Abstract: Gaseous emissions, a side effect of livestock and poultry production, need to be mitigated to improve sustainability. Emissions of ammonia (NH₃), hydrogen sulfide (H₂S), greenhouse gases (GHGs), and odorous volatile organic compounds (VOCs) have a detrimental effect on the environment, climate, and quality of life in rural communities. We are building on previous research to bring advanced oxidation technologies from the lab to the farm. To date, we have shown that ultraviolet A (UV-A) has the potential to mitigate selected odorous gases and GHGs in the context of swine production. Much less research on emissions mitigation has been conducted in the context of poultry production. Thus, the study objective was to investigate whether the UV-A can mitigate NH₃, H₂S, GHGs, and O₃ in the simulated poultry barn environment. The effects of several variables were tested: the presence of photocatalyst, relative humidity, treatment time, and dust accumulation under two different light intensities (facilitated with fluorescent and light-emitting diode, LED, lamps). The results provide evidence that photocatalysis with TiO₂ coating and UV-A light can reduce gas concentrations of NH₃, CO₂, N₂O, and O₃, without a significant effect on H₂S and CH₄. The particular % reduction depends on the presence of photocatalysts, relative humidity (RH), light type (intensity), treatment time, and dust accumulation on the photocatalyst surface. In the case of NH₃, the reduction varied from 2.6–18.7% and was affected by RH and light intensity. The % reduction of NH₃ was the highest at 12% RH and increased with treatment time and light intensity. The % reduction of NH₃ decreased with the accumulation of poultry dust. The % reduction for H₂S had no statistical difference under any experimental conditions. The proposed treatment of NH₃ and H₂S was evaluated for a potential impact on important ambient air quality parameters, the possibility of simultaneously mitigating or generating GHGs. There was no statistically significant change in CH₄ concentrations under any experimental conditions. CO₂ was reduced at 3.8%–4.4%. N₂O and O₃ concentrations were reduced by both direct photolysis and photocatalysis, with the latter having greater % reductions. As much as 6.9–12.2% of the statistically-significant mitigation of N₂O was observed. The % reduction for O₃ ranged from 12.4–48.4%. The results warrant scaling up to a pilot-scale where the technology could be evaluated with economic analyses.

Keywords: air pollution, air quality; poultry; livestock; photocatalysis; photolysis; LED UV; odor; titanium dioxide; emissions
1. Introduction

Gaseous emissions, an unwanted side effect of livestock and poultry production, must be mitigated to improve the sustainability of the industry [1]. This is because the gaseous emissions include various components such as ammonia (NH$_3$), hydrogen sulfide (H$_2$S), greenhouse gases (GHGs), and odorous volatile organic compounds (VOCs) that have a detrimental effect on the environment, climate, and quality of life in rural communities [2,3]. Maurer et al. [4] reported on the effectiveness of technologies to reduce gas emissions from livestock and poultry housing, manure storage and treatment, and land application. The maturity and the number of technologies for poultry housing are far below those available for the swine industry [4].

Mitigation technologies can be divided into ‘end-of-pipe’ and ‘source-based’ types [5]. The source-based solution is a method of treating the manure as a source of emissions, such as surficial application of biochar [6], soybean peroxidase [7–9], zeolites and bentonites [10,11], urease inhibitors [12,13], feed additives [14], and manure aeration [15]. The end-of-pipe approach is the physicochemical and biological treatment for mitigating emissions from, for example, barns. Typical examples of the end-of-pipe solution are the use of biofilters [16,17] and scrubbers. Ultraviolet light (UV) can be considered as both end-of-pipe (treating exhaust air from barns) and a source-based (e.g., for improvement of indoor air quality; inside the barn) [1,18–21].

Near-UV (UV-A) irradiative treatment has been evaluated to reduce gas and fine particulate concentrations inside a swine barn as well as for increased feed conversion rates that lower the carbon footprint and improves the sustainability [18]. The ultraviolet range is traditionally broken up into wavelength ranges, labeled A, B, and C, corresponding to progressively shorter and more destructive wavelengths. UV-A (roughly 320–400 nm) is the least toxic of the UV range and is commonly used in commercial indoor tanning and other consumer applications. Treatment can be based on photolysis only (i.e., mitigation primarily via direct absorption UV light) and photocatalysis (i.e., primarily via surface-based reactivity based on the catalyst absorbing the light). Photocatalysis is commonly facilitated with nanoparticulate titanium dioxide (TiO$_2$), a material that is considered efficient, stable, reasonably durable, and cost-efficient [22–24]. Novel materials for TiO$_2$-based photocatalysis can improve the efficiency of photolytic UV-A treatment, as shown in the context of swine production [1,20].

The photocatalysis reaction is initiated when photons of sufficient energy (more than bandgap) irradiates the TiO$_2$ surface, resulting in electron ($e^-$)/hole ($h^+$) generation [23,25,26]. Activation of TiO$_2$ occurs at wavelengths $<400$ nm [27]. Although the detailed mechanism of photocatalysis varies with different target pollutants, it is commonly agreed that the primary reactions responsible are interfacial redox reactions of electrons and holes with adsorbed pollutants or mediators such as water [23,28,29].

Gaseous emission treatment in the barn through photocatalysis with TiO$_2$ and UV-A light has been shown to be effective in reducing NH$_3$, GHGs, VOCs, and odor [1,18,19,21] in the context of swine production. However, it is necessary to test whether UV treatment is useful for conditions associated with the poultry barn due to the lack of previous research. In addition, recent advancements in UV, such as novel TiO$_2$ coatings and energy-efficient UV-A lamps (i.e., light-emitting diode, LED) warrant testing of their applications to poultry housing.

This study was conducted to determine the potential for application of photocatalysis to poultry barn prior to pilot or farm-scale experiments. In other words, the objective of this study was to evaluate the UV-A treatment of NH$_3$, H$_2$S, GHGs, and O$_3$ in simulated (lab-scale) conditions of a poultry barn. The effects of several variables were tested: (a) treatment time, (b) TiO$_2$-based photocatalysis vs. direct photolysis, (c) light intensity (LED vs. fluorescent lamps), (c) poultry dust accumulation on photocatalyst, and (d) relative humidity, RH. Our working hypothesis was that longer treatment time, photocatalysis, LED light, and the presence of moisture, should improve the apparent treatment efficiency, while the presence of dust should not affect it. The experimental NH$_3$ and H$_2$S concentrations, treatment times, and RH were selected to provide realistic conditions in poultry barns, and thus to provide useful data for UV-A treatment scaling up. The GHGs and O$_3$ were measured for a
preliminary assessment of the broader impact of proposed treatment on important ambient and indoor air quality parameters.

2. Methods

2.1. Experimental System

An experimental system to evaluate gas emission reduction efficacy under UV-A irradiation was based on a modified setup from previous research, Figure 1 [21,30]. Three mass flow controllers were used to control the dilution of the standard gases and pure air and the RH. A 500 mL glass gas sampling bulb (Supelco, Bellefonte, PA, USA) was installed before and after the UV treatment reactor. The standard gases flowing through the 200 mL reactor were irradiated with UV-A through a quartz window. The reactor bottom was made from an ordinary glass that was coated with a photocatalyst (nanostructured TiO$_2$ at 10 µg·cm$^{-2}$ from PureTi, Cincinnati, OH, USA). The reactor temperature was maintained at 25 ± 3 °C while the heat generated by the UV lamps was discharged from the UV chamber by circulating-cooling tubes connected to the isothermal water bath.

![Figure 1. Schematic of UV-based mitigation of target gases at treatment times consistent with scaled-down conditions in the poultry barn.](image)

The gas flow rate into the reactor ranged from 60–300 mL·min$^{-1}$, resulting in a range of 40 s to 200 s treatment time. The treatment time was selected to represent typical air exchange rates inside poultry barns. NH$_3$ standard gas (70.5 ppm in N$_2$, ultra-high-purity, UHP grade, Praxair, Ames, IA, USA) was diluted to 30 ppm, a typical concentration reported inside poultry barns [31–33]. Similarly, H$_2$S standard gas (5.2 ppm in N$_2$, UHP grade, Praxair) was diluted to 0.5 ppm. The humidifier was used to adjust to three RH levels (approximately 0, 12%, 40%, and 60%). GHGs and O$_3$ concentrations were measured simultaneously with changes to NH$_3$ and H$_2$S. Because ambient air was used as a source, a certain naturally occurring level of GHG and O$_3$ naturally exists in the background of all experiments in the absence of all treatments. Typical values of NH$_3$, H$_2$S, CH$_4$, CO$_2$, N$_2$O, and O$_3$ were 30 ppm, 0.5 ppm, 2.2 ppm, 350 ppm, 0.2 ppm, and 23 ppb in the absence of any photolytic treatment, i.e., background control runs. The detection methods for each are described below. These environmental parameters were consistent with those observed in typical USA poultry and livestock production barns [34,35]. All experiments were performed in triplicate.
2.2. UV-A Irradiation Sources

Fluorescent lamps (Spectroline, Westbury, NY, USA) and an LED lamp (ONCE, Plymouth, MN, USA) were used; both UV lamps have a primary wavelength of 365 nm (Table 1). The lamps were installed 0.20 m above the UV treatment reactor. The light intensity was measured at 0.20 m distance from the source with an ILT-1700 radiometer equipped with an NS365 filter and SED033 detector (International Light Technologies, Peabody, MA, USA). The LED had ~4× greater intensity compared with the fluorescent lamp for nearly identical power consumption (measured w/ P3 wattage meter, Lexington, NY, USA).

Table 1. Comparison of UV-A lamps.

|                        | Fluorescent | LED  |
|------------------------|-------------|------|
| Total light intensity (mW cm^{-2}) | 0.44        | 4.85 |
| Power consumption (W)   | 48.2        | 43.3 |

Lamps position inside the UV chamber (4 fluorescent lamps and an array of 108 LED chips on an Al board sources were used)

2.3. Ammonia and Hydrogen Sulfide

NH₃ concentrations were measured in real-time using a Drager Xam 5600 portable gas analyzer (Luebeck, Germany) with NH₃ sensors (range: 0–300 ppm). The Drager analyzer was calibrated using Drager calibration software and standard gases. H₂S was measured (also in real-time) using a gas monitoring system (OMS-300, Smart Control & Sensing Inc., Daejeon, Rep. of Korea) equipped with the H₂S/C-50 electrochemical gas sensors from Membrapor Co. (Wallisellen, Switzerland; range: 0–50 ppm. The H₂S gas sensor was calibrated using standard gases. The flow rate used in this study was 60,300 mL min⁻¹, NH₃, and H₂S samples were collected in 5 L Tedlar bags to overcome the limitations associated with the sample collection flow rates required by the portable analyzers (NH₃: 0.5 L min⁻¹ and H₂S: 2 L min⁻¹).

2.4. Greenhouse Gases

GHGs samples were collected using syringes by drawing gas from the sampling bulbs and injecting them into evacuated 5.9 mL Exetainer vials (Labco Ltd, UK). Samples were analyzed on a gas chromatography (GC) equipped with a flame ionization detector (FID) and electron capture detector (ECD) detectors (SRI Instruments, Torrance, CA, USA). Standard calibrations were constructed daily using 10.3 ppm and 20.5 ppm CH₄; 1,005 ppm and 4,010 ppm CO₂; 0.101 ppm and 1.01 ppm N₂O; and pure helium was used at 0 ppm (Air Liquide America, Plumsteadville, PA, USA) [36]. Samples were stored at 4 °C immediately after collection and analyzed within one day after sampling.

2.5. Ozone

A real-time O₃ detector (Gas Sensing, Hull, IA, USA) was connected to the monitoring system (Series 500 monitor, Aeroqual, New Zealand) and installed in the UV treatment chamber. The O₃ concentration was analyzed by measuring the concentration of O₃ collected in a 0.5 L glass gas sampling bulb connected downstream from the UV reactor. The sensor was factory-calibrated before use. The detection range was from 0–0.05 ppm.
2.6. Dust Collection in A Poultry Barn

The presence of accumulated dust could potentially compromise the effectiveness of photocatalyst. Thus, in order to evaluate the effect of dust on mitigation efficiency, dust was collected at Poultry Teaching Farm (Ames, IA, USA). Three Styrofoam boxes that held two glass plates (blank and coated with TiO$_2$) were placed inside the barn horizontally and accumulated dust over time (Figure 2, part a). Also, three aluminum (Al) foil coupons were attached to simultaneously measure the weight of accumulated dust per area. The Styrofoam boxes were then removed from the barn, one by one, at one-week intervals for three weeks. Then, the same glass plates were mounted into the UV reactor (as the ‘Bottom layer: Glass in Figure 1) for testing. The weight of accumulated dust was estimated by subtracting the final from the initial Al foil coupon weight and extrapolated to the entire bottom layer glass area of the reactor. In addition, the effect of accumulated dust on light absorption at the glass with and without TiO$_2$ was measured using a 300-lumen bulb and a radiometer equipped with an XRD340B detector (International Light Technologies, Peabody, MA, USA), Figure 2 (part b).

![Figure 2](image_url)

**Figure 2.** Investigation of the effect of accumulated poultry dust on photocatalysis. (a) Dust collection box; (b) Schematic of the method used for measuring the light absorption by the accumulated dust on the glass (i.e., the bottom layer of the reactor in Figure 1) with and without TiO$_2$.

2.7. Data analysis, Accounting for Sample Losses Due to Adsorption

Gas samples were collected after a 1 h of equilibration time under each treatment condition. Small, yet consistent losses to target gases were observed over the course of experiments with the photocatalyst. Thus, the standard gas recoveries were also measured and reported as ‘adsorption’ series in the Results. The adsorption to the photocatalyst was assumed to be responsible for the losses and accounted for in the analyses. The overall mean reduction for each measured gas was estimated using:

\[
\% \text{ Reduction} = \frac{C_{\text{Con}} - C_{\text{Treat}}}{C_{\text{Con}}} \times 100\% \tag{1}
\]

where: $C_{\text{Con}}$ and $C_{\text{Treat}}$ are the mean measured concentrations in control and treated air, respectively.

2.8. Statistical Analysis

The R program (version 3.4.2) was used to analyze the effects of the catalyst, lamp-type, and environmental parameters on the reduction of the target gases by one way ANOVA. This statistical analysis generated $p$-values for evaluating whether a specific parameter/factor had a significant influence on treatment. A significant difference was defined for a $p$-value <0.05.
3. Results

3.1. Ammonia

In general, longer treatment time, use of photocatalyst, increased light intensity, and the presence of moisture in treated air improved the % NH$_3$ reduction. The highest reduction was 18.7% for 200 s treatment, LED photocatalysis at 12% RH, and no dust conditions. Dust decreased the performance of the photocatalyst. Detailed summaries and statistical significance of the effects of each treatment are presented in the subsections below.

3.1.1. Effect of the Photocatalyst, Relative Humidity, Light Intensity, and Treatment Time

The controlled NH$_3$ concentration used in the control group using the standard gas was 29.8 ± 1.2 ppm. Figure 3 illustrates the NH$_3$ reduction at three treatment conditions (direct photolysis, photocatalysis, and adsorption (by TiO$_2$)) under different RH, and 40 s (part a) and 200 s (part b) treatment time, respectively. Photocatalysis resulted in a 2.6–18.7% reduction, which was statistically significant for nearly all conditions (Tables A1 and A2, Appendix A). In comparison, direct photolysis resulted in no treatment or negligible % reduction and was not statistically significant.

![Figure 3. Comparison of NH$_3$ mitigation under different treatment types and light intensities. (a) % reduction at treatment time of 40 s; (b) % reduction at treatment time of 200 s; Superscript (*) signifies a statistical difference compared to the control (p < 0.05), and the different characters (a, b) signify statistical difference when comparing different light intensities (fluorescent vs. LED) at the same relative humidity (p < 0.05). The % reduction was the highest at 12% (7.3–18.7%, p < 0.05). Error bars signify ± standard deviation.](image-url)
Closer inspection of the patterns in the effectiveness of photocatalysis showed that it was affected by RH, light (type) intensity, and treatment time. The LED lamp (having ~4× higher intensity) facilitated a higher % reduction, the greatest (~2×) improvement observed at 12% RH. Moreover, the statistical difference in this improvement was shown for both RH 12% and 40% at 200 s treatment (Figure 3, part b).

Figure 4 highlights the % reduction with different treatment times and RH. The LED-based photocatalysis at lower RH (12% and 40%) outperformed the fluorescent-based treatment for NH₃ mitigation.

![Figure 4](image-url)  
*Figure 4. Comparison of NH₃ mitigation under different relative humidity and treatment time. Superscript (*) signifies a statistical difference compared to the control (*p* < 0.05), and the different characters (a, b, c, d) signify the statistical difference between treatments associated with one UV lamp type (*p* < 0.05). Error bars signify ± standard deviation.*

3.1.2. Effect of Poultry Dust

Dust accumulation on TiO₂ had a detrimental effect on the effectiveness of photocatalysis (Figure 5, Tables A3 and A4), particularly at low RH (12%). In addition, accumulated poultry dust absorbed light, and the linear increase (from 14.1 to 40.1%) in light absorption with dust accumulation on the photocatalyst surface over time (from 6.9 to 16.3 mg·cm⁻²) was observed. The average light absorption was 27 ± 12%, and the dust accumulation was 11 ± 4 mg·cm⁻² (Table 2).

| Dust Accumulation Duration | Light Absorption (%) | Dust Accumulation (mg·cm⁻²) |
|---------------------------|----------------------|-----------------------------|
| 1 week                    | 14.1 ± 3.6           | 6.9 ± 0.4                   |
| 2 weeks                   | 27.1 ± 4.0           | 11.0 ± 0.7                  |
| 3 weeks                   | 40.1 ± 5.9           | 16.3 ± 1.3                  |
| Average                   | 27.1 ± 12            | 11.4 ± 4.2                  |

The values in the table report the mean ± standard deviation.
Figure 5. Comparison of NH$_3$ mitigation under different poultry dust levels. (a) % reduction at relative humidity of 12%; (b) % reduction at relative humidity of 60%; Superscript (*) signifies a statistical difference compared to the control ($p < 0.05$), and the different characters (a, b) signify statistical difference at the same treatment time and the same light intensity ($p < 0.05$). Error bars signify ± standard deviation.

There was no statistical significance of the change in the reduction at RH 60% (Figure 5, part b). The low (12%) RH had the most considerable decrease in mitigation (from 18.7% to 5.1%) under the LED light, yet it was still statistically significant even with the highest dust accumulation of 16.3 mg·cm$^{-2}$ ($p < 0.05$). In other words, the LED-based treatment was still performing well, regardless of dust accumulation ($p < 0.05$).
3.2. Hydrogen Sulfide

The controlled H$_2$S concentration in the control group using the standard gas was 0.52 $\pm$ 0.02 ppm. No statistically significant reduction in H$_2$S concentration was observed under any experimental conditions ($p > 0.05$), even with the most favorable conditions of 200 s, photocatalyst usage, LED irradiation, and elevated moisture (Figure 6). Similarly, there was no statistical difference associated with the dust accumulation at 12% RH regardless of the light type (intensity) and treatment time (Figure 7).

![Graph](image1.png)

**Figure 6.** Comparison of H$_2$S mitigation under relative humidity. (a) % reduction at a treatment time of 40 s; (b) % reduction at a treatment time of 200 s. Error bars signify ± standard deviation.
3.3. Greenhouse Gases

The treatment of target gases (NH$_3$, H$_2$S) was evaluated for a potential impact on important ambient air quality parameters, the possibility of simultaneously mitigating or generating GHGs. No GHGs were fed into the reactor; however, as noted previously, the air source naturally contained measurable amounts of these compounds. Thus, the GHGs concentrations in the treatment and control were compared.

3.3.1. Methane

The average concentration in controls was 2.2 ± 0.1 ppm. There was no statistically significant change in CH$_4$ concentration under direct photolysis, photocatalysis, and adsorption to the catalyst. Moreover, there were no statistically significant changes, regardless of RH, light type (intensity), treatment time, and dust accumulation when NH$_3$ and H$_2$S standard gases were treated with UV (Figures 8 and 9).
3.3.2. Carbon Dioxide

The average CO$_2$ concentration in control samples (i.e., present naturally in air) was 350 ± 25 ppm, and no mitigation was observed under photolysis and adsorption. Interestingly, there was a 3.8% (mean) reduction at 200 s photocatalysis with LED at 12% RH (Figure 10 and Table A5). Specifically, the mitigation was 3.2% and 4.4% when NH$_3$ and H$_2$S standard gases were treated, respectively. However, there was no statistical difference between the two standard gases ($p > 0.05$). There was no CO$_2$ reduction under dust accumulation (Figure 11).
were found for more experimental conditions for H2S than NH3. However, there was no significant % reduction were observed for 200 s photocatalysis with LED at 12% RH when NH3 and H2S were treated, respectively (Table 3). In general, statistically-significant % reductions were found for more experimental conditions for H2S than NH3. However, there was no significant difference between the two conditions. There was no apparent relationship between N2O % reduction and other controlled parameters.

### 3.3.3. Nitrous Oxide

In general, mitigation of concentration was observed under both direct photolysis and photocatalysis, with greater reductions with TiO2 photocatalysts. However, there was no statistical difference between the two conditions. There was no apparent relationship between N2O % reduction and other controlled parameters.

#### Comparison of N2O Mitigation when Treating NH3 and H2S Standard Gas

The average N2O concentration in control was 0.24 ± 0.03 ppm. As much as 6.9% and 12.2% of the statistically-significant % reduction were observed for 200 s photocatalysis with LED at 12% RH when NH3 and H2S were treated, respectively (Table 3). In general, statistically-significant % reductions were found for more experimental conditions for H2S than NH3. However, there was no significant
difference between the % reduction resulting from the use of two standard gas treatments (i.e., p-values in Table 3).

**Table 3.** The mitigation of N$_2$O during photocatalysis of NH$_3$ and H$_2$S standard gases.

| Relative Humidity | Type of UV Lamp | Standard Gas 40 s Treatment Time | p-Value$^1$ | Standard Gas 200 s Treatment Time | p-Value$^1$ |
|------------------|----------------|---------------------------------|------------|-----------------------------------|------------|
|                  | NH$_3$         | H$_2$S                          |            | NH$_3$                            |            |
| Dry              | Fluorescent    | 4.1 ± 8.2                       | 0.83       | 2.7 ± 1.7                         | 0.36       |
|                  | LED            | 5.1 ± 3.2                       | 0.95       | 4.2 ± 0.0*                        | 0.49       |
| 12%              | Fluorescent    | 3.0 ± 4.1                       | 0.44       | 1.8 ± 2.1                         | 0.69       |
|                  | LED            | 6.2 ± 4.0                       | 0.09       | 6.8 ± 1.6*                        | 0.05       |
| 40%              | Fluorescent    | 3.4 ± 0.3 *                     | 0.53       | 1.5 ± 1.0                         | 0.49       |
|                  | LED            | 5.5 ± 1.1 *                     | 0.33       | 8.6 ± 3.1                         | 0.09       |
| 60%              | Fluorescent    | 2.4 ± 0.6                       | 0.94       | 5.8 ± 6.5                         | 0.12       |
|                  | LED            | 4.0 ± 1.8                       | 0.85       | 5.3 ± 1.4                         | 0.78       |

The value in the table reports the mean ± standard deviation. Superscript (*) signifies value from the statistical analysis of the N$_2$O concentrations reduced under the two standard gases. Superscript (') signifies a statistical difference compared to the control (p < 0.05).

Effect of Photocatalyst, Light Type, Relative Humidity, Dust, and Treatment Time on N$_2$O

We further investigated the apparent mitigation of N$_2$O (a potent GHG) by averaging the results for H$_2$S and NH$_3$ to elucidate possible mechanisms responsible for this finding. The statistically significant mitigation was observed in both direct photolysis and photocatalysis, at 3.3–6.5% and 2.8–9.5%, respectively (Figure 12, Tables A6 and A7). In general, photocatalysis was more effective for reducing N$_2$O than photolysis alone (Figure 12, parts a and b, Tables A6 and A7). However, there was no statistical difference between the two treatments (i.e., at dry and 12% RH, Table A7) were compared. Similarly, no apparent statistical significance was found for variation of the treatment time, dust accumulation, lamp type, and RH (Figures 13 and 14, Tables A8–A10). This is because there are few statistically significant % reduction of N$_2$O for variable parameters, without any apparent trend.

![Figure 12](image-url)
Figure 12. Comparison of N$_2$O mitigation under different treatment types and light type intensity. Figure 13. Comparison of N$_2$O mitigation under different relative humidity and treatment time. Superscript (*) signifies a statistical difference compared to the control ($p < 0.05$), and the different characters (a, b) signify the statistical difference between treatments associated with one UV lamp type ($p < 0.05$). Error bars signify ± standard deviation.
Concerns about \( \text{O}_3 \) generation when UV light is used were addressed in this research. In general, \( \text{O}_3 \) concentrations were significantly reduced under direct photolysis and photocatalysis. The direct photolysis treatment did not result in a clear relationship between the controlled parameters and the \( \text{O}_3 \) % reduction. Photocatalysis resulted in an improved mitigation dependent on the light type (intensity) at RH of 12% and 60%. However, there was no effect associated with treatment time and dust accumulation.

**Figure 14.** Comparison of \( \text{N}_2 \text{O} \) mitigation under different poultry dust levels at 200 s of treatment time. (a) % reduction at a relative humidity of 12% and 60% in direct photolysis; (b) % reduction at a relative humidity of 12% and 60% in photocatalysis. Superscript (*) signifies a statistical difference compared to the control \( (p < 0.05) \), and the different characters (a, b) signify the statistical difference between treatments associated with one UV lamp type and one relative humidity \( (p < 0.05) \). Error bars signify ± standard deviation.

3.4. Ozone

Concerns about \( \text{O}_3 \) generation when UV light is used were addressed in this research. In general, \( \text{O}_3 \) concentrations were significantly reduced under direct photolysis and photocatalysis. The direct photolysis treatment did not result in a clear relationship between the controlled parameters and the \( \text{O}_3 \) % reduction. Photocatalysis resulted in an improved mitigation dependent on the light type (intensity) at RH of 12% and 60%. However, there was no effect associated with treatment time and dust accumulation.
3.4.1. Comparison of Mitigation under NH₃ and H₂S Standard Gas

The average concentration of O₃ in the control group was 22.6 ± 6.5 ppb. As much as 46.5% & 50.3% of the statistically-significant % reduction in O₃ concentrations were observed for 200 s photocatalysis with LED at 12% RH when NH₃ and H₂S were treated, respectively (Table 4). However, there was no significant difference between the reduction resulting from the use of two standard gas treatments (i.e., p-values, Table 4). In addition, a statistically significant % reduction was found at more experimental conditions under 200 s treatment time compared with 40 s.

Table 4. The mitigation of O₃ at photocatalysis under NH₃ and H₂S standard gas.

| Relative Humidity | Type of UV Lamp | 40 s Treatment Time | 200 s Treatment Time |
|-------------------|----------------|---------------------|---------------------|
|                   |                | Standard Gas        | p-Value |  NH₃  | H₂S  | p-Value | NH₃  | H₂S  |
| Dry               | Fluorescent    | 33.5 ± 15.4         | 0.22    | 27.1 ± 2.1 *| 18.0 ± 0.2 *| 0.13 |
|                   | LED            | 28.4 ± 3.3 *        | 0.50    | 31.7 ± 2.3 *| 25.7 ± 0.5 *| 0.16 |
| 12%               | Fluorescent    | 22.0 ± 17.6         | 0.38    | 24.4 ± 0.9 *| 23.0 ± 4.2 *| 0.27 |
|                   | LED            | 39.3 ± 10.4         | 0.37    | 50.3 ± 2.4 *| 46.5 ± 8.0 *| 0.89 |
| 40%               | Fluorescent    | 34.6 ± 24.0         | 0.67    | 22.3 ± 0.5 *| 21.2 ± 9.0 *| 0.57 |
|                   | LED            | 40.6 ± 4.4 *        | 0.48    | 29.7 ± 5.2 *| 22.4 ± 0.7 *| 0.46 |
| 60%               | Fluorescent    | 23.2 ± 2.5 *        | 0.69    | 23.4 ± 1.2 *| 23.8 ± 0.0 *| 0.40 |
|                   | LED            | 26.1 ± 21.2         | 0.50    | 41.8 ± 0.6 *| 33.3 ± 2.5 *| 0.06 |

Values in the table report the mean ± standard deviation. Superscript (1) signifies value from the statistical analysis of the N₂O concentrations reduced under the two standard gases. Superscript (*) means there is a statistical difference compared to the control (p < 0.05).

3.4.2. Effect of Photocatalyst, Light Type, Relative Humidity, Dust, and Treatment Time on O₃

O₃ % reduction for various parameters was evaluated using the average of % reductions for treatments of NH₃ and H₂S standard gases. The was significant mitigation on direct photolysis and photocatalysis of 12.4–23.5% and 21.6–48.4%, respectively (Figure 15, Tables A11 and A12). In general, photocatalysis was more effective for reducing O₃ concentrations than was direct photolysis. However, there was no statistical difference between the direct photolysis and photocatalysis except the condition of 200 s at dry and 12% RH (Figure 15, part b). Notably, the % reduction increased ~4× for 200 s photocatalysis with LED at 12% RH (Table A12).

In the case of direct photolysis, there was no clear trend and statistical significance for the treatment time, dust accumulation, lamp type, and RH (Figures 15–17, Tables A11–A14). More statistically-significant % reductions were found for 200 s treatments than 40 s. Moreover, even the maximum accumulation of dust did not have a significant impact on % reduction (Figure 17, Tables A15 and A16).
Figure 15. Comparison of O₃ mitigation under different treatment types and light intensity. (a) % reduction at treatment time of 40 s; (b) % reduction at treatment time of 200 s; Superscript (*) signifies a statistical difference compared to the control (p < 0.05), and the different characters (a, b) signify a statistical difference when comparing different light intensities (fluorescent vs. LED) at the same relative humidity (p < 0.05). Error bars signify ± standard deviation.
Figure 16. Comparison of O$_3$ mitigation under different relative humidity and treatment time. Superscript (*) signifies a statistical difference compared to the control ($p < 0.05$), and the different characters (a, b) signify a statistical difference between treatments associated with a lamp type ($p < 0.05$). Error bars signify ± standard deviation.

Figure 17. Comparison of O$_3$ mitigation under different poultry dust levels. Error bars signify ± standard deviation.
4. Discussion

4.1. Ammonia and Hydrogen Sulfide

In this study, NH$_3$ mitigation was only effective when photocatalysis was used, regardless of the type of UV lamp, which is generally consistent with previous research. Research [37,38] suggests that a shorter wavelength (e.g., 220 nm) is needed to mitigate NH$_3$ with photolysis. Other researchers have also reported on the weak adsorption of NH$_3$ to the TiO$_2$ coated surface at room temperature [39,40].

The greatest mitigation of NH$_3$ was at 12% RH in photocatalysis. The % reduction decreased with either dry air or increasing RH. In general, the higher % reduction is achieved under low (or dry) humidity conditions. This is due to the adsorption of water on the TiO$_2$ surface [39,41,42], which, in turn, inhibits the mitigation of the target substances [43–45]. A similar trend (at least for low RH) was observed in this study. However, the % reduction was found to be decreased in the dry condition, which was expected to show the highest % reduction. One explanation could be that the decreased % reduction in dry conditions is due to the absence of HO radicals produced by the photocatalysis of water. HO radicals make it easier to oxidize NH$_3$ [46]. The optimal RH for the % reduction is different depending on the type of target gas. The comparison of optimum RH for selected target gases in the photocatalysis is summarized in Table 5.

Table 5. Comparison of optimum relative humidity for each target gases in the photocatalysis.

| Reference | Target Gas                | UV Type (Wavelength) | Coating Material (Dose) | The Relative Humidity Condition for Optimal % Reduction |
|-----------|---------------------------|----------------------|-------------------------|--------------------------------------------------------|
| [42]      | Ammonia                   | UV-A (355 nm)        | TiO$_2$-P25 (650 µg·cm$^{-2}$) | Low > High                                            |
| [43]      | Toluene                   | UV-A (315–400 nm)    | TiO$_2$-P25 (Not reported) | Dry (1%)                                               |
| [44]      | Acetaldehyde              | UV-A (365 nm)        | TiO$_2$ (Not reported)   | Dry                                                   |
| [47]      | Trichloroethylene         | UV-A (Not reported)  | TiO$_2$ sol-gel films (~1 mg·cm$^{-2}$) | <50%                                                  |
| [48]      | Trichloroethylene         | UV-A (Not reported)  | TiO$_2$-GFC (4.8 g·cm$^{-2}$) | <25%                                                  |
| [49]      | Hydrogen sulfide          | UV-A (Not reported)  | TiO$_2$-ceramic filter (Not reported) | No impact (40–80%)                                    |
|           | Volatile organic compounds| Not reported (280–650 nm) | TiO$_2$-P25 (Thickness of 1–2 mm) | Dry                                                   |
| [50]      | Hydrocarbons mixture      | Not reported         | TiO$_2$-P25 (10 µg·cm$^{-2}$) | 12%                                                   |

Table 6 summarize previous research on the % reduction of selected target gases important in animal production systems via photocatalysis with UV-A. The % reduction of NH$_3$ was ~30%, but it required longer treatment (>6 min). In this study, the % reduction was ~9% on average (max: 18.7%, min: 2.56%) and 200 s. In general, the % reduction increases as the UV light intensity and treatment time of photocatalysis action increase [38,47,51]. This study also showed an increase in NH$_3$ % reduction with increasing light intensity and treatment time.
### Table 6. Summary of mitigation for selected target gas in photocatalysis with UV-A.

| Reference | Experiment Conditions | Coating Material | UV Type (Wavelength) | Light Intensity | Target Gas (% Ave Reduction) |
|-----------|-----------------------|------------------|----------------------|-----------------|------------------------------|
| [1]       | Swine farm Temp: 21.8–26.0 °C RH: 36–80% T time 4 (s): 24, 47 | TiO<sub>2</sub> (10 µg·cm<sup>−2</sup>) | UV-A (365 nm) | <0.04 mW·cm<sup>−2</sup> | CH<sub>4</sub> (~2.2) CO<sub>2</sub> (~3.1) N<sub>2</sub>O (8.7) Odor (16.3) p-cresol (22.0) |

Note: 1 Mean; 2 Temperature; 3 Relative humidity; 4 Treatment time; Bold font signifies a statistical difference (p < 0.05).

Photocatalysis was affected by dust accumulation. In particular, the increase in dust at high RH conditions canceled the NH<sub>3</sub> % reduction effect. This is because when dust accumulated, poultry dust continually increased the absorption of the UV light. Zhu et al. [21] reported that dust accumulation (in a swine barn) had no effect on the % reduction of VOCs. In this study, H<sub>2</sub>S showed no % reduction effect in the treatment system using UV-A light and TiO<sub>2</sub> based photocatalysis. Previous studies with higher TiO<sub>2</sub> coating density and light intensity have shown a mitigation effect [53,54].

### 4.2. Greenhouse Gases and Ozone

CH<sub>4</sub> was not affected by any treatment in this study. The results add to a mixed body of knowledge. Our previous study with PureTi coating [1] did not show a statistically significant % reduction. Another research reported photocatalytic CH<sub>4</sub> % reduction at a low product yield and low energy efficiency [55]. However, two previous studies [18,19] (UV-A light) reported an 11–27% reduction. The reasons for our lack of apparent treatment could be due to low TiO<sub>2</sub> coating density, and the possibility that the mitigation effect was offset by forming CH<sub>4</sub> from the reduction of CO<sub>2</sub> [56–58].

CO<sub>2</sub> showed a 3.8% mitigation only under the RH of 12% with 200 s of LED irradiation. Although there is previous research demonstrating photocatalytic reduction of CO<sub>2</sub> to CH<sub>4</sub> under specific conditions [59], there is no chemical reason to expect that photocatalysis under these conditions (aerobic atmosphere and standard TiO<sub>2</sub> catalyst) could reduce CO<sub>2</sub>; in fact, CO<sub>2</sub> is the oxidative endpoint for photocatalytic oxidation of virtually all carbon-containing compounds. It is thus tempting to suggest that an indirect mechanism for any observed CO<sub>2</sub> mitigation must exist, such as conversion to carbonates or surface absorption. By whatever mechanism, similar CO<sub>2</sub> concentration reductions were also observed by previous studies [19,58].
N$_2$O and O$_3$ were mitigated in both direct photolysis and photocatalysis. In general, N$_2$O and O$_3$ are known not to absorb significantly in the UV-A range, meaning that they are not subject to direct photolytic degradation at these wavelengths. However, indirect effects through more complex reaction paths can certainly affect their observed concentrations. Similarly, under photocatalytic conditions, where direct absorption by the substrate is not required, reasonably direct removal can occur. Previous research [60] reported that the N$_2$O photolysis rate was inhibited at >230 nm, and [61] reported that O$_3$ reduction does not occur efficiently at >305 nm. However, this and our previous study [1] showed the mitigation effect of N$_2$O and O$_3$ under 365 nm. In the case of N$_2$O, the % reduction was about 3.3–6.5%, also in the case of O$_3$, the % reduction was 12.4–24.1% (Table 7).

| Reference | Treatment Time | Direct Photolysis | Photocatalysis |
|-----------|---------------|------------------|---------------|
|           |               | Target Gas (%) Reduction |                |
| [1]       | 24 s          | N$_2$O (4.2)     | N$_2$O (7.3)  |
|           | 47 s          | N$_2$O (7.6)     | N$_2$O (8.7)  |
| This study| 40 s          | N$_2$O (No % reduction) | N$_2$O (2.8–6.8) |
|           |               | O$_3$ (23.5)     | O$_3$ (21.6–37.0) |
|           | 200 s         | N$_2$O (3.3–6.5) | N$_2$O (3.7–9.5) |
|           |               | O$_3$ (12.4–24.1) | O$_3$ (21.8–48.4) |

As expected, photocatalysis showed higher mitigation for N$_2$O than direct photolysis. However, this study result is quite different from those of previous studies. This is because previous research [20,37,38,51,52,62] indicates that by-products like N$_2$O and N$_2$ are generated via photocatalysis reaction in the presence of NH$_3$, but the levels of N$_2$O and N$_2$ vary according to treatment conditions and wavelength. Only one previous study showed a consistent trend with this study [1]. In theory, TiO$_2$ could only be activated by UV light with a wavelength of <387.5 nm due to its considerable bandgap energy [63,64]. Also, N$_2$O has been reported to be mitigated with UV-A, although its efficiency is lower than that of UV-C [63]. How much of this process actually decrease the N$_2$O produced by NH$_3$ decomposition has not been investigated in this study. However, the low but statistically significant % reduction could be due to other factors such as direct reduction by photocatalysis, indirect reduction by electrochemical reactions during the decomposition of other substances such as O$_3$, and adsorption of by-products on the TiO$_2$.

In the case of O$_3$, the previous results are different depending on the type of TiO$_2$ coating material, but it is reported that O$_3$ reduction does not occur >290 nm with TiO$_2$ [65]. However, O$_3$ has been reported to increase the reduction of target gas through the formation of ozonide radicals during photocatalysis [66–69]. Thus, during photocatalysis, O$_3$ concentration can be reduced due to the formation of ozonide radicals that are beneficial for reducing other target gases. In this study, the % reduction was 3.4–9.7% for N$_2$O and 20.4–48.4% for O$_3$.

5. Conclusions

The results of the study provide evidence that photocatalysis with TiO$_2$ coating and UV-A light can reduce gas concentrations of NH$_3$, CO$_2$, N$_2$O, and O$_3$ without significant effect on H$_2$S and CH$_4$. The particular % reduction depends on the presence of photocatalyst, RH, light type (intensity), treatment time, and dust accumulation on the photocatalyst surface. In the case of NH$_3$, the % reduction varied from 2.6–18.7% and was affected by RH and light intensity. The % reduction of NH$_3$ was the highest at 12% RH and increased with treatment time and light intensity. The % reduction of NH$_3$ decreased with the accumulation of poultry dust. The % reduction for H$_2$S had no statistical difference under any experimental conditions. The proposed treatment of NH$_3$ and H$_2$S was evaluated for a potential impact on important ambient air quality parameters, the possibility of simultaneously
mitigating/generating GHGs. There was no statistically significant change in CH$_4$ concentrations under any tested conditions. CO$_2$ was reduced at 3.8–4.4%. N$_2$O and O$_3$ concentrations were reduced by both direct photolysis and photocatalysis, with the latter having greater % reductions. As much as 6.9–12.2% of the statistically-significant % reduction of N$_2$O was observed. The % reduction for O$_3$ ranged from 12.4–48.4%. The results warrant scaling up to pilot-scale where the technology could be evaluated with economic analyses. It is necessary to investigate the practical applicability to the real system through large scale studies.
