to $k_f = 6$, compared with the NANOGrav 12.5-year 2σ contours (as shown in Fig. 1). Additionally, the gray and black dashed horizontal lines show the CMB and BBN integrated bounds on $h_0^2\Omega_{GW}(f)$ (see [92] for details). Upper right: Contours representing four different cosmic string average power spectrum models with different tensions, as described in [110]: mono (orange), kink (green), cusp (blue), and a spectrum computed from a simulated gravitational backreaction model (magenta). Lower left: Contour representing the $n_T - r$ (tensor spectral index and tensor-to-scalar ratio, respectively) parameter space consistent with the NANOGrav 12.5-year 5-frequency power-law 2σ confidence contour considering the Bicep2-Keck Array and Planck constraint that $r < 0.07$ [9]. Lower right: NANOGrav 12.5-year contours for SMBHBs, which are expected to have a spectral index of $\gamma_{CP} = 13/3$, corresponding to $A_{CP} = [1.4, 2.7] \times 10^{-15}$ from the NANOGrav 12.5-year 5-frequency and broken power law 2σ contours.)
limits on GWs from magnetohydrodynamic (MHD) turbulence at QCD for \( k_t \) from 2 to 6 (corresponding to Runs noh5,6, hel5,6, and noh7,8) around the NANOGrav sensitivity range. Additionally, we show the integrated bounds on \( h_0^2 \Omega_{GW} \) from the CMB and BBN [92], noting that the actual bound on the peak of \( h_0^2 \Omega_{GW} \) can fall above these lines. Contours in the upper right correspond to four different models for the average power spectrum of GWs from a network of cosmic strings of different tensions [110]. The bottom left contour corresponds to the parameter space of \( n_T - r \) (tensor spectral index and tensor-to-scalar ratio) consistent with the 2\( \sigma \) contours of the NANOGrav 12.5-year 5-frequency power law. This corresponds to Figs. 1 and 2 of Ref. [9]. The lower right contour represents the NANOGrav 12.5-year 2\( \sigma \) contours for the 5-frequency and broken power laws for a population of SMBHBs, expected to have a spectral index of \( \gamma_{CP} = 13/3 \). In this work we found \( \Omega_{GW}(f) \sim f^{1/2} \) for nonhelical turbulence, corresponding to a spectral index of \( \gamma_{CP} = 4.5 \), which falls at the edge of the 1\( \sigma \) confidence contours for the NANOGrav 5-frequency and broken power laws. The scaling \( \Omega_{GW}(f) \sim f \), which we found in the case of helical turbulence, corresponds to \( \gamma_{CP} = 4 \) and falls within the 2\( \sigma \) contours from NANOGrav. The spectral index for SMBHBs, \( \gamma_{CP} = 13/3 \) falls between these.

VI. CONCLUSIONS

In the present work, we have shown that the magnetic stress from hydrodynamic and MHD turbulence with scales comparable to the cosmological horizon scale at the time of the QCD phase transition can drive GWs in the range accessible to NANOGrav, if the magnetic energy density is \( 3-10\% \) of the radiation energy density. The low-frequency tail below the peak frequency at 10 nHz or so is shallower in the nonhelical case than in the helical one, i.e., \( \propto f^{1/2} \) compared to \( \propto f \). Both scalings are, however, shallower than what was expected based on earlier analytical calculations. Also the inertial range spectrum above the peak is shallower without helicity than with, but here, both spectra are steeper than what is expected if the GW spectrum was a direct consequence of the MHD turbulence spectrum [99,111]. The reason for this is primarily the relatively short time of turbulent driving (one Hubble time). It is short compared with the turnover time which, for our runs with the smallest \( k_t \) of two, is much longer; 16 (100) Hubble times for our runs without (with) helicity. Therefore, there was not enough time to fully establish the GW spectrum at high wave numbers. For our earlier runs with larger values of \( k_t \), this effect was less pronounced than for smaller values of \( k_t \), but it is still quite noticeable, especially in the helical case where forward cascading is weaker than in the nonhelical case.

Our work has led to new insights regarding the possibility of using an observed GW spectrum for making statements about the nature of the underlying turbulence in the early universe. One is the already mentioned slope of the subinertial range spectrum. Another is the position of the peak of the spectrum. Finally, there is the strength of the drop of the spectral power for frequencies above the peak frequency, and the subsequent slope after the drop, which is most likely too small to be detectable. This, however, depends on the duration of turbulent driving and could be higher if the driving time was longer. The specific features of the spectrum near the peak are different for helical and nonhelical turbulence. This could, in principle, give information about the presence of parity violation, when would also lead to circularly polarized GWs.
