Background: Proton-nucleus collisions have been used as an intermediate baseline for the determination of cold medium effects. They lie between proton-proton collisions in vacuum and nucleus-nucleus collisions which are expected to be dominated by hot matter effects. Modifications of the quark densities in nuclei relative to those of the proton are well established although those of the gluons in the nucleus are not well understood. We focus on the effect of these on quarkonium production in proton-lead collisions at the LHC at a center of mass energy of 5.02 TeV.

Purpose: We determine whether it is possible for the LHC proton-lead data to be described by nuclear modifications of the parton densities, referred to as shadowing, alone. We compare our results to the nuclear modification factor and to the forward-backward ratio, both as a function of transverse momentum, $p_T$, and rapidity, $y$.

Methods: We employ the color evaporation model of quarkonium production at next-to-leading order in the total cross section and leading order in the transverse momentum dependence. We use the EPS09 NLO modifications as a standard of comparison. We study the effect of the proton parton density and the choice of shadowing parameterization on the $p_T$ and rapidity dependence of the result. We check whether or not the calculations at leading and next-to-leading order give consistent shadowing results. We also investigate the size of the mass and scale uncertainties relative to the uncertainty on the shadowing parameterization. Finally, we check whether the expected cold matter effect in nucleus-nucleus collisions can be modeled as the product of proton-nucleus results at forward and backward rapidity.

Results: We find that the rapidity and $p_T$ dependence of the nuclear modification factor are generally consistent with the next-to-leading order calculations in the color evaporation model. The forward-backward ratio is more difficult to describe with shadowing alone. The leading and next-to-leading order calculations are inconsistent for EPS09 while other available parameterizations are consistent. The mass and scale uncertainties on quarkonium production are larger than those of the nuclear parton densities.

Conclusions: While shadowing is consistent with the nuclear suppression factors within the uncertainties, it is not consistent with the measured forward-backward asymmetry, especially as a function of transverse momentum. Data from $p+p$ collisions at the same energy are needed.

I. INTRODUCTION

In this paper we concentrate on comparison to the 2013 LHC $p+$Pb data on quarkonium production at $\sqrt{s_{NN}} = 5.02$ TeV. The inclusive $J/\psi$ and $\Upsilon$ production data, binned as a function of rapidity and $p_T$ ($J/\psi$) or rapidity alone ($\Upsilon$), come from the ALICE [1-3] and LHCb [4, 5] collaborations. We briefly discuss the detector acceptances for each experiment in turn here but provide a more complete description of the data in Sec. II.

Runs with mass asymmetric beams are different at the LHC than at RHIC because the LHC beams are not symmetric in energy. Instead, in the 2013 LHC $p+$Pb run a 4 TeV proton beam interacted with a $4(Z_{{Pb}}/A_{Pb}) = 1.58$ TeV/nucleon Pb beam. The nucleon-nucleon center of mass frame does not coincide with the laboratory frame in an energy-asymmetric collision system. Instead the center of mass frame is shifted by $\Delta y = 0.465$, taken to be in the direction of the proton beam, as defined by experiments. In addition, the ALICE and LHCb detector systems are not symmetric around the interaction point, with muon spectrometers on only one side of midrapidity. Therefore the beams have to be run in two modes, Pb+p and p+Pb. In the first case the lead beam is defined to move toward forward rapidity while in the second, the proton beam does. Because the second configuration is most similar to fixed-target operation and corresponds to small parton momentum fractions in the nucleus, both setups are analyzed according to the convention that the proton beam moves to positive rapidity. Thus the case of Pb+p collisions corresponds to larger parton momentum fractions in the nucleus.

The ALICE $J/\psi$ measurement has been presented in both the central and forward/backward regions. Their muon spectrometer covers the pseudorapidity range $-4 < y_{lab} < -2.5$ in the laboratory frame. Due to the rapidity shift in the asymmetric energy beams, the backward rapidity range for dimuon coverage is $-4.46 < y_{\text{cms}} < -2.96$. 
while the forward rapidity range for dimuon coverage is $2.03 < y_{\text{lab}} < 3.53$. The ALICE central detector includes dielectron coverage for $y_{\text{lab}} < 0.8$. The quarkonium measurements in this region correspond to the rapidity range $-1.37 < y_{\text{lab}} < 0.43$. 

The LHCb detector covers $2 < y_{\text{lab}} < 5$ in the laboratory frame. Like ALICE, they define the forward direction as the direction of the proton beam so that their backward coverage is $-5 < y_{\text{lab}} < -2.5$ and the forward coverage is $1.5 < y_{\text{lab}} < 4$.

Because there is not yet a measured $p+p$ baseline, the nuclear modification factor,

$$R_{p\text{p}b}(y,p_T) = \frac{d\sigma_{p\text{p}b}(y,p_T)/dydp_T}{T_{\text{p}b}d\sigma_{\text{p}b}(y,p_T)/dydp_T},$$

(1)

relies on an interpolation of the $p+p$ cross section. The rapidity shift was taken into account to obtain the $p+p$ cross section in the rapidity ranges of the $p+\text{Pb}$ measurement. The factor $T_{\text{p}b}$ in the denominator of Eq. (1) takes the centrality of the collision into account and is calculated in a Glauber model. In this paper, we concentrate only on the minimum bias results. See Ref. [6] for a discussion of the centrality dependence of the $J/\psi$ measurement at RHIC. Work is in progress on the centrality dependence at the LHC [7].

In addition to studying the nuclear modification factors in these rapidity ranges, the forward-backward ratio,

$$R_{\text{FB}}(y,p_T) = \frac{d\sigma_{p\text{p}b}(y > 0,p_T)/dydp_T}{d\sigma_{\text{p}b}(y < 0,p_T)/dydp_T},$$

(2)

has also been presented [1][3]. The unmeasured quantities $T_{\text{p}b}$ and $\sigma_{\text{p}b}$ cancel for a rapidity range symmetric around $y_{\text{lab}} = 0$. Therefore $R_{\text{FB}}$ is formed in the rapidity region where the forward and backward acceptances completely overlap, $2.96 < |y_{\text{lab}}| < 3.53$ for ALICE and $2.5 < |y_{\text{lab}}| < 4$ for LHCb. Some systematic uncertainties also cancel in the ratio. This ratio is perhaps a more faithful representation of cold matter effects on the $p+\text{Pb}$ cross section. However, for theoretical interpretation, $R_{p\text{p}b}$ is still desirable because even a wrong model can produce the right ratio.

In a previous paper [8], predictions were made for $pA$ collisions at $\sqrt{s}_{NN} = 8.8$ and 5.5 TeV and ratios were formed both to $p+p$ collisions at the same energy and to $p+p$ collisions at the anticipated top energy of $\sqrt{s} = 14$ TeV. These calculations were made before the LHC turned on and so did not employ the same energies at which data were ultimately taken in LHC Run 1: $\sqrt{s} = 2.76$, 7 and 8 TeV for $p+p$ collisions and 5.02 TeV for $p+\text{Pb}$. These calculations assumed that the leading and next-to-leading order treatments of the modifications of the parton densities in nuclei, when employed consistently, would be identical, as discussed in more detail later.

More recently, calculations were made for the nuclear modification factor as a function of $y$ and $p_T$ at the energy appropriate for the $p+\text{Pb}$ run [9] but not taking the rapidity shift into account for the $p_T$ acceptance. In addition, the $p_T$ dependent ratio was presented for forward rapidity only. These predictions, along with other, updated, CEM calculations with EPS09 NLO nuclear parton densities (nPDFs) were compared to the ALICE and LHCb $J/\psi$ and $\Upsilon$ data [1][3][13][12]. In those calculations, the incorrect factorization scale, $\mu_F$, was passed to the nuclear parton densities. (The square of the scale was passed instead of the scale itself, as required by most shadowing parameterizations, so that the overall cold matter effect was reduced relative to the true value. This was not the case for the LO predictions in Ref. [8].) In this paper, this error is corrected and the $p_T$-dependent ratios calculated in the CEM are presented for the first time.

In the next section, Sec. [III] we provide a brief summary of the ALICE and LHCb $J/\psi$ and $\Upsilon$ measurements to place our calculations in context.

We then summarize our calculation of quarkonium production in $p+p$ collisions in Sec. [III]. We compare the $J/\psi$ and $\Upsilon$ distributions obtained with several different sets of proton parton densities. Comparison of these calculations to available $p+p$ data can be found in Refs. [13][14]. A short summary of cold nuclear matter effects is given in Sec. [IV].

The nuclear parton density modifications used in this paper are described in Sec. [V]. The calculations are compared to the $p+\text{Pb}$ data from ALICE and LHCb on $J/\psi$ and $\Upsilon$ production at $\sqrt{s}_{NN} = 5$ TeV in Sec. [VI]. We calculate both $R_{p\text{p}b}$ and $R_{\text{FB}}$ as functions of rapidity and transverse momentum. The data are first compared to the EPS09 uncertainty bands. We contrast the leading order (LO) and next-to-leading order (NLO) results for order-by-order consistency. Next, the data are compared to all the nuclear parton densities discussed in Sec. [V] to see if any parameterizations are particularly favored. The mass and scale dependence of the results is also shown. Finally, we discuss how closely the $A+A$ calculations can be reproduced by a convolution of $p+A$ and $A+p$ collisions and also compare to the RHIC data.
II. DESCRIPTION OF THE p+PB QUARKONIUM DATA

In this section, we describe the quarkonium data for J/ψ and Υ(1S) from ALICE and LHCb. Since there has been no p + p run at $\sqrt{s} = 5$ TeV to date, the denominator of $R_{pPb}$ has to be interpolated between available measurements at other energies. The p + p cross sections also had to be adjusted to the rapidity ranges of the p + Pb measurement.

The interpolation methods used by the collaborations depend on the quarkonium state, the observable, and the previously available data. However, in all cases, the quarkonium states were assumed to be produced unpolarized.

To obtain $R_{pPb}(y)$ for the J/ψ, the ALICE Collaboration used an energy interpolation between their p + p measurements at 2.76 and 7 TeV to obtain the $\sqrt{s}$ dependence of the p + p cross section. They presented their J/ψ p + Pb data in both a single rapidity interval as well as in six rapidity bins measured for p + p collisions (of course without the rapidity shift in p + p). These first results were for $R_{pPb}$ at forward and backward rapidity and $R_{FB}$ as a function of $p_T$ and y [1].

Their energy interpolation was based on three assumed shapes: linear, power law and exponential. The central value of the result for each rapidity bin is an average of the three shapes while the uncertainty is the quadrature sum of a term related to the uncertainty on the data used for the interpolation and a term related to the spread between results with different shapes.

An additional small systematic uncertainty was obtained by comparing the shapes with those of the leading order CEM and the fixed-order next-to-leading logarithm (FONLL) approach for inclusive open heavy flavor production [1]. We note that the LO and NLO CEM energy dependence should be similar if the same mass and scale parameters, as well as the same proton parton densities are used. (The shapes will not be similar if e.g. CTEQ6M is used at NLO and CTEQ6L1 is used at LO.) Using the FONLL calculation for the total $\sigma$ cross section may produce a shape similar to the CEM but the magnitude, of course, will be quite different.

In a later paper, the ALICE Collaboration presented results for the midrapidity $R_{pPb}$, a bin around $-1.37 < y_{c_{ms}} < -0.43$ to add to $R_{pPb}(y)$ as well as the ratios $R_{pPb}(p_T)$ at forward, backward and midrapidity [2]. While the forward-backward ratio as a function of $p_T$ was published in Ref. [1], the separate values of $R_{pPb}(p_T)$ were not yet available.

The p + p baseline for the $p_T$-dependent ratios was obtained through interpolation. At midrapidity, data from $\sqrt{s} = 0.2, 1.96, 2.76$ and 7 TeV were used. The 1.96 TeV results from p + p collisions from the Tevatron were considered on the same basis as p + p collisions because, at these high energies, production is dominated by the $gg$ process. Scaling in $x_T = m_T/\sqrt{s}$ was used to compare the disparate energies. Only exponential, logarithmic and power law dependencies were considered in this case because there is no $p_T$ dependence in the LO CEM and the FONLL approach is for single inclusive distributions, not pairs, so the $p_T$ slope is not available from these calculations.

At forward rapidity, the only data available to include in the $\sqrt{s}$ interpolation are the 2.76 and 7 TeV data from ALICE. (They did not employ the LHCb results in their interpolation.) In this region, the dependencies were linear, power law and exponential. The results for $R_{pPb}(p_T)$ are only shown up to 8 GeV because the p + p data were limited to this $p_T$ range. The non-prompt J/ψ production from b decays increases with $p_T$, giving a $\sim 20\%$ correction at $p_T \sim 8$ GeV [2].

ALICE has also measured the ψ' in p+Pb collisions, finding significantly more suppression [15]. Since this difference cannot be due to initial state effects alone, we do not address that result in this work.

The ALICE Collaboration also measured the inclusive Υ(1S) and Υ(2S) rates. The rapidity dependence of $R_{pPb}$ was reported in Ref. [3]. The Υ yields are not large so that only one rapidity bin is reported. To obtain the p + p baseline for $R_{pPb}$, they used the LHCb results for Υ production at $\sqrt{s} = 2.76, 7$ and 8 TeV, divided into rapidity bins. They employed 21 different shapes, 15 from the LO CEM with different proton PDFs and factorization scale choices; 3 based on the FONLL b quark distributions; while linear, power-law, and exponential shapes rounded out the set. The agreement of all the shapes with the data was generally poor so the fits with the worst $\chi^2$/dof were discarded for the final fits. In addition to the J/ψ uncertainties described above, they also considered small rapidity shifts between the ALICE and LHCb rapidity bins.

They found that the Υ $R_{pPb}$ is quite similar to that of J/ψ at forward rapidity while at negative rapidity the Υ $R_{pPb}$ is compatible with unity but lower than that of the J/ψ. This is a fairly remarkable result since nuclear effects are generally expected to be smaller for the Υ than for J/ψ so that the Υ $R_{pPb}$ should be closer to unity at low $p_T$ where the difference in mass is the dominant effect. At higher $p_T$, where $p_T \gg m$, the results should be similar for the two quarkonium states.

They reported the Υ(2S)/Υ(1S) ratios at forward and backward rapidity, $0.26 \pm 0.09 \pm 0.04$ and $0.27 \pm 0.08 \pm 0.04$ respectively [3]. The result is consistent with the p + p ratio at 7 TeV. This is also consistent with shadowing being

---

0 Note that the FONLL approach calculates the single inclusive heavy flavor distributions, not those of the Q̅Q̅ pair as in the CEM.
the dominant cold matter effect since it affects the excited states the same way as the ground state.

The LHCb Collaboration has also measured $J/\psi$ and $\Upsilon$ production in their muon spectrometer. In addition to the inclusive $J/\psi$ result, they also separate $b \rightarrow J/\psi$ decays to present a non-prompt $J/\psi$ result. Their primary functional dependence to interpolate between their $p+p$ results at 2.76, 7 and 8 TeV is a power law, $\sigma(\sqrt{s}) = (\sqrt{s}/p_0)^{p_1}$. They use linear and exponential dependencies to obtain a systematic uncertainty on their interpolation. They do not use any production models for the energy interpolation [4]. A similar, power-law-based method is used to obtain the $p_T$ dependence of the $J/\psi$ baseline for $\Upsilon$ production [5].

Recently, the ATLAS Collaboration has presented results on the forward-backward $J/\psi$ ratio as a function of $y$ in the region $8 < p_T < 30$ GeV and as a function of rapidity in the rapidity range $|y_{\text{cms}}| < 1.94$ [16]. Their results for $R_{FB}$ are consistent with unity within the uncertainties of the data. CMS also recently presented the prompt $J/\psi$ $R_{FB}$ as a function of $p_T$ and as a function of rapidity for high $p_T$ [17]. Their results are consistent with those of ATLAS. The LHCb $\Upsilon$ measurement includes low statistics for the $\Upsilon(3S)$ states, as well as the 1S and 2S states. The ratios $\Upsilon(2S)/\Upsilon(1S)$ are 0.28±0.14±0.05 in the backward direction and 0.20±0.05±0.01 at forward rapidity, both consistent with $p+p$ measurements [8]. While the $\Upsilon(3S)/\Upsilon(1S)$ ratios are also consistent with those in $p+p$ collisions, their low statistics reduces their significance.

Finally, we note that we do not discuss the intriguing CMS $\Upsilon(1S)/\Upsilon(1S)$ ratios measured as a function of both the number of tracks at midrapidity and the transverse energy at forward rapidity [18]. This effect, also seen in $p+p$ collisions, is not attributable to initial-state modifications of the parton densities and, as such, is outside the scope of this work.

The quarkonium yields for all the ALICE and LHCb results discussed here are given in Table I.

### III. PRODUCTION IN $p+p$ COLLISIONS

Following our previous work [8, 13], we treat quarkonium production within the color evaporation model (CEM). In the CEM, heavy flavor and quarkonium production are treated on an equal footing. The CEM has enjoyed considerable phenomenological success when applied at NLO in the total cross section and LO in the quarkonium $p_T$ distribution [13, 19, 21]. (See Ref. [13] for comparison of the $\sqrt{s} = 2.76$ and 7 TeV ALICE data with the same CEM calculation employed here.)

#### A. Color Evaporation Model Calculation

In the CEM, the quarkonium production cross section is some fraction, $F_C$, of all $Q\bar{Q}$ pairs below the $H\bar{H}$ threshold where $H$ is the lowest mass heavy-flavor hadron. Thus the CEM cross section is simply the $Q\bar{Q}$ production cross section with a cut on the pair mass but without any constraints on the color or spin of the final state. The color of the octet $Q\bar{Q}$ state is ‘evaporated’ through an unspecified process which does not change the momentum. The additional energy needed to produce heavy-flavored hadrons when the partonic center-of-mass energy, $\sqrt{s}$, is less than $2m_H$, the $H\bar{H}$ threshold energy, is nonperturbatively obtained from the color field in the interaction region. Thus the quarkonium yield may be only a small fraction of the total $Q\bar{Q}$ cross section below $2m_H$. At leading order, the production cross section of quarkonium state $C$ in a $p+p$ collision is

$$\sigma_C^\text{CEM}(s, n_n) = F_C \sum_{i,j} \int_{4m^2}^{4m_H^2} d\hat{s} \int dx_1 dx_2 \ f_i^p(x_1, \mu_F^2) \ f_j^p(x_2, \mu_F^2) \ J(\hat{s})\hat{s}_{ij}(\hat{s}, \mu_F^2, \mu_R^2),$$  (3)
where \( ij = q\bar{q} \) or \( gg \) and \( \delta_{ij}(s) \) is the \( ij \rightarrow Q\bar{Q} \) subprocess cross section. Here \( J(\hat{s}) \) is a kinematics-dependent Jacobian. At LO \( J(\hat{s}) = \delta(\hat{s} - x_{1}x_{2}s) / s \), at NLO and for differential cross sections, the expressions are more complex.

The fraction \( F_C \) must be universal so that, once it is fixed by data, the quarkonium production ratios should be constant as a function of \( \sqrt{s} \), \( y \) and \( p_T \). The actual value of \( F_C \) depends on the heavy quark mass, \( m \), the scale parameters, the parton densities and the order of the calculation.

We fit \( F_{J/\psi} \) to both the full data set as well as to more limited sets. Our final \( J/\psi \) result is based on the total cross section data with only \( p \), Be, Li, C, and Si targets respectively. In this way, we avoid uncertainties due to ignoring any cold nuclear matter effects which are on the order of a few percent in light targets. We also restricted ourselves to the forward cross sections only, rather than include the \( B_{ij}d\sigma / dy_{IJ} = 0 \) data in the fits. The rapidity distributions calculated in the MNR code are subject to fluctuations about the mean, even with high statistics calculations. The total cross sections, not subject to these fluctuations, are thus more accurate. See Ref. [13] for more detail.

In the case of \( \Upsilon \) production, however, most of the reported cross section values are for \( B_{ij}d\sigma / dy_{IJ} = 0 \). The branching ratio \( B_{ij} \) here is a composite for the three \( \Upsilon \) \( S \) states which were not separated at fixed-target energies. For later experiments, with sufficient resolution to separate the mass peaks, the individual \( y = 0 \) cross sections were multiplied by the PDG values of the branching ratios and summed [14]. The data in the \( \Upsilon \) fits are from fixed-target energies, 19.4 \( \leq \sqrt{s} \leq 44 \text{ GeV} \), and collider data from the ISR, SPS and the Tevatron. The \( p + \bar{p} \) data from the SPS and the Tevatron are fit with the same coefficient as the lower energy \( p + p \) data. At \( \sqrt{s} = 630 \text{ GeV} \), the difference between the \( p + p \) and \( p + \bar{p} \) \( b\bar{b} \) cross sections is less than 0.5%, too small to affect the fit results.

We use the same values of the charm quark mass and scale parameters as found in Ref. [13] to obtain the normalization \( F_C \) for the \( J/\psi \), \( (m, \mu_F/m, \mu_R/m) = (1.27 \pm 0.09 \text{ GeV}, 2.1^{+2.55}_{-1.6^{+0.9}_{-0.12}}) \). In the case of \( \Upsilon \) production, we employ \( (m, \mu_F/m, \mu_R/m) = (4.65 \pm 0.09 \text{ GeV}, 1.4^{+0.49}_{-0.11^{+0.22}_{-0.20}}) \). We determine \( F_C \) only for the central parameter set in each case and scale all the other calculations by the same value of \( F_C \) to obtain the extent of the \( J/\psi \) and \( \Upsilon \) mass and scale uncertainty bands, as described in detail in Sec. [VI].

We find \( F_{J/\psi} = 0.020393 \) for the central result with \( (m, \mu_F/m, \mu_R/m) = (1.27 \text{ GeV}, 2.1, 1.6) \) employing the CT10 parton densities [13]. We obtain \( F_{\Upsilon - \Upsilon} = 0.0077 \) for the central \( y = 0 \) result for the combined \( \Upsilon \) \( S \) states with the CT10 parton densities and \( (m, \mu_F/m, \mu_R/m) = (4.65 \text{ GeV}, 1.4, 1.1) \). After separating the \( S \) states, the inclusive \( 1S \) value is \( F_{\Upsilon} = 0.022 \) [14].

Our CEM calculations use the NLO \( Q\bar{Q} \) code of Mangano et al. (MNR) [22] with the \( H\bar{H} \) mass cut in Eq. [43], as described in Refs. [13, 23]. Because the NLO \( Q\bar{Q} \) code is an exclusive calculation, we take the mass cut on the invariant average over kinematic variables of the \( c \) and \( \bar{c} \). Thus, instead of defining \( \mu_F \) and \( \mu_R \) relative to the quark mass, they are defined relative to the transverse mass, \( \mu_F, \rho \propto m_T = \sqrt{m^2 + p_T^2} \) where \( p_T \) is that of the \( Q\bar{Q} \) pair, \( p_T^2 = 0.5(p_T^2 + \hat{p}_T^2) \).

At LO in the total cross section, the \( Q\bar{Q} \) pair \( p_T \) is zero. Thus, while our calculation is NLO in the total cross section, it is LO in the quarkonium \( p_T \) distributions. In the exclusive NLO calculation [22] both the \( Q \) and \( \bar{Q} \) variables are integrated to obtain the pair distributions, recall \( \mu_F, R \propto m_T \).

Results on open heavy flavors indicate that some level of transverse momentum broadening is needed to obtain agreement with the low \( p_T \) data. This is often done by including some intrinsic transverse momentum, \( k_T \), smearing to the initial-state parton densities. The implementation of intrinsic \( k_T \) in the MNR code is not handled in the same way as calculations of other hard processes due to the nature of the code. In the MNR code, the cancellation of divergences is done numerically. Since adding additional numerical Monte-Carlo integrations would slow the simulation of events, in addition to requiring multiple runs with the same setup but different intrinsic \( k_T \) kicks, the kick is added in the final, rather than the initial, state. In Eq. [4], the Gaussian function \( g_p(k_T) \),

\[
g_p(k_T) = \frac{1}{\pi(k_T)^p} \exp\left(-\frac{k_T^2}{(k_T)^p}\right),
\]

multiplies the parton distribution functions for both hadrons, assuming the \( x \) and \( k_T \) dependencies in the initial partons completely factorize. If factorization applies, it does not matter whether the \( k_T \) dependence appears in the initial or final state if the kick is not too large. In Ref. [24], \( (k_T^2)^p = 1 \text{ GeV}^2 \), along with the Peterson fragmentation function with parameter \( \epsilon = 0.06 \), was found to best describe fixed-target charm production. We note that currently Peterson fragmentation with \( \epsilon = 0.06 \) is considered too strong. The FONLL fragmentation scheme for open heavy flavor is softer [25].

In the code, the \( Q\bar{Q} \) system is boosted to rest from its longitudinal center-of-mass frame. Intrinsic transverse momenta of the incoming partons, \( \vec{k}_{T1} \) and \( \vec{k}_{T2} \), are chosen at random with \( k_{T1}^2 \) and \( k_{T2}^2 \) distributed according to Eq. [4]. A second transverse boost out of the pair rest frame changes the initial transverse momentum of the \( Q\bar{Q} \) pair, \( \vec{p}_T \), to \( \vec{p}_T + \vec{k}_{T1} + \vec{k}_{T2} \). The initial \( k_T \) of the partons could have alternatively been given to the entire final-state system, as is essentially done if applied in the initial state, instead of to the \( Q\bar{Q} \) pair. There is no difference if the calculation is LO but at NLO an additional light parton can also appear in the final state so the correspondence is
not exact. In Ref. [24], the difference between the two implementations is claimed to be small if \(k_T^2 \leq 2 \text{GeV}^2\). We note that the rapidity distribution, integrated over all \(p_T\), is unaffected by the intrinsic \(k_T\).

The effect of the intrinsic \(k_T\) on the shape of the quarkonium \(p_T\) distribution can be expected to decrease as \(\sqrt{s}\) increases because the average \(p_T\) also increases with energy. However, the value of \(\langle k_T^2 \rangle\) may increase with \(\sqrt{s}\) so that effect remains important at higher energies. We assume the form \(\langle k_T^2 \rangle = 1 + (1/n) \ln(\sqrt{s}/20) \text{GeV}^2\). Using the RHIC \(J/\psi\) data, we found that \(n = 12\) gave the best description of the \(p_T\) distribution both at central and forward rapidity \[13\]. A larger value of \(n\) and thus of \(\langle k_T^2 \rangle\) is required for the \(\Upsilon\) \(p_T\) distribution. We set \(n = 3\) for \(\Upsilon\) from comparison to the Tevatron results at \(\sqrt{s} = 1.8 \text{TeV}\) \[14\]. For this study, \(n\) is not modified by the nuclear medium.

We note that most approaches to quarkonium production: the CEM; the color singlet model (CSM); and the Nonrelativistic QCD approach (NRQCD), assume the validity of collinear factorization which separates the initial, nonperturbative parton densities from the perturbatively-calculable hard scattering that produces the final state. We assume collinear factorization to hold for quarkonium production in the CEM. Factorization has been proved for quarkonium production in NRQCD at high \(p_T\) \[26\] but not at low \(p_T\). The open charm flavor results at low \(p_T\) at the LHC \[13\] agree with calculations employing collinear factorization \[13\] better than calculations employing \(k_T\) factorization \[27\]. Collinear factorization should work better for bottom since the factorization scale and the \(x\) region probed are both larger.

Since the start of the LHC, several groups have performed global analyses of the nonperturbative matrix elements in the NRQCD approach up to NLO, see Ref. \[28\] and references therein for discussion and comparison of the results for \(J/\psi\) production data in \(e^+e^-, e+p, p+p\) and \(p+\bar{p}\) collisions. In Ref. \[28\], it is clear that the nonperturbative matrix elements are quite sensitive to the minimum \(p_T\) employed in the fits. These matrix elements do not appear to be universal since different data sets lead to quite different values of the matrix elements. Indeed, the agreement with the \(e^+e^-\) and \(e+p\) data is poor unless the minimum \(p_T\) is low, \(p_T \sim 3 \text{GeV}\), but these fits cannot reproduce the measured high \(p_T\) quarkonium polarization \[28\].

In addition, if the fitted matrix elements are used to calculate the \(J/\psi\) cross section at \(y = 0\) in \(p+p\) collisions as a function of \(\sqrt{s}\), good agreement with neither the shape nor the magnitude of the cross section can be obtained, see Ref. \[24\]. The results overshoot the measured cross sections significantly, sometimes by an order of magnitude \[24\]. This is not a surprising outcome because the integrated \(y = 0\) cross section is dominated by low \(p_T\) \(J/\psi\) production. In the same paper, the CSM cross sections are also compared to these data. It was found that only the LO CSM calculation produces a physical \(\sqrt{s}\) dependence that agrees relatively well with the data, at NLO some values of \(\mu_F\) give an unphysical energy dependence \[24\]. They also point out that the CEM produces the best agreement with the \(\sqrt{s}\) dependence over the entire range.

We also note that, while the CSM and NRQCD make predictions for the \(p_T\) dependence at relatively high \(p_T\), the region of interest for nuclear effects on the parton densities, as addressed here, is at low \(p_T\) and the CEM, through the application of \(k_T\) smearing, is the only production model that addresses the entire \(p_T\) range. Since the average \(k_T\) is an energy-dependent parameter, ideally this should be replaced by a low-\(p_T\) resummation.

Some recent results may provide improvements for NRQCD, at least at collider energies \[26,30,31\]. References \[30,31\] perform small \(x\) resummation in the color-glass condensate (CGC) in the NLO NRQCD approach with the nonperturbative matrix elements taken from the high \(p_T\) fits of Chao et al. \[32\]. The CGC gluon distribution is employed in the CGC+NRQCD calculation at low \(p_T\). This matches well with the high \(p_T\) NLO NRQCD calculation in the intermediate \(p_T\) range. Thus the entire \(p_T\) range of the data can be described within the combined approaches, both in \(p+p\) and \(p+\Lambda\) collisions for forward rapidities and sufficiently high \(\sqrt{s}\) \[30,31\]. The energy dependence of \(d\sigma/dy|_{y=0}\) is also reproduced quite well for \(\sqrt{s} > 0.2 \text{TeV}\) although agreement with the midrapidity RHIC data is rather poor \[30\]. This approach is inapplicable at lower \(\sqrt{s}\). Reference \[26\] presents a factorized power expansion for quarkonium production, including next-to-leading power (NLP) contributions to the perturbative part. This formalism requires fragmentation functions for heavy \(Q\bar{Q}\) pairs as well as for light partons. With the fragmentation functions and the NLP contributions included in NRQCD, it was found that the \(1S_0^{[1]}\) and \(1S_0^{[8]}\) components of the cross section are dominated by the NLP contributions over all \(p_T\), independent of the nonperturbative matrix elements \[26\]. This formalism describes \(J/\psi\) production well at collider energies for \(p_T > 10 \text{GeV}\). The possible dominance of the \(1S_0^{[8]}\) contribution in the total production rate could explain the apparent unpolarized \(J/\psi\) production. This conclusion is consistent with the data-driven approach to polarization in Ref. \[33\].

We note that the polarization has not yet been calculated in the CEM. While it should be straightforward at LO, to go to NLO one would have to start from a polarized \(Q\bar{Q}\) pair production code.

### B. Comparison of \(p+p\) Results

We now turn to a comparison of the \(J/\psi\) and \(\Upsilon\) \(p_T\) and rapidity distribution in \(p+p\) collisions for different proton parton densities. Our main results are obtained with the CT10 \[34\] parton densities, also used in our evaluations of
FIG. 1: (Color online) The gluon distribution function at the factorization scale for $J/\psi$ (a) and $\Upsilon$ (b) production. The CT10 (black), CTEQ5M (blue), CTEQ6M (red) and MSTW (magenta) are compared, all calculated with the same input parameters.

The charm and bottom cross sections [13, 14] where we find good agreement with the present quarkonium data within the mass and scale uncertainties. In Fig. 1 we compare the NLO CT10 gluon distributions to those from CTEQ5M [35], CTEQ6M [36] and MSTW [37]. The MSTW central NLO set is a rather recent, frequently used parton density shown as an alternative to CT10. It is available at LO, NLO and NNLO and has a low starting scale of $\mu_0^2 = 1$ GeV$^2$.

The CTEQ sets and CT10, at LO and NLO, have a starting scale of $\mu_0^2 = X$ GeV$^2$. The vertical lines at the top of the plots indicate the gluon density at forward, mid- and backward rapidity.

The CTEQ6M and CTEQ5M distributions were chosen because they have been used to extract the modifications of the parton densities in the nucleus. The CTEQ6M distributions were used in a global analysis of the nuclear modifications of the parton densities to obtain the EPS09 NLO sets [38]. They were also used in previous estimates of the quarkonium cross sections at the LHC [39]. The corresponding EPS09 LO sets were obtained based on the CTEQ61L densities, as we discuss in more detail later. The CTEQ5M distributions were used to extract the NLO nuclear modifications in the FGS sets [40]. Older distributions used to extract nuclear modifications are CTEQ4L [41] and GRV LO (EKS98 [43, 44]) and GRV98 LO and NLO (nDS [46]). Since these proton PDFs are now outdated, we do not show them here.

Figure 1 shows the gluon densities in the proton at the scales used to calculate $J/\psi$ (a) and $\Upsilon$ (b) production. The CT10 distributions, the most recent of all those considered, follow the previous CTEQ6 global analysis. The CT10 and CTEQ6M gluon distributions are almost identical. The earlier CTEQ5M set is quite different: the lowest $x$ value included in the analysis is $10^{-5}$ and, instead of extrapolating smoothly to lower values of $x$, the density is frozen such that $x g(x, \mu_0^2) \equiv x g(x = 10^{-5}, \mu_0^2)$. It also tends to be higher than the other gluon PDFs for $10^{-5} < x < 10^{-3}$.

The MSTW distribution is below the others for the $J/\psi$ factorization scale. All the gluon distributions are more similar at the $\Upsilon$ scale even though CTEQ5M is still somewhat higher for $10^{-5} < x < 10^{-2}$.

In Fig. 2, we show the shapes of the $J/\psi$ $p_T$ and $y$ distributions for the proton parton densities presented in Fig. 1. The $p_T$ distributions are shown in the region of rapidity overlap with the shifted $p+Pb$ range at forward rapidity, $2.96 < y < 3.53$. In $p+p$ collisions, the $p_T$ distributions at forward and backward rapidity are identical because the $y$ distributions are symmetric.

The results are given with the same CEM normalization, $F_C$, as found for the CT10 fits in Ref. [13]. Because the low $x$ gluon distributions differ in shape and magnitude, the values of the cross sections also differ by as much as $15 - 20\%$. If fits of $F_C$ were made with the three additional proton parton densities, the values of $F_C$ would clearly
FIG. 2: (Color online) The $J/\psi$ $p_T$ distribution at forward rapidity in $p + p$ collisions (a) and the $p_T$-integrated $y$ distribution (b). Results from CT10 (black), CTEQ5M (blue), CTEQ6M (red) and MSTW (magenta) are compared, all calculated with the same input parameters and using the same value of $F_C$ as for CT10.

FIG. 3: (Color online) The ratios of $J/\psi$ production as a function of $p_T$ at forward rapidity in $p + p$ collisions (a) and $y$ integrated over all $p_T$ (b) relative to CT10 for CTEQ5M (blue), CTEQ6M (red) and MSTW (magenta). By employing the same value of $F_C$ for all the sets, we emphasize the differences in magnitude as well as shape. The CTEQ5M distribution, higher than the other gluon densities at the $J/\psi$ scale for $x < 0.01$, results in a 20% larger overall cross section. This manifests itself at low $p_T$ where the integral difference is 32% and, most prominently, in the rapidity distribution around $y \sim 0$ where it is $\sim 50\%$ higher. The CTEQ5M gluon distribution, as already noted, takes a constant value for $x < 10^{-5}$. The rapidity distribution for the PDF is consequently narrower than the other three shown. The corresponding $p_T$ distributions do not reflect the $x < 10^{-5}$ behavior because, in the rapidity range illustrated, the low $p_T$ $J/\psi$’s are at higher $x$ values, see the $y = 4$ line in Fig. 1(a).

The similarity of the CT10 and CTEQ6M gluon distributions results in very similar $p_T$ and $y$ distributions. The
FIG. 4: (Color online) The Υ distribution at forward rapidity in $p + p$ collisions (a) and the $p_T$-integrated $y$ distribution (b). Results from CT10 (black), CTEQ5M (blue), CTEQ6M (red) and MSTW (magenta) are compared, all calculated with the same input parameters and using the same value of $F_C$ as for CT10.

MSTW set gives a 15% lower cross section for the $J/\psi$ with most of the difference at low $p_T$. The rapidity distributions are also slightly narrower than CT10 but less than that of the CTEQ5M calculation.

Figure 4 presents the ratios of the CTEQ5M, CTEQ6M and MSTW calculations to the CT10 results as a function of $p_T$ and $y$. Aside from the lowest $p_T$ bins, the ratios in Fig. 4(a) are practically independent of $p_T$ except for CTEQ5M which seems to show slow growth with $p_T$ after a strong drop at $p_T < 5$ GeV. For $5 < p_T < 30$ GeV, the ratios to CT10 all agree within 10%. The CTEQ6M result differs from CT10 by ~ 2% for $p_T > 5$ GeV. The $p_T$-integrated rapidity distributions in Fig. 4 are all quite different. While the CTEQ6M result is within 5% of that of CT10 over all rapidity, the other ratios are narrower. Note that the $p_T > 0$ ratio in Fig. 4(b) is larger than the ratio at $p_T > 5$ GeV in 4(a) because the $y$ distribution is dominated by low $p_T$. The sharp drop for CTEQ5M is where $x \sim 10^{-5}$. Since the MSTW gluon distributions do not have the same behavior, they are broader than CTEQ5M but the ratio is less than 0.7.

The corresponding Υ results are displayed in Figs. 4 and 5. The larger factorization scale makes the results all very similar in magnitude for this case with the integrated cross sections differing by less than 10%, even for CTEQ5M. The ratios as a function of $p_T$ are all relatively flat, especially between CTEQ6M and CT10. The largest difference among the results appears at large rapidities where there is a sudden increase in the ratio for $|y| \sim 5$, dropping off afterward where $x \sim 10^{-5}$ is reached for Υ production.

We have shown that the rapidity distributions are more dependent on the chosen baseline proton parton densities than the $p_T$ distributions. This arises because of the differing behavior of the low $x$ gluon densities. Due to the larger scale, the dependence on the proton parton densities is less important for the higher mass Υ.

IV. COLD NUCLEAR MATTER EFFECTS

To go beyond $p + p$ collisions, the proton parton densities must be replaced by those of the nucleus. We assume that if $A$ is a nucleus, the nuclear parton densities, $f_i^A(x_2, \mu^2)$, factorize into the nucleon parton density, $f_i^p(x_2, \mu^2)$, independent of $A$; and a shadowing ratio, $S_i^{p,S}(A, x_2, \mu^2)$ that parameterizes the modifications of the nucleon parton densities in the nucleus. The centrality dependence will be discussed elsewhere so here we deal with $S_i^A(A, x_2, \mu^2)$ alone. (Note that we refer to $x_2$ here since this is the $x_F$ dependence clearly shows that shadowing is not the only contribution to the
FIG. 5: (Color online) The ratios of $\Upsilon$ production as a function of $p_T$ at forward rapidity in $p+p$ collisions (a) and $y$ integrated over all $p_T$ (b) relative to CT10 for CTEQ5M (blue), CTEQ6M (red) and MSTW (magenta).

$J/\psi$ nuclear dependence as a function of Feynman $x_F = 2p_z/\sqrt{s}$ for the final-state particle \cite{47,48}. Indeed, the characteristic decrease of $\alpha(x_F)$ (in $d\sigma_{pA}/dx_F = (d\sigma_{pp}/dx_F)A^n(x_F)$) for $x_F \geq 0.25$ cannot be explained by shadowing alone \cite{49}. In fact, the data so far suggest approximate scaling with $x_F$, not the target momentum fraction $x_T$ \cite{50}.

The PHENIX data are consistent with an increase of effective ‘absorption’ at forward rapidity, as discussed in Ref. \cite{6}, similar to that seen in fixed-target experiments at large $x_F$ \cite{51}. We will compare our results for shadowing alone with the PHENIX data at the end of this paper.

Effects we do not consider here which affect the forward rapidity region in particular are energy loss in cold matter and intrinsic charm. The effect of energy loss, both with and without including shadowing, has been discussed in detail in Ref. \cite{52,53}. However, given the rather simple power law dependence employed for the $p+p$ distribution, it would be worth pursuing embedding this approach within a production model such as the CEM. Intrinsic charm is not considered here because the interesting region, $x_F \geq 0.25$, is inaccessible for quarkonium production in $|y| \leq 5$, see Ref. \cite{8}.

We do not include absorption by nucleons or comovers, which could affect the entire rapidity region, in this paper. The effective $J/\psi$ absorption cross section has been seen to decrease with energy at midrapidity \cite{54}. When shadowing is included, the $\sqrt{s}$ dependence is somewhat stronger due to the increased shadowing effect at low $x$ \cite{54}. If the nuclear crossing time is shorter than the $J/\psi$ formation time, the effective absorption decreases with $\sqrt{s_{NN}}$ as the state remains small during the entire time it spends in the target. However, absorption may play a role at the most backward rapidities when the quarkonium state is slow and can convert from the pre-resonance state to the final-state $J/\psi$ in the target \cite{6,55}. The $\Upsilon(1S)$ absorption cross section is expected to be smaller than that of the $J/\psi$ because of its smaller radius.

While the $J/\psi$-comover cross section is smaller than the nucleon absorption cross section, comovers may be more important for the excited charmonium and bottomonium states. (While these states have larger radii than the ground state quarkonium, this does not affect their potential absorption by nucleons since they still pass through the nuclear matter in their pre-resonant state.) Strong differences between the $J/\psi$ and $\psi'$ $R_{dAu}$ at RHIC as a function of collision centrality \cite{54} would support the importance of comovers since their density increases with centrality. Recent comover-based $p+Pb$ calculations show that this interpretation is consistent with the data \cite{57}.

V. NUCLEAR MODIFICATIONS OF THE PARTON DENSITIES

We use several parameterizations of the nuclear modifications in the parton densities (nPDFs) to probe the possible range of shadowing effects: EPS09 \cite{38}, EKS98 \cite{43,44}, nDS and nDSg \cite{46}, and the two FGS sets, FGS-H and FGS-L \cite{40}. Since $gg$ processes dominate quarkonium production over all measurable rapidities at the LHC, we focus more
on the behavior of the nuclear gluon parton densities in this section. Our main results in this paper are obtained with EPS09 NLO to make a fully consistent NLO calculation with the NLO CEM cross sections. However, in the following section, we will discuss the differences between the nPDF sets and between their LO and NLO manifestations on $J/\psi$ and $\Upsilon$ production in $p+\Pb$ collisions at $\sqrt{s_{NN}}=5$ TeV.

All these sets involve some data fitting, typically nuclear deep-inelastic scattering (nDIS) data with additional constraints from other observables such as Drell-Yan dimuon production. The fact that these sets also include Drell-Yan production and do not include initial-state energy loss in matter in their global analyses, they exclude the possibility of additional quark energy loss since incorporating both over counts the effect on the sea quark densities. (Of course, if energy loss is generated by gluon emission either from an initial-state gluon or from the produced $Q\bar{Q}$ pair, there is no energy loss possible in the Drell-Yan process, $q\bar{q} \rightarrow l^+l^-$, since a virtual photon generates a lepton pair.) None of these data provide any direct constraint on the nuclear gluon density. It is thus obtained through fits to the $\mu^2$ dependence of the nuclear structure function, $F_2^A$, and the momentum sum rule. The useful perturbative $\mu^2$ range of the nDIS data is rather limited since these data are only available at fixed-target energies. Thus the reach in momentum fraction, $x$, is also limited and there is little available data for $x<10^{-2}$ at perturbative values of $\mu^2$. This situation is likely not to improve until an $eA$ collider is constructed \cite{58}. We discuss the various nuclear modifications in order of their release.

The EKS98 parameterization, by Eskola and collaborators \cite{43, 44}, available for $A>2$, is a leading order fit using the GRV LO \cite{42} proton parton densities as a baseline. The first EKS98 fits \cite{42} used the GRV LO proton densities from 1992 \cite{42}. This set employed a starting scale of $\mu_0^2 = 0.3$ GeV. The set eventually released as EKS98 was constructed with CTEQ4L \cite{41} with initial scale of $\mu_0 = 1.6$ GeV. To match the starting scale of the EKS98 nPDF set, the CTEQ4L distributions were backward evolved from $\mu = 1.6$ GeV to 1.5 GeV \cite{44}. They checked that the nPDF results from these two proton PDFs were consistent even though the proton PDFs themselves were quite different: the GRV LO set employed a valence-like gluon distribution at the starting scale, $xg(x, \mu_0^2) \sim x^{\alpha} P(x)$ where $\alpha>0$ and $P(x)$ is a polynomial function, while CTEQ4L takes $\alpha<0$, giving $xg(x, \mu_0^2)$ a finite value as $x \to 0$. The minimum scales of the two sets are also very different. The kinematic range of EKS98, the only leading order set we consider since no NLO set was obtained at the time, is $1.5 \leq \mu \leq 100$ GeV and $10^{-6} \leq x < 1$. All the sets produced by Eskola and collaborators are based on piecewise functions at the minimum scale of the set that include small $x$ shadowing, antishadowing at intermediate $x$, an EMC region (named for the effect first identified by the European Muon Collaboration) with $R_g < 1$ at larger $x$ and Fermi motion as $x \to 1$.

deflorian and Sassot produced the nDS and nDSg parameterizations \cite{46} at both leading and next-to-leading order for $4 < A < 208$. Their results were based on the GRV98 proton PDFs at LO and NLO \cite{43}, using the same starting scales as GRV98, $\mu_{0,LO}^2 = 0.40$ GeV, and $\mu_{0,NLO}^2 = 0.25$ GeV. GRV98 assumed valence-like input for the sea quarks and gluons at the minimum scales with $x\bar{g}(x, \mu_0^2) = 0$. The GRV98 gluon densities are not significantly different at low $x$ when evolved to higher scales. The leading order set has a somewhat higher gluon density at low $x$ \cite{42}. Of the two deFlorian and Sassot sets, nDS and nDSg, the first, nDS, is an unconstrained fit that gives the best fit, $\chi^2$. To provide a set with stronger gluon shadowing, they constrained a second fit to give $S_{3g}^N \equiv 0.75$ at $x = 0.001$ and $\mu^2 = 5$ GeV$^2$. This set, nDSg, was a much poorer fit to the New Muon Collaboration (NMC) and SLAC nDIS data and the E772 Drell-Yan cross sections \cite{46}.

They showed that their results for the suppression factor for $\pi^0$ production at RHIC, $R_{\pi^0}(p_T)$, at both LO and NLO were in agreement with each other \cite{46}. This should be the case for a consistent order-by-order extraction of the nPDFs: not that the shadowing ratios are similar but that they give similar observable results, such as the nuclear suppression factors. The kinematic reach in $x$ is the same as EKS98 while the $\mu^2$ range is larger, $1 < \mu^2 < 10^6$ GeV$^2$.

The FGS sets by Frankfurt, Guzey and Strikman take the highest initial scale of all the nPDF sets, $\mu = 2$ GeV \cite{49}. They only provide NLO sets. Instead of a general global analysis, their nPDFs are based on the leading-twist approximation and rely on the diffractive PDFs. The Gribov-Glauber approach employed naturally introduces a centrality dependence for the shadowing. Their baseline proton parton densities are the CTEQ5M distributions. Therefore, their extraction is only good for $x > 10^{-5}$.

They extracted two sets to represent an upper and a lower bound on the shadowing ratios. FGS-H is gives stronger shadowing based on the two-nucleon scattering cross section. FGS-L is based instead on the $\pi N$ scattering cross section. Since this is larger than the two-nucleon scattering cross section, the shadowing effect derived in this case is weaker. Their approach is only applicable for $x \leq 0.1$. For $x > 0.1$, the sea quark ratio relative to the nucleon is fixed to unity and gluon antishadowing is obtained through the momentum sum rule. Hence, in this high $x$ region, the two parameterizations are identical. Their approach does not allow predictions for shadowing on the valence quark distributions, these are taken from the LO EKS98 set. The FGS sets are available only for some specific nuclei where diffractive data exist: $^{12}$C, $^{40}$Ca, $^{110}$Pd, $^{197}$Au and $^{208}$Pb. The sets are valid in $10^{-5} < x < 0.95$ and $2 < \mu < 100$ GeV.

The EPS09 \cite{38} LO and NLO parameterizations included uncertainties on the global analyses, both at LO and NLO, by varying one of the 15 fit parameters within its extremes while holding the others fixed. The upper and
lower bounds on EPS09 shadowing are obtained by adding the resulting uncertainties in quadrature. The EPS09 central LO results are in quite good agreement with the older EKS98 parameterization. The EPS09 LO sets are based on the CTEQ61L densities which are nearly flat at the initial scale as \( x \to 0 \). The EPS09 NLO densities are based on the CTEQ6M densities. Starting with CTEQ6M, a valence-like shape for the gluon distribution was adopted at the starting scale, in this case the charm mass threshold of \( \mu_0 = 1.3 \text{ GeV} \). The EPS09 sets assume the same starting scale as the CTEQ6 sets and is valid in the range \( 10^{-6} < x < 1 \).

Figure 6 shows the sets we have discussed in this section at the scale of \( J/\psi \) (a) and \( \Upsilon \) (b) production. The results are shown for \( x \) values as low as \( 10^{-6} \). The EPS09 NLO sets are shown in the black solid and dotted curves. The solid curves show the central results while the dotted curves outline the NLO bands. The EPS09 results for \( J/\psi \) show a change in curvature, almost a dip, at \( x \sim 0.01 \), with a small rise at lower \( x \) followed by an eventual decrease. There is a rather strong antishadowing peak from \( 0.02 < x < 0.2 \) where the ratio drops below unity again, in the EMC region.

The EKS98 LO ratio is similar to that of the central EPS09 LO set but decreases more smoothly, giving a stronger shadowing at lower \( x \) than the NLO set, a 40% shadowing effect at \( x = 10^{-6} \) rather than the 30% effect at NLO. At the lowest \( x \) values, the central EPS09 LO is equivalent to the lower limit of the EPS09 NLO band.

The FGS-H and FGS-L sets are similar to the others but are somewhat narrower in the antishadowing region. However, they decrease faster with decreasing \( x \) than any of the other sets shown. They drop sharply at \( x = 10^{-5} \). Instead of either fixing the ratio at its value at \( x = 10^{-5} \), as in the CTEQ5M proton PDF set, or trying to make a smooth extrapolation to lower \( x \), it simply falls off more like a step function.

The nDS set has somewhat stronger shadowing that the upper limit of the EPS09 NLO set while the nDSg set is between the EPS09 NLO central and lower limits. These sets, of all the results shown, have no antishadowing at all.

The same features can be observed for the shadowing ratios at the \( \Upsilon \) scale. The EPS09 band now decreases more smoothly as \( x \) decreases. The FGS-H and FGS-L ratios show the steep drop at the limit where \( x = 10^{-5} \) more clearly at the larger scale. All the slopes of the other nPDF sets become rather similar.

VI. RESULTS

We now show calculations of the \( J/\psi \) and \( \Upsilon \) production ratios, \( R_{p_{\text{Pb}}} \) and \( R_{FB} \) as a function of rapidity and \( p_T \), taking only nuclear shadowing effects into account. We begin with comparing results with the same shadowing
FIG. 7: (Color online) The $J/\psi$ ratio $R_{pPb}(p_T)$ for ALICE at forward rapidity $2$ (a) and $p_T$-integrated as a function of rapidity $1$ (b). The ratios are shown for CT10 (black), CTEQ6M (blue), CTEQ5M (red) and MSTW (magenta).

parameterization calculated with different proton PDFs in Sec. VI A These results are shown for the $J/\psi$ only and compared to a subset of the available data. In the remainder of this section, we compare the calculations to the full $J/\psi$ and $\Upsilon$ data sets from ALICE and LHCb. We show the measurements compared to the EPS09 NLO uncertainty bands in Sec. VI B. Next, we compare and contrast the leading and next-to-leading order shadowing results of EPS09 and nDS in Sec. VI C. Thereafter, the results from the nPDF sets shown in Fig. 6 are compared to the data and each other in Sec. VI D. The mass and scale uncertainties on the central EPS09 set are compared to the uncertainties in the shadowing parameterizations themselves in Sec. VI E. Next we discuss how well the $A+A$ results factorize into a product of $p+A$ and $A+p$ collisions in Sec. VI F. Finally, we present the EPS09 NLO uncertainty bands for RHIC kinematics in Sec. VI G.

A. Comparison of EPS09 NLO for Different Proton PDFs

To begin, we check whether or not the shadowing results depend on the chosen set of proton parton distributions. As demonstrated in Sec. III B the choice of proton PDF has a strong effect on the shape of the individual $p+p$ distributions. We now want to find out of this also means a change in the shape of the nuclear suppression factors since each shadowing parameterization is based on different proton PDFs. We employ the central EPS09 NLO set for this study.

The results for $R_{pPb}(p_T)$ and $R_{pPb}(y)$ are shown in Fig. 7. The left hand side shows $R_{pPb}(p_T)$ for the ALICE forward rapidity bin, $2.03 < y_{\text{cms}} < 3.53$ while the right-hand side displays the $p_T$-integrated $R_{pPb}(y)$. The only visible difference between the results is for the lowest $p_T$ bin shown, $1 < p_T < 2$ GeV, where the difference is $\sim 4\%$ between the ratios with CTEQ5M and MSTW relative to CT10. There is no difference in the CT10 and CTEQ6M ratios. At higher $p_T$, the difference is negligible. Some variation on the order of the percent level is seen as a function of rapidity, particularly in the backward region. Since these variations are significantly less than those between the nPDFs themselves, we see that the choice of proton PDF has a negligible effect on the results.

B. EPS09 NLO Uncertainties

Here we present the EPS09 NLO uncertainties in $J/\psi$ and $\Upsilon$ production. We will compare the calculated nuclear suppression factor, $R_{pPb}$, and the forward-backward ratio, $R_{FB}$, to the ALICE and LHCb data.
FIG. 8: (Color online) The $J/\psi$ ratio $R_{p\text{Pb}}$($p_T$) in the ALICE acceptance at forward (a), backward (b) and central (c) rapidity. The ratio $R_{p\text{Pb}}$($y$) is shown in (d). The EPS09 NLO uncertainty band is shown.

1. $J/\psi$

Figure 8 compares the suppression factors for $J/\psi \rightarrow \mu^+\mu^-$ as a function of $p_T$ at forward (a) and backward (b) rapidity as well as for $J/\psi \rightarrow e^+e^-$ at midrapidity (c). The rapidity dependent ratio is shown in (d). The solid curves show the EPS09 NLO central results while the dashed curves outline the upper and lower limits of the EPS09 NLO uncertainty band. In all cases, the bands on the EPS09 NLO uncertainties are obtained by adding the differences in the results obtained by varying each parameter separately by one standard deviation of the fit in quadrature.

In general, the $p_T$-dependent data are in relatively good agreement with the EPS09 NLO bands, if not with the central values themselves. In the forward region, the measured $R_{p\text{Pb}}$ is compatible with the lower edge of the uncertainty band for $p_T < 6$ GeV. The data at backward rapidity also suggest a somewhat stronger cold matter effect, compatible with the upper edge of the band. While the uncertainties on the data at midrapidity are larger than those on the calculation, the data again indicate a somewhat stronger effect than suggested by EPS09 NLO. However, within the uncertainties of both the data and the calculations, the results are, in general agreement.
FIG. 9: (Color online) The $J/\psi$ forward-backward ratio $R_{FB}(p_T)$ in the ALICE overlap region, $2.96 < y_{\text{cms}} < 3.53$ (a) and $R_{FB}(y)$ (b). The EPS09 NLO uncertainty band is shown with the ALICE [1] and LHCb [4] data.

A similar conclusion can be drawn from the $p_T$-integrated rapidity dependence. The ALICE data at forward and backward rapidity are shown in two ways: a single $p_T$-integrated point over the entire rapidity acceptance and with each broad $y$ bin broken up into six separate bins. While the smaller bins are almost independent of $y$ in the backward region, there is a decrease in $R_{p\text{Pb}}(y)$ in the forward region. The overall observed dependence of $R_{p\text{Pb}}(y)$ is in good agreement with the $p_T$-dependent results in Fig. 8(a)-(c). While the LHCb are within one standard deviation of the ALICE data, they are somewhat lower.

As discussed previously, the suppression factor $R_{p\text{Pb}}$ is somewhat artificial since there is currently no $p+p$ reference measurement at the same energy as the $p+\text{Pb}$ data. Instead the reference is obtained from an interpolation between the $p+p$ measurements at 2.76 and 7 TeV, as described in Sec. II. The forward-backward ratio reduces the systematic uncertainty.

The results are compared to the $J/\psi$ calculations in Fig. 9. We note that the uncertainties on the ratio are narrower than those of the forward and backward regions separately, as shown in Fig. 8. The uncertainty bands are formed by taking the forward-backward ratios for each of the 31 EPS09 sets individually and then adding the uncertainties in quadrature. The calculated ratios are almost independent of $p_T$. This behavior is due to the fact that the forward ratio is less than unity and increasing with $p_T$ while the backward ratio is greater than unity over most of the $p_T$ range. The data instead show a minimum at low $p_T$, increasing to $R_{p\text{Pb}} \sim 0.8$ at $p_T \sim 8$ GeV, albeit with large statistical uncertainties.

The calculated ratios as a function of rapidity are very narrow for $y < 2.5$ before broadening at larger $y$. This behavior is obvious from looking at $R_{p\text{Pb}}(y)$ since, for $y > -2.5$ the uncertainty band is parallel to the central value and almost linear so that when the forward-backward ratio is formed, the band is compressed. The ratio $R_{FB}(y)$ broadens and decreases at $y > 3$, where, at backward $y$, $R_{p\text{Pb}}(y)$ enters the antishadowing region. The forward-backward ratio narrows again at $y \sim 4$, near the ‘pinch’ in $R_{p\text{Pb}}(y)$, where the data are best constrained, and finally broadens again in the antishadowing regime where the constraints are poorer. The data are below the calculated band because, while the backward region is rather well described, the central value is above the data at forward rapidity. We note that while the ALICE $R_{FB}(y)$, in a smaller rapidity range, is almost flat, the LHCb ratio varies more. However, in the bin where the rapidity ranges of the two experiments overlap, they are in good agreement.

Finally we remark on the recent ATLAS forward-backward measurement of $R_{FB}(p_T)$ in the central region, $|y_{\text{cms}}| < 1.94$ and $R_{FB}(y)$ for $8 < p_T < 30$ GeV [16]. Their results are consistent with unity in both $p_T$ and $y$ and agree well with our EPS09 NLO calculations. The results shown in Fig. 9(a) are in the forward region while the ATLAS measurement is at midrapidity. Given the higher scale implicit in the $p_T$ range covered by ATLAS, as well as the higher $x$ in the rapidity range covered by ATLAS, it is unsurprising that the EPS09 NLO result is consistent with unity here. Similarly, given that the EPS09 NLO result integrated over $p_T$ in Fig. 9(b) is already similar to unity for $|y| < 1.5$, we can expect that the same ratio for $p_T > 8$ GeV has a more shallow slope and deviates less from unity.
than the results compared to ALICE and LHCb here.

2. \( \Upsilon \)

The results for the \( \Upsilon \) suppression factor, \( R_{pPb} \), are shown in Fig. 10. In this case, the data are insufficient to form \( R_{pPb}(p_T) \) or \( R_{FEB}(p_T) \). In addition, no midrapidity \( e^+e^- \) \( \Upsilon \) measurement has been reported. It is also not possible to separate \( R_{pPb}(y) \) into smaller bins due to the low statistics. Finally, the ALICE and LHCb \( \Upsilon \) data, in the forward and backward rapidity bins, while within one standard deviation of each other, do not appear to be in very good agreement with each other. Therefore, it is more difficult to draw conclusions about the \( \Upsilon \) results.

The \( p_T \)-dependent ratios differ from those for \( J/\psi \) most at low \( p_T \). In particular, the backward rapidity region shows an antishadowing effect already at low \( p_T \). At higher \( p_T \) values, the scales are similar since \( p_T > m \) in both cases. The EPS09 NLO uncertainty band is somewhat narrower, especially as a function of rapidity, where the ALICE and LHCb \( \Upsilon \) data are both shown. The agreement with the LHCb data is quite good while the agreement with ALICE is rather poor. The two data sets are approximately within one standard deviation of each other but LHCb is indicative of antishadowing at the approximate rapidity of the EPS09 NLO antishadowing peak while the ALICE result is not. At forward rapidity, the ALICE \( J/\psi \) and \( \Upsilon \) results for \( R_{pPb} \) are similar.

The \( \Upsilon \) forward-backward ratio is shown in Fig. 11. The \( p_T \)-dependent ratio is lower than that of \( J/\psi \) due to the greater \( \Upsilon \) antishadowing. The uncertainty is larger because the uncertainty on the backward rapidity \( J/\psi \) \( R_{pPb} \) is narrower than for \( \Upsilon \) since the ALICE \( J/\psi \) region is near the ‘pinch’ between the shadowing and antishadowing regions while the \( \Upsilon \) rapidity is directly in the region where the uncertainties are larger for gluons. This is also reflected by the rapidity dependence.

C. Comparison of Leading and Next-to-Leading Order Results

Previously we reported that the shadowing parameterizations gave the same results for the LO and NLO cross sections \([59]\). That result was based, however, on employing the LO EKS98 set in the LO and NLO CEM calculations. In addition, other authors have suggested that the order of the calculation does not matter and NLO nPDF sets can be used with LO quarkonium calculations. It is worth checking these assumptions in detail.

As discussed in the previous section, the nDS and nDSg LO and NLO sets were checked for consistency for the PHENIX \( \pi^0 \) data \([40]\). We now do the same for \( J/\psi \) and \( \Upsilon \) production as a function of rapidity for EPS09 LO and NLO and for nDS and nDSg LO and NLO in Fig. 12.

The shadowing parameterizations are compared in Fig. 12 (a) and (b). There are considerable differences between the EPS09 bands at \( x < 0.01 \). The NLO result has a different curvature than the LO one, changing slope and becoming flatter, decreasing slowly as \( x \) is lowered. On the other hand the LO bands decrease smoothly. There is, however, very little difference in the upper limit of the band, with the weakest shadowing effect. The difference is more pronounced for the central sets and striking for the lower limit of the band, with the strongest shadowing. In this case, the lower NLO limit is close to the central EPS09 LO set. There is also some difference between the nDS and nDSg parameterizations. While the difference is essentially negligible for the nDS set, there is a stronger deviation between the nDSg curves, particularly around \( x \sim 0.01 \). For \( x < 0.002 \), the ratios are parallel.

We now turn to whether these differences affect \( R_{pPb}(y) \) for quarkonium production. The EPS09 LO calculation is made with a fully LO CEM calculation in \( 2 \rightarrow 1 \) kinematics. The NLO calculation is with the NLO matrix elements in the CEM.

Results are shown for in Fig. 12 (c) and (d). There is clearly a strong effect for EPS09 with the central LO result passing through the ALICE and LHCb data while only the lower limit of the NLO band reaches the data, an ap+proximate 15% difference between the two results. However, the nDS and nDSg results, while clearly not on top of each other, as they are for the \( \pi^0 \) calculation \([40]\), agree within \( \sim 3\% \).

Why is one derivation nearly consistent order by order and the other is not? We suspect that the primary cause is the low \( x \) behavior of the baseline proton parton densities, as already mentioned in Sec. \( \blacksquare \). The CTEQ6M, GRV98 LO and GRV98 NLO gluon distributions are all based on valence-like initial distributions at \( \mu_0 \), \( x^\alpha P(x) \). However, the CTEQ6IL gluon density takes an almost constant finite value at \( \mu_0^2 \), i.e. \( \alpha \sim 0 \). This initial difference carries forward over all \( \mu^2 \) because the NLO set must have stronger \( \mu^2 \) evolution to fit the same sets of DIS data as at LO. Thus the CTEQ6IL distribution evolves much more rapidly in \( \mu^2 \) than does CTEQ6IL. At the factorization scale of \( \Upsilon \) production, the difference between CTEQ6M and CTEQ6IL is still substantial while the GRV98 LO and NLO gluon distributions, with similar starting behavior, are closer together. The EPS09 LO shadowing thus has to be stronger at low \( x \) to produce the same behavior at higher scales as the EPS09 NLO shadowing. The compensation does not have
FIG. 10: (Color online) The Υ ratio $R_{pPb}(y)$ in the ALICE acceptance at forward (a), backward (b) and central (c) rapidity. The ratio $R_{pPb}(y)$ is shown in (d). The EPS09 NLO uncertainty band is shown.

There are, however, valid reasons for there to be a few percent difference between the LO and NLO results seen with nDS and nDSg. The LO CEM calculation is a $2 \rightarrow 1$ process with fixed values of $x_1$ and $x_2$ for a given $y$ since there is no $p_T$ scale in the calculation, only in the factorization scale which can be adjusted to include an average value of $p_T$. The NLO calculation, on the other hand, includes $2 \rightarrow 2$ and $2 \rightarrow 3$ processes (the LO+virtual and real contributions respectively) to the NLO CEM result. The NLO CEM calculation does not have a fixed correspondence between $x_1$, $x_2$ and $y$ because of the $p_T$ scale. This higher scale can also lead, on average, to a larger factorization scale and a somewhat larger $x_2$ on average in the NLO calculation. All these differences can cumulatively lead to the $2 - 3\%$ effect between LO and NLO observed for the nDS sets. Similar arguments can also explain the differences to be as large for the nDS sets since the GRV98 LO and NLO sets are more similar at low $x$ and the scale relevant for quarkonium production.

The agreement between the EPS09 LO and NLO results is not improved for the higher scale of Υ production, as shown in Fig. 12 (e) and (f). The higher scale, as already noted, weakens the shadowing and narrows the uncertainty bands but does not bring the central results at LO and NLO into better agreement. This conclusion is likely independent of the specific final state as long as its production is dominated by low $x$ gluons.
FIG. 11: (Color online) The $\Upsilon$ forward-backward ratio $R_{FB}(p_T)$ in the ALICE overlap region (a) and $R_{FB}(y)$ (b). The EPS09 NLO uncertainty band is shown, along with the ALICE [3] and LHCb [5] data.

between the LO CEM and LO CSM [60] results and are not directly attributable to the production mechanism per se.

D. Comparison of Shadowing Parameterizations

In this section, we compare the central EPS09 NLO results to those with other shadowing parameterizations.

1. $J/\psi$

Figures 13 and 14 compare the NLO nDS, nDSg, FGS-H and FGS-L results to the central EPS09 NLO result (shown in black). The results with the EKS98 LO set are also shown. In the $p_T$ ratios, the EPS09 central set tends to underestimate the effect relative to the data except at backward rapidity. Indeed, at forward and midrapidity, the nDS set is the only one that underestimates the data more since it has the weakest gluon shadowing. At backward rapidity, the nDS result is close to unity over all $p_T$ while nDSg exhibits some shadowing. This is because these two sets have no gluon antishadowing. At forward rapidity, the FGS-H and FGS-L sets result in the strongest effect, significantly stronger than the data in the case of FGS-H. The set that comes closest to agreement with the data in all three rapidity regions is EKS98 which only overestimates the shadowing effect for $p_T > 6$ GeV.

In all cases the $p_T$-dependent results for all the nPDF sets shown agree within 10% for $p_T > 10$ GeV. This can be expected because the evolution of the modifications is relatively strong for the gluons.

As seen in Fig. 13(a), the spread between predictions is largest in the forward region where the shadowing predictions differ most. Indeed, in the $p_T$ bin centered at 1.5 GeV, there is a factor of $\sim 8$ between the values of $R_{p\text{Pb}}$. The gap is reduced to $\sim 1.3$ by $p_T \sim 3.5$ GeV. The weakest $p_T$ dependence is given by the calculations with nDS and the central EPS09 NLO set. The nDSg set also results in a weak $p_T$ dependence but has a stronger overall shadowing effect. The strongest shadowing comes from the FGS sets which overpredict the shadowing strength. The best agreement with the ALICE data is obtained for the EKS98 LO set which has no NLO counterpart. We note that the measured $R_{p\text{Pb}}$ approaches unity at $p_T \sim 7$ GeV while none of the shadowing parameterizations give a result approaching unity over the entire $p_T$ range shown.

In the backward region, illustrated in Fig. 13(b), the results show some antishadowing, except for nDS and nDSg which specifically exclude it. All the calculations lie below the centroids of the data, partly because the ALICE acceptance is centered on the side of the antishadowing peak so that the calculated antishadowing is, on average,
FIG. 12: (Color online) The EPS09 central results, as well as the uncertainty bands, are shown in (a), (c) and (e). In all cases, the solid red curve shows the central NLO result while the dashed red curves delineate the NLO uncertainty band. The dot-dashed blue curve is the LO central result while the dotted curves outline the LO uncertainty band. The nDS and nDSg results are presented in (b), (d) and (f). The red solid curves show the NLO nDS result while the dashed red curves are the
FIG. 13: (Color online) The $J/\psi$ ratio $R_{p\text{b}}(p_T)$ in the ALICE acceptance at forward (a), backward (b) and central (c) rapidity [2]. The ratio $R_{p\text{b}}(y)$ for ALICE [1] and LHCb [4] is shown in (d). The results are shown for central EPS09 NLO (black), nDS NLO (blue dashed), nDSg NLO (blue dot-dashed) and EKS98 LO (magenta dot-dot-dash-dashed), FGS-H (red dot-dash-dash-dashed) and FGS-L (red dot-dot-dot-dash).

The $p_T$-dependent results from the nPDF sets come closest together in the midrapidity bin, with a spread of at most 30%, as seen in Fig. 13(c). Although the data again suggest stronger shadowing at midrapidity than the calculations, the uncertainties in the data are large since the number of $J/\psi$ in this bin are lower by more than a factor of 100 than in the forward and backward bins, see Table I. In this rapidity range, the shadowing effect is reduced to less than 10% for $p_T > 10$ GeV with all sets.

The largest difference in the $R_{p\text{b}}$ ratios is as a function of rapidity, shown in Fig. 13(d), since the $p_T$-integrated ratios access the lowest $x$ values. The ratios are closest at backward rapidity, not surprisingly, because the EPS09 NLO and EKS98 sets follow each other closely for $x > 0.002$, see Fig. 13(a). Since the FGS sets are somewhat narrower in the antishadowing $x$ region, this is manifested as an apparent shift toward negative rapidity in the antishadowing peak for the $J/\psi$. The EPS09 NLO and EKS98 are in closest agreement with the integrated ALICE rapidity bin which lower than that of the data. Note also that the antishadowing peak is broad in $p_T$, with some antishadowing remaining at $p_T \sim 15$ GeV.
FIG. 14: The $J/\psi$ forward-backward ratio $R_{FB}(p_T)$ in the ALICE overlap region (a) and $R_{FB}(y)$ (b) \[1\]. The ratios are for central EPS09 NLO (black), nDS NLO (blue dashed), nDSg NLO (blue dot-dashed) and EKS98 LO (magenta dot-dot-dot-dash), FGS-H (red dot-dash-dash-dashed) and FGS-L (red dot-dot-dot-dot-dash).

is larger than unity. The ALICE data were split into six smaller bins in both the forward and backward rapidity bins. In the backward region, the smaller bins are almost independent of rapidity which is not consistent with any of the shadowing results. Since the LHCb backward rapidity result is below unity, only the nDS result is not in agreement with LHCb.

The ratios separate further in the shadowing regions at mid and forward rapidity. Since the ALICE $p_T$-integrated ratio at midrapidity is almost the same as that at forward rapidity, albeit with somewhat larger uncertainty, the midrapidity point is only in agreement with the FGS-L and FGS-H sets. This is not surprising: because of their steep drop at low $x$, they show stronger shadowing than EKS98 already at $x \sim 0.001$ and considerably overestimate the effect at forward rapidity where $x < 10^{-5}$. In the forward bin, the EKS98 and nDSg results are in best agreement with the ALICE and LHCb results. The ALICE forward bin, when split into smaller bins, shows a linear dependence on rapidity but with a slope steeper than any of the shadowing calculations. Overall the EKS98 parameterization, one of the oldest and LO only, agrees best with the data. Since it is similar in shape to the EPS09 LO central set, shown in Fig. 12(a), this is not surprising. The EPS09 LO and EKS98 sets, based on CTEQ61L and CTEQ4L respectively, are the only sets of those from EPS09 and nDS that are not based on valence-like gluon distributions in the proton and are thus subject to slower scale evolution.

In Fig. 14 the forward-backward ratios are shown as functions of $p_T$ and $y$. The EPS09, nDS and nDSg ratios are nearly independent of $p_T$, thus above the data over most of the $p_T$ range. The EKS98 and FGS sets have a somewhat stronger dependence on $p_T$ and thus agree more closely with the forward-backward ratio at low $p_T$. However, of these, only the FGS-L and EKS98 sets are in agreement with the rapidity-dependent ratio. All the sets, with the exception of the central EPS09 NLO set, give forward-backward ratios that are linear in $y$. As already discussed this is due to the abrupt change in slope of EPS09 NLO at $x \sim 0.002$, see Fig. 6(a), at the transition from shadowing to antishadowing, absent from the other sets shown.

Overall, the EKS98 LO set seems to agree best with the $J/\psi$ data, both $R_{pPb}$ and $R_{FB}$. This is somewhat less than satisfying since we are using a LO nPDF set with a NLO cross section calculation. In addition, it is one of the older sets employed here. However, it agrees rather well with EPS09 LO when calculated with LO matrix elements, even though the baseline proton PDF and its behavior at low $x$ is very different. We had previously demonstrated that the ratio $R_{pA}(y)$, calculated at LO and NLO with the EKS98 LO set, gave almost identical results at each order 59. This is not a surprise since the $gg$ contribution dominates production both at LO and NLO and the shift in $x$ and $\mu^2$ due to the different scales is small when integrated over $p_T$. 
2. Υ

Figures 15 and 16 present the results for Υ production in the same rapidity ranges. The $p_T$-dependent $R_{pPb}$ ratios shown in Fig. 15(a)-(c) exhibit somewhat less spread than the counterpart $J/\psi$ calculations. The main difference is that now, at the higher scale and correspondingly larger $x$ probed, the antishadowing peak for Υ production is fully within the acceptance of ALICE and LHCb in the backward direction. Thus $R_{pPb}(p_T) > 1$ over all $p_T$ in Fig. 15(b) with $R_{pPb}(p_T \sim 1.5 \text{ GeV}) \sim 1.2$.

The rapidity-dependent ratio, $R_{pPb}(y)$, shown in Fig. 15(d) echoes the low $p_T$ results. Even the nDS and nDSg ratios are above unity in the backward rapidity region, albeit in the backward edge of the experimental acceptance. This is because, in the high-$x$ region, these sets become large as $x \to 1$ with the turn on of this effect beginning at $x \sim 0.5$ and the region of $x \sim 0.1$ is where the gluon distribution becomes larger than unity. We note that even though the FGS gluon ratios are only somewhat narrower than the EPS09 NLO ratio for the same scale, see Fig. 6(b),
The forward-backward ratio $R_{FB}(p_T)$ in the ALICE overlap region (a) and $R_{FB}(y)$ (b). The ALICE [3] and LHCb [5] data are shown in (b). The ratios are shown for central EPS09 NLO (black), nDS NLO (blue dashed), nDSg NLO (blue dot-dashed) and EKS98 LO (magenta dot-dot-dash-dashed), FGS-H (red dot-dash-dash-dashed) and FGS-L (red dot-dot-dot-dash).

FIG. 16: The Υ forward-backward ratio $R_{FB}(p_T)$ in the ALICE overlap region (a) and $R_{FB}(y)$ (b). The ALICE [3] and LHCb [5] data are shown in (b). The ratios are shown for central EPS09 NLO (black), nDS NLO (blue dashed), nDSg NLO (blue dot-dashed) and EKS98 LO (magenta dot-dot-dash-dashed), FGS-H (red dot-dash-dash-dashed) and FGS-L (red dot-dot-dot-dash).

E. Mass and Scale Dependence

In this section, we discuss the mass and scale dependence of the shadowing ratios, using the EPS09 NLO set as an example. Similar results are expected for the other nPDFs but we choose EPS09 NLO here be-
cause we can compare the shadowing uncertainty to that of the mass and scale. Recall that for charm-$J/\psi$ we employ \((m, \mu_F/m, \mu_R/m) = (1.27 \pm 0.09 \text{ GeV}, 2.1^{+2.55}_{-0.85}, 1.6^{+0.11}_{-0.12})\) while for bottom-$\Upsilon$ production, we employ \((m, \mu_F/m, \mu_R/m) = (4.65 \pm 0.09 \text{ GeV}, 1.4^{+0.77}_{-0.49}, 1.1^{+0.22}_{-0.20})\).

The uncertainties of the EPS09 NLO nPDF sets compared to those of the mass and scale uncertainties on \(d\sigma/dp_T\) for the $J/\psi$ are illustrated in Fig. [17] Here the ALICE $p_T$ distributions in $p+\text{Pb}$ collisions [2] are compared to our NLO CEM calculations. The red solid and dashed curves are the central EPS09 NLO results with the uncertainty band due to the EPS09 parameter variations. This band is rather narrow on the scale of the plots with the only clear separation between the curves at low $p_T$ where the shadowing effects are largest. Clearly, a 20-40% effect on $R_{\text{pPb}}(p_T)$ on a linear scale in this region results in a narrow band on the $p_T$ distribution itself on a logarithmic scale. We do not show the lowest $p_T$ results because the underlying $p+p$ calculation does not accurately numerically cancel the divergences in the negative weight Monte Carlo [22]. The intrinsic $k_T$ kick used to obtain the shape of the $p_T$ distribution in the low-$p_T$ region was fixed at RHIC energies and successfully compared to the $J/\psi$ $p_T$ distributions at $\sqrt{s} = 7 \text{ TeV}$ [13].

The magenta curves in Fig. [17] show the uncertainty due to the mass and scale variations. The mass and scale uncertainties are calculated based on results using the one standard deviation uncertainties on the quark mass and scale parameters. If the central, upper and lower limits of $\mu_F/m$ are denoted as $C$, $H$, and $L$ respectively, then the seven sets corresponding to the scale uncertainty are \(\{(\mu_F/m, \mu_F/m)\} = \{(C,C), (H,H), (L,L), (C,L), (C,H), (H,C)\}\). The uncertainty band can be obtained for the best fit sets by adding the uncertainties from the mass and scale variations in quadrature. The envelope containing the resulting curvatures,

\[
\frac{d\sigma_{\text{max}}}{dX} = \frac{d\sigma_{\text{cent}}}{dX} + \sqrt{\left(\frac{d\sigma_{\mu_{\text{max}}}}{dX} - \frac{d\sigma_{\text{cent}}}{dX}\right)^2 + \left(\frac{d\sigma_{\mu_{\text{min}}}}{dX} - \frac{d\sigma_{\text{cent}}}{dX}\right)^2},
\]

\[
\frac{d\sigma_{\text{min}}}{dX} = \frac{d\sigma_{\text{cent}}}{dX} - \sqrt{\left(\frac{d\sigma_{\mu_{\text{max}}}}{dX} - \frac{d\sigma_{\text{cent}}}{dX}\right)^2 + \left(\frac{d\sigma_{\mu_{\text{min}}}}{dX} - \frac{d\sigma_{\text{cent}}}{dX}\right)^2},
\]

defines the uncertainty on the cross section where $X$ can be either $p_T$ or $y$. The EPS09 uncertainty band is based on the mass and scale set with the central mass value and $(\mu_F/m, \mu_F/m) = (C,C)$.

In Fig. [17] the mass and scale uncertainties are clearly significantly larger than those of the shadowing parameterizations alone, still a factor of $\sim 2$ on the $J/\psi$ $p_T$ distributions over a wide $p_T$ range. Thus, even though the uncertainties on the $J/\psi$ cross section in the CEM are reduced relative to those calculated previously, see Ref. [13], they are still significantly larger than those of shadowing on the central mass and scale values. One would naively expect the uncertainties on $R_{\text{pPb}}$ and $R_{FB}$ to reflect the results shown in Fig. [17] but, as we will show, it depends on the method used to calculate the uncertainty.

We have tried several ways of estimating the size of the mass and scale uncertainty on the ratios which we describe first before comparing to the data. We note that all of these calculations are based on the EPS09 NLO central set rather than making a global nPDF + mass + scale uncertainty by calculating the 30 error sets for EPS09 with the 8 additional mass and scale combinations that define the mass and scale uncertainty on the cross section for $p+p$ and $p+\text{Pb}$.

The most naive, labeled $m/\mu_F/\mu_R v1$ on Figs. [18] and [22] above. Thus the uncertainty band is based on the $R_{\text{pPb}}$ of each set. Since the ratios are all close to unity (within 20-40% in most cases), and similar to each other, this method would tend to underestimate the uncertainty.

The second, labeled $m/\mu_F/\mu_R v2$ on Figs. [18] and [22] reflects the uncertainty calculation of Eqs. [5] and [6]. We calculate the maxima and minima of $d\sigma/dx$, as in Fig. [17] and then form $R_{\text{pPb}}$ by dividing by the central value of the $p+p$ cross section in the corresponding rapidity bin (for the $p_T$-dependent results) or the $p_T$-integrated cross section (for the rapidity dependence). Thus the shadowing ratios for $v2$ are based on cross sections only. We expect a larger uncertainty band for this calculation, especially at low $p_T$.

We note, however, that there is actually no difference between the $v2$ and $v1$ calculations of the uncertainty in the forward-backward ratios because we calculate the forward-backward ratios for each mass and scale combination before calculating the uncertainty to ensure that we make a one-to-one correspondence in $R_{FB}$. Thus, there is no $v2$ result in the plots of $R_{FB}$.

The above methods of calculating the mass and scale uncertainty, relying on Eqs. [5] and [6], are not actually calculated the same way as the EPS09 uncertainty band because they rely only on the extrema of the mass and scale dependent cross sections from the central values rather than adding the excursions from the central value in quadrature, as in the EPS09 uncertainty calculation. Therefore, finally, for $m/\mu_F/\mu_R v3$, we add the mass and scale uncertainties in quadrature, a la EPS09, and then form $R_{\mu_R}$ by dividing by the central $p+p$ cross section. Since this is a cumulative uncertainty rather than based on the greatest excursion from the mean, we expect this to give the largest overall uncertainty. The $v3$ uncertainty band was calculated assuming that the appropriate $\mu_F/m$ and $\mu_R/m$ pairs are $[(H,H), (L,L)], [(H,C), (L,C)]$ and $[(C,H), (C,L)]$. Other choices could lead to different results. (There is only one possible pair for the mass uncertainty thus this part of the calculation is the same for $v2$ and $v3$.)
FIG. 17: (Color online) The ALICE $J/\psi$ $p_T$ distributions at forward (a), backward (b) and midrapidity (c) at NLO in the CEM\cite{T2}. The solid red curve is the EPS09 NLO central value while the dashed red curves are the EPS09 NLO uncertainties and the dot-dashed magenta curves are the mass and scale uncertainties.

Results using all three methods are shown for $J/\psi$ and $\Upsilon$ in the remainder of this section.

1. $J/\psi$

Figure 18 shows the relative uncertainties for the EPS09 NLO band and the three ways of calculating the mass and scale uncertainty for $R_{pPb}$. As expected, the $v1$ procedure gives the smallest uncertainty since there is little variation in the individual values of $R_{pPb}$ for each mass and scale choice for the central EPS09 set. Therefore, the $v1$ band is narrower than that of the EPS09 band itself, underestimating the uncertainty.

On the other hand, the $v2$ and $v3$ bands are wider, especially for $p_T < 5$ GeV, as expected. Also, as mentioned previously, the $v3$ band is broader than that of $v2$ over all $p_T$ although the two methods merge at the highest $p_T$ values. The $R_{pPb}(p_T)$ found for the $v2$ method is in agreement with what one might expect looking at the bands
FIG. 18: (Color online) The mass and scale uncertainties in the $J/\psi$ ratio $R_{p\text{p}/\text{Pb}}(p_T)$ in the ALICE acceptance at forward (a), backward (b) and central (c) rapidity [2]. The ratio $R_{p\text{p}/\text{Pb}}(y)$ is compared to the ALICE [1] and LHCb [4] data in (d). The EPS09 NLO uncertainty band is shown in red while the uncertainties calculated with method $v_1$ in blue, $v_2$ in magenta and $v_3$ in black.

The ratios as a function of $p_T$ are relatively regular even though, at least for $v1$ and $v2$, the combination of factorization and renormalization scales that give the extreme values for that $p_T$ does depend on $p_T$.

The situation is somewhat different as a function of rapidity, in part because the rapidity distributions fluctuate somewhat, especially at midrapidity. The size of the fluctuations depends on the scale choice and, depending on which scale set determines the extreme value, these fluctuations can manifest themselves in $R_{p\text{p}/\text{Pb}}(y)$. This effect is obvious in Fig. 18(d) where the upper bound on $v1$ is visibly above the central value of the ratio for $|y| > 2$ and almost on top of it for $|y| < 2$. The abrupt change of slope occurs because the maximum value of the ratio is obtained with set $(H,H)$ away from midrapidity and with set $(C,L)$ at midrapidity. This is illustrated in Fig. 19 where the $p+p$ and $p+\text{Pb}$ rapidity distributions are shown for each of these combinations. The change in the $p+\text{Pb}$ rapidity distribution is a stronger function of $y$ for the $(H,H)$ set than for the $(C,L)$ set. There are also larger fluctuations in the distribution at midrapidity for the $(H,H)$ set. To emphasize this difference, we present the rapidity distributions as histograms rather than smoothed curves. We note that these fluctuations are not due to limited statistics in the background.
calculation but are more likely due to the uneven distribution of low $p_T$ negative-weight events in the MNR code at midrapidity. The presence of these events may also flatten the rapidity distribution in the LHC energy regime so that while the $p + p$ rapidity distribution is within the mass and scale uncertainty band the slope is somewhat flatter than the measured one, see Ref. [13].

The $v_2$ and $v_3$ ratios are more separated and, because they are obtained by taking the ratio to the $p + p$ distribution calculated with the central mass and scale set, they are also smoother. The ‘kink’ in the central EPS09 NLO ratio noted previously is sharpened for the upper limit of these bands and reduced, but still present, in the lower limits. The upper limits obtained for $v_2$ and $v_3$ are very similar. Indeed these upper limits are almost indistinguishable for most of the illustrated rapidity range. The numerical values are generally different, with the $v_3$ values larger than those of $v_2$, but the difference is not large enough to be visible on the scale of the plot. This similarity likely stems from the aforementioned fluctuations in the rapidity distributions. Since these fluctuations tend to be smaller for the lower limits of $R_{p\text{\!}Pb}(y)$, there is a large separation between the lower bounds on $v_2$ and $v_3$.

In all the cases shown, except for the ratios calculated with $v_1$, the envelope of ratios described by the mass and scale uncertainties contains the data. This can be expected because this is the designed purpose of Eqs. (5) and (6) for the $p + p$ distributions and, when applied correctly, it does the same for the nuclear suppression factor $R_{p\text{\!}Pb}$ as well.

This is not necessarily the case for the forward-backward ratios, shown in Fig. 20. Indeed, in this case the ratios calculated with methods $v_1$ and $v_3$ are nearly identical. Recall that there is no difference between $v_1$ and $v_2$ uncertainties for the forward-backward ratios. The most interesting thing to note here is that the ratios of the mass and scale uncertainty as a function of rapidity have different slopes than those of the EPS09 NLO uncertainty. The stronger rise in $R_{p\text{\!}Pb}(y)$ at backward rapidity, combined with the weak dependence on rapidity in the forward direction makes the upper limit on the mass and scale dependence larger than the central EPS09 set at $y < 2$. At larger rapidities, these values are almost coincident. On the other hand, the weaker rise in $R_{p\text{\!}Pb}(y)$ for the lower limit in the backward direction makes the lower limit of the forward-backward ratio decrease more rapidly than the central set for $y > 3$.

2. $\Upsilon$

The results for the mass and scale uncertainties on the ratios for $\Upsilon$ production are presented in Figs. 21 and 22. Overall the trends are quite similar to those for the $J/\psi$ even though the $p_T$-dependent results here are almost independent of $p_T$. However, we note that the results for $R_{p\text{\!}Pb}$ show much smaller differences between $v_2$ and $v_3$ over the entire $p_T$ range, as well as a function of rapidity. In this case also, the shape of the limits on the mass and scale uncertainty bands for $R_{pp\text{\!}Pb}(y)$ is the same as that of the central EPS09 NLO value so the shape of that ratio has a
FIG. 20: (Color online) The mass and scale uncertainties in the $J/\psi$ forward-backward ratio $R_{FB}(p_T)$ in the ALICE overlap region (a) and $R_{FB}(y)$ (b). The EPS09 NLO uncertainty band is shown in red while the uncertainties calculated with method v1 in blue and v3 in black. The ALICE [1] and LHCb [4] data are also shown.

weaker scale dependence than the $J/\psi$. The band on $R_{pPb}(y)$ is broad enough to encompass the range of the low statistics $\Upsilon$ data.

The uncertainties on the forward-backward ratio in Fig. 22 are again small. They are, in fact, considerably smaller than those due to EPS09 which, as we saw previously, is not because the uncertainties on the distributions in an individual rapidity bin, for $R_{FB}(p_T)$, are small. Instead, these uncertainties are somewhat canceled in the ratio, even though we still expect the largest excursion from the central value for $v3$.

F. Factorization

The question of whether cold nuclear matter effects factorize has been much discussed. If so, then at the same energy, the product of the nuclear modification factors at forward and backward rapidity in $pA$ collisions would give the predicted cold matter result for $A + A$ collisions at the same energy.

In their latest paper on the $J/\psi$ $p+Pb$ results [2], the ALICE Collaboration compared the product of their $R_{pPb}(p_T)$ ratios in the forward and backward rapidity regions at $\sqrt{s_{NN}} = 5.02$ TeV, $2.03 < y_{cms} < 3.53$ and $-4.46 < y_{cms} < -2.96$ respectively, to the $R_{pPb}(p_T)$ ratio in the region $2.5 < y < 4.0$ (symmetric around midrapidity) at $\sqrt{s_{NN}} = 2.76$ TeV. They did the same for the square of the midrapidity ratio measured in $-1.37 < y_{cms} < -0.43$ in $p+Pb$ collisions at $\sqrt{s_{NN}} = 5.02$ TeV to $R_{PbPb}$ in $|y| < 0.8$ at $\sqrt{s_{NN}} = 2.76$ TeV. From these comparisons they were able to obtain an estimate of the cold nuclear matter effects on $Pb+Pb$ collisions, assuming that the ratios in the forward and backward regions factorize. They then used their $p+Pb$ measurements at the higher energy to form the ratio $S_{J/\psi} = R_{PbPb}(+/y) \times R_{pPb}(+/y)$. From this comparison, they were able to deduce that, at least for their dimuon measurement, the $Pb+Pb$ data are significantly more surprised than expected for cold matter effects alone [2].

However, the comparison in Ref. [2] is made for different rapidity regions due to the asymmetric beams in $p+Pb$ collisions. In addition, the difference in the nucleon-nucleon center of mass energy is almost a factor of two. These two effects will cause the $x$ values probed in $p+Pb$ and $Pb+Pb$ collisions to be shifted so that the correspondence is not exact.

In this section, we compare the $R_{PbPb}$ and $R_{pPb}$ ratios at LO (rapidity only) and NLO (rapidity and $p_T$ in symmetric forward and backward regions) at the same energy for $p+Pb$ and $Pb+Pb$ so that the correspondence between the $x$ values should be exact. In addition, since we employ the same $\sqrt{s_{NN}}$, there no rapidity shift in $p+Pb$ relative to $Pb+Pb$. We can thus check this factorization does indeed explicitly hold for shadowing effects in the CEM. In our calculations here, we employ the central EPS09 sets. The results should be similar for other nPDF sets.
FIG. 21: (Color online) The mass and scale uncertainties in the Υ ratio $R_{p\text{Pb}}(p_T)$ in the ALICE acceptance at forward (a), backward (b) and central (c) rapidity. The ratio $R_{p\text{Pb}}(y)$ is compared to the ALICE [3] and LHCb [5] data in (d). The EPS09 NLO uncertainty band is shown in red while the uncertainties calculated with method $v_1$ in blue, $v_2$ in magenta and $v_3$ in black.

It is straightforward to make this comparison at leading order in the color evaporation model (CEM) where the $p_T$ of the $Q\bar{Q}$ pair is zero and the $x_1$ and $x_2$ values are related to the quarkonium rapidity by $x_1, x_2 = (M/\sqrt{s}) \exp(\pm y)$. As long as factorization is assumed for the parton densities, the individual shadowing ratios applied to each also factorize. The result is compared for the EPS09 LO central shadowing set in Figs. 23(a) and 24(a) for $\sqrt{s}_{NN} = 2.76$ TeV. In these $2 \rightarrow 1$ kinematics, the relation $R_{AA}(y) = R_{p\text{A}}(y) \times R_{p\text{A}}(-y)$ is exact.

Here the dashed and dot-dashed curves show the ratios $R_{p\text{Pb}}$ at positive and negative rapidities respectively. (In this case, the $-y$ refers to the ion beam moving toward positive rapidity while $+y$ is the standard assumption that the proton beam moves toward positive rapidity, the convention adopted throughout this paper.) The blue dots represent the product of $R_{p\text{Pb}}(+y)$ and $R_{p\text{Pb}}(-y)$. At LO, they lie exactly on top of the red solid curve calculated for Pb+Pb.

A consequence of the lower energy is that the antishadowing peak moves close to midrapidity. This effect is most clearly seen for the Υ in Fig. 23(a) where the drop into the EMC region and the subsequent rise into the Fermi motion region at high $x$ is clearly visible.
It is also obvious, both for the $J/\psi$ and $\Upsilon$, that the Pb+Pb ratio gives stronger shadowing at midrapidity than at forward (and backward) rapidity since, at $y \sim 0$, the ratios $R_{PbPb}$ at $\pm y$ are both less than unity while, at $2.5 < |y| < 4.0$, these ratios are in the antishadowing region. Therefore, the combination of the two in Pb+Pb interactions is always less than unity with stronger shadowing at midrapidity.

This was also the case for RHIC cold matter $A+A$ calculations at $\sqrt{s_{NN}} = 200$ GeV [23]. More suppression is predicted at $y = 0$ than at forward and backward rapidities with all the shadowing parameterizations for both $J/\psi$ and $\Upsilon$ production. At RHIC, the $A+A$ data are more suppressed at forward rapidity than at central rapidity, both in the minimum bias data as a function of rapidity and as a function of collision centrality, as quantified by the number of participant nucleons. Standard models of shadowing alone or shadowing with absorption by nucleons in cold nuclear matter or shadowing combined with dissociation in a quark-gluon plasma leads to strong suppression at central rapidities. However, $J/\psi$ regeneration by dynamical coalescence of $c$ and $\overline{c}$ quarks in the medium [39, 61] is biased toward central rapidities and could lead to more suppression at forward rapidity relative to central rapidity since the rapidity distribution of $J/\psi$ production by coalescence is expected to be narrower than the initial $J/\psi$ rapidity distribution [61]. Thus, with coalescence, there should be more suppression at forward $y$ than at midrapidity. Statistical coalescence [62], which is based only on the energy density of the medium, which is higher at $y \sim 0$, would also support this picture. The same trend has been observed at the LHC, see Ref. [28] and references therein. Coalescence production of the $J/\psi$ should be more important than at RHIC since more $c\bar{c}$ pairs are created in a central Pb+Pb collision at $\sqrt{s_{NN}} = 2.76$ TeV. We can also expect $\Upsilon$ production by coalescence at the LHC to be similar to that expected for the $J/\psi$ at RHIC since the $b\bar{b}$ production cross section at the LHC will be similar to the $c\bar{c}$ production cross section at RHIC [22].

At next-to-leading order, the assumption of factorization of shadowing is less straightforward because quarkonium production in the CEM includes a large contribution from $2 \rightarrow 3$ diagrams so that the correlation between the initial momentum fractions $x_1$ and $x_2$ with the rapidity of the quarkonium state is weaker, particularly for high $p_T$. However, factorization is seen to still hold as a function of rapidity at NLO, as shown in Figs. 23(b) and 24(b), calculated with the EPS09 NLO central set, also at $\sqrt{s_{NN}} = 2.76$ TeV. There are some small fluctuations in the points relative to the curve but these are within the size of the points and are therefore negligible.

The same trend has been observed at the LHC, see Ref. [28] and references therein. Coalescence production of the $J/\psi$ should be more important than at RHIC since more $c\bar{c}$ pairs are created in a central Pb+Pb collision at $\sqrt{s_{NN}} = 2.76$ TeV. We can also expect $\Upsilon$ production by coalescence at the LHC to be similar to that expected for the $J/\psi$ at RHIC since the $b\bar{b}$ production cross section at the LHC will be similar to the $c\bar{c}$ production cross section at RHIC [22].

At next-to-leading order, the assumption of factorization of shadowing is less straightforward because quarkonium production in the CEM includes a large contribution from $2 \rightarrow 3$ diagrams so that the correlation between the initial momentum fractions $x_1$ and $x_2$ with the rapidity of the quarkonium state is weaker, particularly for high $p_T$. However, factorization is seen to still hold as a function of rapidity at NLO, as shown in Figs. 23(b) and 24(b), calculated with the EPS09 NLO central set, also at $\sqrt{s_{NN}} = 2.76$ TeV. There are some small fluctuations in the points relative to the curve but these are within the size of the points and are therefore negligible.

Note, however, that there is a significant difference in the shape of the shadowing ratios as a function of rapidity between the LO and NLO results of Figs. 23(a) and (b) as well as between Figs. 24(a) and (b). As discussed in Sec. VIIC this is due to the differences in the EPS09 LO and NLO sets themselves and gives some indication of the uncertainty inherent in the extraction of the nuclear gluon density.

Finally, we turn to the $p_T$ dependence at NLO, unavailable in the CEM at LO. We might expect to see the largest
FIG. 23: (Color online) The $J/\psi$ $R_{AA}$ (red) ratio is compared to the product $R_{pA}(+y) \times R_{pA}(-y)$ (points) along with the individual $pA$ ratios at forward (dashed) and backward (dot-dashed) rapidity. Results are compared for the rapidity distributions at LO (a) and NLO (b) as well as for the $p_T$ dependence at NLO (c). Results are shown up to $p_T = 30$ GeV.

deviations in this comparison because of the different kinematics in $2 \rightarrow 2$ and $2 \rightarrow 3$ interactions in the CEM at NLO. At high $p_T$, the $2 \rightarrow 3$ kinematics is dominant. However, the agreement between the factorized product and the direct Pb+Pb calculation is very good for both $J/\psi$ and $\Upsilon$ up to quite high $p_T$, see Figs. 23(c) and 24(c). (The result is shown up to $p_T = 30$ GeV.) There are more fluctuations in the $\Upsilon$ calculations. Despite this, the agreement is still very good.

The comparisons shown here, at the same energy for both $p$+Pb and Pb+Pb collisions, demonstrate that the cold matter effects due to shadowing in heavy-ion collisions can be effectively deduced from proton-nucleus collisions, preferably at the same energy.
FIG. 24: (Color online) The $\Upsilon$ $R_{AA}$ (red) ratio is compared to the product $R_{pA}(+y) \times R_{pA}(-y)$ (points) along with the individual $pA$ ratios at forward (dashed) and backward (dot-dashed) rapidity. Results are compared for the rapidity distributions at LO (a) and NLO (b) as well as for the $p_T$ dependence at NLO (c).

G. Comparison to RHIC results

Finally, we compare the EPS09 NLO calculations to the RHIC $J/\psi$ and $\Upsilon$ data in Figs. 25 and 26. No absorption is included here, even though the absorption cross section may be non-negligible at RHIC energies. The EPS09 LO calculations were employed by the PHENIX Collaboration [63] to extract the putative absorption cross section required to make a shadowing and absorption scenario agree with the data. The NLO calculations are presented as a function of $p_T$ and rapidity together for the first time.

The $J/\psi$ $p_T$-dependent data, shown in Fig. 25(a)-(c), follows approximately the same trend at forward, backward and midrapidity. At $p_T \sim 0$, $R_{dAu} \sim 0.7 - 0.8$. The ratio then increases with $p_T$ until becoming compatible with unity, albeit it with rather poor statistics, at $p_T \geq 4$ GeV. At forward and midrapidity the calculations agree with the trends of the data rather well. At low $p_T$, the $x$ range is in the shadowing region but moves toward the antishadowing region as $p_T$ increases, see the shape of $R_{dAu}(y)$ in Fig. 24(d). However, at backward rapidity at RHIC, the calculations suggest that, at low $p_T$, the antishadowing region is probed while, at higher $p_T$, the EMC region is reached. Thus,
FIG. 25: (Color online) The $J/\psi$ ratio $R_{dAu}(p_T)$ from PHENIX at forward (a), backward (b) and central (c) rapidity. The ratio $R_{dAu}(y)$ is shown (d). The EPS09 NLO uncertainty band is compared to the data.

For $p_T < 2$ GeV, the trend of the data and the calculations are opposite. For $p_T > 2$ GeV, the uncertainties in the data and the calculations are large enough for the results to be compatible.

A recent calculation studied the centrality dependence of gluon shadowing. The impact parameter dependence, together with a rapidity-dependent absorption cross section, was extracted from the centrality dependence of $R_{dAu}(y)$. The large absorption cross section required at backward rapidity was explained in the context of an expanding color octet that reaches its final-state size at backward rapidity but has a negligible effect at forward rapidity because the primordial $J/\psi$ passes through the target before reaching its full size. Presumably, this would also have the desired effect on the $p_T$ dependence in the backward region since low $p_T J/\psi$'s will be strongly absorbed in this region while those at higher $p_T$ will again pass through the transverse direction of the target before fully forming, maintaining the agreement of the calculation with the data at higher $p_T$.

Finally, we discuss the $\Upsilon$ results shown in Fig. 25. There is only limited data for the $\Upsilon$, including the low statistics PHENIX [65] and STAR [66] data presented in Fig. 25(d). The uncertainties on the measurements, along with the large uncertainties in the calculation at backward rapidity, allow the calculation and the data to agree within the errors, except for the STAR point at $y \sim 0$. Although it has the lowest statistical uncertainty, it exhibits strong
FIG. 26: (Color online) The Υ ratio \( R_{dAu}(p_T) \) for RHIC at forward (a), backward (b) and central (c) rapidity. The ratio \( R_{dAu}(y) \) is also shown (d). The EPS09 NLO uncertainty band is compared to the PHENIX [65] and STAR [66] data on \( R_{dAu}(y) \) data in (d).

suppression in a rapidity region where antishadowing is predicted. The \( p_T \) dependence has not yet been measured.

The calculated \( p_T \) dependence in the forward region, Fig. 26(a), is already entering the antishadowing region for \( p_T > 6 \text{ GeV} \). At midrapidity, the entire \( p_T \) range is in this region so that \( R_{dAu}(p_T) > 1 \) for all \( p_T \). On the other hand, at backward rapidity, most of the \( p_T \) region is, in fact, in the EMC region where the uncertainties in the calculated \( R_{dAu}(p_T) \) are large, see Fig. 26(b).

It is unlikely that the situation for Υ can be improved with the current RHIC detectors. However, the future sPHENIX detector [67] is expected to be able to separate the three Υ(S) states. This improved mass resolution, together with the higher efficiency expected for sPHENIX and higher luminosity of the sPHENIX runs, means that the \( p_T \) dependence could be measured, if a d+Au run is made during the sPHENIX lifetime.
VII. SUMMARY

The results with EPS09 NLO shadowing agree with the measured $R_{pPb}$ within the uncertainties of both the calculation and the data. However, the forward-backward ratios, independent of the interpolated $p+p$ baseline, are not as well described. The older EKS98 LO parameterization, although not applied consistently in a NLO calculation, does the best job of describing all the data.

The shadowing parameterizations used in our study exhibit a wide range of behavior for the nuclear gluon density at low $x$, an $x$ region outside the current range of the fits from fixed-target nDIS data at higher $x$ and low $\mu_F$. If nuclear data were available from high energy $e + A$ collisions, the nuclear gluon densities could be more precisely pinned down by global analyses of the scale dependence of the nuclear structure functions. In hadroproduction, direct photon or open charm production, dominated by gluon-induced processes but without the additional complexities of nuclear absorption, could be utilized to study the nuclear gluon density. The LHC data, with the lower $x$ reach, should be incorporated into a new fit of the nuclear parton densities.

We note that, since we have assumed absorption is negligible at the LHC and include no other cold nuclear matter effect, the uncertainties on the ratios can be obtained from the EPS09 NLO bands shown in the figures. However, if other effects are incorporated, a more extensive error analysis, including the uncertainties on these other effects, is necessary.

Acknowledgements
