ABSTRACT

BACKGROUND AND PURPOSE: Computational fluid dynamics modeling is useful in the study of the hemodynamic environment of cerebral aneurysms, but patient-specific measurements of boundary conditions, such as blood flow velocity and pressure, have not been previously applied to the study of flow-diverting stents. We integrated patient-specific intravascular blood flow velocity and pressure measurements into computational models of aneurysms before and after treatment with flow-diverting stents to determine stent effects on aneurysm hemodynamics.

MATERIALS AND METHODS: Blood flow velocity and pressure were measured in peri-aneurysmal locations by use of an intravascular dual-sensor pressure and Doppler velocity guidewire before and after flow-diverting stent treatment of 4 unruptured cerebral aneurysms. These measurements defined inflow and outflow boundary conditions for computational models. Intra-aneurysmal flow rates, wall shear stress, and wall shear stress gradient were calculated.

RESULTS: Measurements of inflow velocity and outflow pressure were successful in all 4 patients. Computational models incorporating these measurements demonstrated significant reductions in intra-aneurysmal wall shear stress and wall shear stress gradient and a trend in reduced intra-aneurysmal blood flow.

CONCLUSIONS: Integration of intravascular dual-sensor guidewire measurements of blood flow velocity and blood pressure provided patient-specific computational models of cerebral aneurysms. Aneurysm treatment with flow-diverting stents reduces blood flow and hemodynamic shear stress in the aneurysm dome.

ABBREVIATIONS: CFD = computational fluid dynamics; WSS = wall shear stress; WSSG = wall shear stress gradient; TCD = transcranial Doppler ultrasonography; pcMRA = phase-contrast MRA

Flow-diverting stent technology is thought to reduce blood flow (and hence hemodynamic stresses) inside cerebral aneurysms, promoting thrombosis and lowering rupture risk. Flow-diverting stent technology is thought to reduce blood flow (and hence hemodynamic stresses) inside cerebral aneurysms, promoting thrombosis and lowering rupture risk. However, 15–35% of aneurysms treated with flow-diverting stents remain patent at midterm angiographic follow-up. Risk factors for persistent aneurysm patency include previous aneurysm treatment and female sex, though accurate predictors of treatment failure and delayed hemorrhagic complications have not been completely elucidated.

Computational fluid dynamics (CFD) modeling of aneurysms and the surrounding cerebral vasculature allows investigators to study important hemodynamic characteristics such as wall shear stress (WSS) and wall shear stress gradient (WSSG), which have been implicated in aneurysm growth, rupture, and treatment failure. Recently, CFD analysis has been applied to the effects of flow-diverting stent treatment in an attempt to understand how flow diversion affects aneurysm hemodynamics for both treatment success and complication avoidance. However, these reports did not use patient-specific measurements of blood flow velocity and blood pressure when creating CFD models, which may have affected their results.
We incorporated patient-specific measurements of blood flow velocity and blood pressure in the peri-aneurysmal environment into the boundary conditions of CFD to determine the hemodynamic effects of flow-diverting stents on unruptured aneurysms.

**MATERIALS AND METHODS**

**Population**

Four patients with unruptured cerebral aneurysms were included in this institutional review board–approved prospective study, and informed consent was obtained. Patient, aneurysm, anatomic, and device characteristics are shown in On-line Table 1. All patients underwent endovascular flow-diverting stent placement by use of the Pipeline Embolization Device (Covidien/ev3, Irvine, California) under isoflurane inhalational anesthesia. The aneurysm in patient 1 was also partially coiled. Patient temperature, hematocrit, and end-tidal CO₂ were recorded. Three-dimensional rotational angiography was obtained before aneurysm treatment, and contrast-enhanced flat panel CT was obtained after treatment for stent visualization.²⁰

**Patient-Specific Data Collection**

Blood flow velocity and blood pressure were measured by use of the dual-sensor pressure and Doppler velocity guidewire (ComboWire, Volcano Corporation, Rancho Cordova, California) and workstation (ComboMap, Volcano). The tip of the 0.014-inch wire contains a piezoresistive pressure sensor and piezoelectrode Doppler device that emits a 45° sonogram beam that measures velocity 5 mm beyond the tip. This wire has been used to measure patient-specific blood pressure and blood flow velocity in both coronary²¹ and cerebral vessels,²₂,²³ with excellent anatomic specificity and correlation to measured blood flow.²⁴ In the current study, pressure and velocity were sampled every 5 ms, and peak systolic, diastolic, and average pressures and velocities were calculated automatically by the workstation on the basis of the cardiac cycle.

Before aneurysm treatment, the dual-sensor guidewire was placed in 2 predetermined peri-aneurysmal locations: 1) proximal petrous carotid artery, and 2) 5 mm distal to the aneurysm neck. The wire was oriented along the long axis of vessel flow to maximize the flow velocity signal, and radiographs of the location of the wire were obtained. Blood pressure and blood flow velocity were recorded for at least 10 cardiac cycles at each location before wire removal. After aneurysm treatment, the wire was reintroduced and the same measurements were taken again at all locations. Effort was made to reproduce the exact wire locations during pretreatment measurements as recorded in previous radiographs. Blood pressure and blood flow velocity measurements were exported to a workstation for CFD analysis.

**Computational Modeling**

Three-dimensional reconstructions of the vessels were created from the rotational angiographic images by use of the Vascular Modeling Toolkit (Bergamo, Italy; www.vmtk.org). Ophthalmic and posterior communicating arteries and other small side-branching vessels were eliminated from each model, except for the posterior communicating artery in patient 1 because they had a negligible effect on hemodynamic calculations (On-line Appendix). A “virtual stent” was placed into each reconstruction for posttreatment simulations by inserting a saddle-shaped surface to the location of the stent boundary on the basis of its location in the posttreatment CT. The stent was modeled as a thin, porous surface with specified pressure-loss coefficients, taken from a previous study²⁵ that computed the pressure drops over low-porosity flow-diverting stents. Pressure drops were parameterized as 2 unique loss coefficients integrated into our CFD model (On-line Appendix). In patient 1 (in whom the aneurysm was partially coiled), a shear and shear gradient value of zero was assigned to the area of the aneurysm dome excluded after coiling, and the remaining volume was used for hemodynamic calculations. Tetrahedral meshes were generated for all simulations by use of the ANSYS Gambit package, release 2.4 (ANSYS, Canonsburg, Pennsylvania). The characteristic width of the computational mesh cells was 0.2 mm for all cases. Simulations were executed by use of ANSYS Fluent, release 12.1 (ANSYS), a finite-volume-based solver. The blood was assumed to be incompressible and Newtonian, with an attenuation of 1050 kg/m³ and viscosity of 3.5 cP.

At the proximal vessel, the time-dependent Womersley velocity profile was prescribed by use of velocity measurements from the dual-sensor guidewire at position 1 (petrous carotid artery). These measured velocities were matched to the centerline velocity of the Womersley flow and used as inflow conditions, incorporating the cross-sectional vessel area from the pretreatment and posttreatment 3D vessel reconstructions (Fig 1, On-line Appendix). At distal vessels, pressures were prescribed by use of measurements from the dual-sensor guidewire at position 2 (5 mm distal to the aneurysm neck) for use as outflow conditions. Velocity and pressure waveforms were phase-averaged over at least 10 cardiac cycles before CFD modeling. Flow rates were computed directly from the wire-derived Womersley velocity profile. Slight changes in heart rate, mean arterial pressure, and blood flow after treatment were incorporated into posttreatment CFD models. The CFD simulations were computed over 3 cardiac cycles, and the first 2 cycles were excluded from analysis to ensure that the simulation was independent of the initializing condition. Intra-aneurysmal blood flow, WSS, and WSSG were calculated over the entire aneurysm volume in each patient (On-line Appendix). Flow rates, WSS, and WSSG were determined both at the moment of peak systole and averaged over an entire cardiac cycle. Pressure drops were also simulated between the 2 wire locations (petrous carotid artery and 5 mm distal to the aneurysm neck), without patient-specific guidewire-derived pressure values. Statistical comparisons were made by use of the Student t test.

**RESULTS**

**Patient-Specific Measurements**

Proximal blood flow velocity and distal blood pressure measurements were successful in all 4 patients both before and after treatment. Blood flow velocity and flow rates at position 1 (petrous carotid, used for inflow velocity boundary conditions) are shown in Table 1. Flow rates are presented both as an average over the entire cardiac cycle and at the moment of peak systole. The differences between pretreatment and posttreatment velocity and blood flow (both average and peak systolic) at the petrous carotid artery were not significant (P > .17).
The premise of aneurysmal flow diversion is the reduction of blood flow into the aneurysm dome, promoting intra-aneurysmal thrombosis and promoting endothelialization of the stent wall, which reconstructs the parent vessel excluding the aneurysm. Reduction of hemodynamic stress is thought to be crucial in achieving this goal, and the determination of such stress is a key application of CFD analysis. We observed a reduction of flow rate, WSS, and WSSG in the aneurysmal domes. Previous reports of CFD modeling for aneurysmal flow diversion have shown similar reductions in intra-aneurysmal velocity and WSS, though WSSG has not been consistently described. We also observed a (nonsignificant) increase in blood flow in the parent vessel after treatment, possibly the result of the exclusionary effect of flow diversion on aneurysmal blood capacitance.

Increased pressure within the aneurysm dome has been suggested as a possible mechanism for delayed aneurysm rupture after flow-diverting stent treatment. However, in the current study, blood pressure measurements in peri-aneurysmal locations did not change substantially after aneurysm treatment, nor did simulated pressure drops. This is in contrast to a previous CFD study of large pressure drops and increased mural tension after flow diversion but similar to previous CFD and in vivo intra-aneurysmal pressure measurements that did not demonstrate changes after flow-diverting stent treatment. Although we did not measure pressure within the aneurysm lumen directly, it is unlikely that a substantial intraluminal increase occurred in the face of such small pressure drops, especially considering the lack of preaneurysmal stenosis in the aneurysms we studied.

Average peak inflow velocity in the petrous carotid artery pre-treatment and posttreatment was 43.58 cm/s and 46.02 cm/s, respectively, with a mean flow rate of 143.70 mL/min. Studies of sonography and phase-contrast MRA (pcMRA) velocities of healthy volunteers showed average flow rates of 234 and 277 mL/min, respectively. The use of idealized assumptions of blood flow velocity and blood pressure (rather than patient-specific measurements) as boundary conditions would have significantly affected the results of our hemodynamic calculations. The origin of our lower flow rate values is unclear; however, healthy volunteers in studies of reference velocity were younger than our patients (average age, 28 ± 7 years). Age is inversely correlated to the measured flow rate in the cerebral vasculature in some studies but not in others. However, we are confident that our direct physiologic measurements with the use of the dual-sensor guidewire were accurate when measuring such parameters in vivo, as shown in animal studies comparing such measurements with direct measurements of blood flow.

Efforts to improve the accuracy of CFD for better applicability to an individual patient’s treatment have led to the incorporation of patient-specific blood flow measurements derived from trans-

Complications

There were no intra-procedural or periprocedural complications associated with the use of the dual-sensor guidewire. No vascular injury, thromboembolic event, or new neurologic deficit was observed in any patient.

Computational Modeling

Modeling of WSS and WSSG is shown for each patient in Fig 1. Colorized maps of the top row of each panel demonstrate pre-treatment conditions, the middle row shows posttreatment, and the bottom row shows the effect of treatment, as calculated by the difference between pretreatment and posttreatment. In patient 1, after flow diversion and partial coiling, both WSS and WSSG were reduced at the aneurysm neck and impact area of the wall opposite the inflow zone (Fig 1A). In patient 2, the sidewall aneurysm demonstrated similar findings of WSS and WSSG reduction in the neck and impact area, with corresponding increase in the downstream parent vessel (Fig 1B). Modeling of patient 3, with a more spherical aneurysm, showed reduction in WSS in nearly the entirety of the aneurysm dome and neck and a slight increase in WSSG in the neck midpoint (Fig 1C). WSS and WSSG were reduced in the small sidewall aneurysm of patient 4, with increases in these parameters in the surrounding parent vessel (Fig 1D).

The wire-based CFD calculations of the effects of flow-diverting stent treatment on intra-aneurysmal hemodynamics are shown in Table 2. Reduction of all parameters was observed in all patients, with significant decreases in WSS and peak-systolic WSSG and trends in reduced blood flow ($P = .07$) and cardiac cycle–averaged WSSG ($P = .06$). Simulated pressure drops across the entire CFD model are shown in On-line Table 2. The average and peak-systolic change in pressure drop after treatment were $-0.09 ± 0.26$ mm Hg and $-0.85 ± 2.08$ mm Hg, respectively. The differences were not significant ($P = .55$ and $.47$).

**DISCUSSION**

We have successfully incorporated patient-specific measurements of blood flow velocity and blood pressure into CFD modeling of unruptured cerebral aneurysms before and after treatment with flow-diverting stents. The method of applying patient-specific boundary conditions to CFD modeling and quantifying the effects of flow-diverting stents on aneurysmal hemodynamics has not been previously reported. This method may improve the ability of CFD to determine hemodynamic factors associated with treatment, including aneurysm occlusion, persistent patency, or delayed hemorrhagic complications.

ditional CFD, flow rates acquired with pcMRA have a lower temporal resolution and may underestimate peak velocity by up to 30%, especially in smaller-diameter vessels. This degree of error may substantially influence WSS results. Additionally, pcMRA velocity data must be acquired outside of the angiographic workflow, are both time-consuming and expensive to acquire, and require transport that may be dangerous in critically ill patients. These disadvantages reduce the utility of pcMRA- and TCD-derived flow velocities.

The dual-sensor guidewire has several advantages over the above techniques in acquiring patient-specific measurements. Unlike TCD, it can be used in a highly anatomically specific manner in any major blood vessel, including in the vertebrobasilar system, and does not require temporal bone windows. Advantages over pcMRA include the real-time integration of blood flow velocity measurements during angiography, without transport to and from MR imaging. In addition, a previous report of direct comparison between blood flow velocity measured by pcMRA and from MR imaging. In addition, a previous report of direct
dermographic workflow, are both time-consuming and expensive to acquire, and require transport that may be dangerous in critically ill patients. These disadvantages reduce the utility of pcMRA- and TCD-derived flow velocities.

This study has several limitations. First, a small number of patients were studied with variable aneurysmal size and morphology, reducing the study's generalizability (though aneurysm location, vessel diameter, measured velocity, and waveform morphology were similar among all 4 studied patients). Second, although we attempted to recreate the exact location of the dual-sensor guidewire in pretreatment and posttreatment conditions, small variations in the location or angle of the wire may have influenced blood pressure and velocity measurements. Third, the position of the virtual stent in posttreatment CFD and the CFD-derived velocities may not precisely match their in vivo locations. These localization errors were minimized by use of multiple-projection radiographs and 3D volumes to plan virtual wire and stent placement. Fourth, changes in patient systemic hemodynamic status over the course of treatment may have influenced velocity and pressure measurements through the variance of systemic blood pressure, temperature, and end-tidal CO2. Fifth, subtle changes in stent porosity caused by deformity in curved cerebral vessels was not incorporated into CFD simulations. Finally, though the wire was manipulated in an attempt to measure the most robust velocity signal, it is possible that the measured blood flow velocity was not perfectly aligned within the center of the vessel, resulting in slight underestimations or error in these measurements.

CONCLUSIONS

We have successfully incorporated dual-sensor guidewire measurements of blood pressure and blood flow velocity into patient-specific CFD analyses of unruptured cerebral aneurysms before and after flow-diverting stent treatment. In accordance with the therapeutic intent of flow-diverting stents, significant intra-aneurysmal reductions in WSS and WSSG and a trend in reduced blood flow were observed after treatment.
