Abstract

The two-step model with \( \pi \), \( \rho \) and \( \omega \) exchanges taken into account is applied to investigate the reactions \( pn \rightarrow d\eta \) and \( pn \rightarrow d\eta' \) near the corresponding thresholds. The existing experimental data on the reaction \( pn \rightarrow d\eta \) are analyzed and predictions for the cross section of the reaction \( pn \rightarrow d\eta' \) are presented. It is found that \( \pi \)- as well as \( \rho \)-meson exchanges yield significant contributions in both reactions. Furthermore, the effect of the \( \eta N \) final-state interaction is studied. It is shown that an \( \eta N \)-scattering length of \( \text{Re } a_{\eta N} \leq 0.3 \text{ fm} \) is sufficient to reproduce the observed enhancement of the \( pn \rightarrow d\eta \) cross section close to threshold.

\textit{PACS} 25.10.+s; 13.75.-n

\textit{Key words:} Meson production; Eta; pn.

Recently, the total cross section of the reaction \( pn \rightarrow d\eta \) has been measured close to threshold at CELSIUS in Uppsala [1,2]. These data are remarkable for a variety of reasons: E. g., they reveal that an older estimate yielding a rather large near-threshold production cross section for the reaction \( pn \rightarrow d\eta \) [3,4] is definitely ruled out [2]. Furthermore, they show that the production cross section very close to threshold is significantly enhanced over the expectation

for a two-body phase-space behaviour [2], indicating the presence of a strong final-state interaction.

Though there is a large body of theoretical papers about the reaction $pp \rightarrow pp\eta$ only a few of them have also dealt with aspects of the near-threshold $pn \rightarrow d\eta$ and $pn \rightarrow (pn)_{I=0}\eta$ production [3–7]. Moreover, all of them rely on the old and now obsolete data point of Ref. [3]. Thus, in the following we want to present a timely re-analysis of this reaction utilizing now the new data from CELSIUS. In particular, we are going to present results of a microscopic calculation of the $pn \rightarrow d\eta$ cross section within the framework of the two-step model (TSM), previously applied to the description of the Pontecorvo reactions $\bar{p}d \rightarrow pM$ (see, e.g., Ref. [8] and references therein). We start from the $\pi$ exchange contribution to the $\eta$-meson production and study the relevance of other production mechanisms such as the $\rho$ and $\omega$ exchange. Furthermore, we investigate the effect of the final-state interaction between the $\eta$ meson and the nucleons employing an optical-potential model as well as a multiple scattering approach. Finally, as an application of our model, we present predictions for the cross section of the reaction $pn \rightarrow d\eta'$ near threshold.

In the TSM the reaction $pn \rightarrow dM$ proceeds in two steps: i) the initial nucleons produce an $\eta$ or $\eta'$ meson (denoted as $M$) via virtual $\pi$-, $\rho$- or $\omega$-meson exchange; ii) the proton and neutron form a deuteron in the final state (see Fig. 1).

The amplitude which describes the contribution of the $\pi^0$ exchange can be written in the form

$$T^\pi_{pm\rightarrow dM}(s, t, u) = A^\pi_{pm\rightarrow dM}(s, t) + A^\pi_{pm\rightarrow dM}(s, u),$$

where $M$ is the pseudoscalar meson $\eta$ or $\eta'$. $s = (p_1 + p_2)^2$, $t = (p_3 - p_1)^2$, and $u = (p_3 - p_2)^2$ where $p_1$, $p_2$, $p_3$, and $p_4$ are the 4-momenta of the proton, neutron, $M$-meson and deuteron, respectively. Treating the nucleons inside the deuteron nonrelativistically, the two terms on the right hand side of Eq. (1) are given by (see, e.g., Ref. [9])

$$A^\pi_{pm\rightarrow dM}(s, t) = \frac{f_\pi}{m_\pi} \varphi_\lambda_2(p_2) (-i\sigma_2) \bar{\sigma} \cdot \vec{M}^\pi(p_1) \bar{\sigma} \cdot \hat{\epsilon}_d \varphi_\lambda_1(p_1) \times A^\pi_{\pi^0 N\rightarrow MN}(s_1, t),$$

$$A^\pi_{pm\rightarrow dM}(s, u) = \frac{f_\pi}{m_\pi} \varphi^T_\lambda_1(p_1) (-i\sigma_2) \bar{\sigma} \cdot \vec{M}^\pi(-p_1) \bar{\sigma} \cdot \hat{\epsilon}_d \varphi_\lambda_2(p_2) \times A^\pi_{\pi^0 N\rightarrow MN}(s_1, u),$$

2
where \( \vec{\epsilon}_d \) is the polarization vector of the deuteron and \( \varphi_\lambda \) the spinors of the nucleons in the initial state. \( f_\pi \) is the \( \pi NN \) coupling constant, for which we use the value \( f_\pi^2/(4\pi) = 0.08 \). Furthermore we have

\[
\hat{M}_\pi(p_1) = \sqrt{2m} \int (\vec{k} + \vec{p}_1) \Phi_\pi(\vec{k}, \vec{p}_1) \Psi_d(\vec{k}) \frac{d^3k}{(2\pi)^{3/2}},
\]

\[
\Phi_\pi(\vec{k}, \vec{p}_1) = \frac{F_\pi(q^2)}{q^2 - m_\pi^2},
\]

with the kinematics

\[ q^2 = m_\pi^2 - \delta_0(\vec{k}^2 + \beta(\vec{p}_1^2)) - 2\vec{p}_1 \vec{k}, \quad \vec{q} = \vec{k} + \vec{p}_1, \]

\[ \beta(\vec{p}_1) = (p_1^2 + p_2^2 - T_1^2)/\delta_0, \quad \delta_0 = 1 + T_1/m, \quad T_1 = \sqrt{p_1^2 + m^2 - m}. \]

In Eqs. (4) and (5) \( \Psi_d(\vec{k}) \) is the deuteron wave function, \( F_\pi(q^2) \) the form factor at the \( \pi NN \) vertex and \( m \) the nucleon mass. Note that the amplitude \( \hat{M}_\pi \) corresponds to the exchange of a neutral \( \pi \) meson only (see the left diagrams in Fig. 1). To take into account also the charged pion exchange we have to multiply amplitude (1) with an isospin factor (which is equal to 3).

The form factor \( F_\pi(q^2) \) is taken to be of monopole type with a cutoff mass \( \Lambda_\pi = 0.8 \text{ GeV}/c \), in line with recent QCD lattice calculations [10] and other information [11]. The D-wave part of the deuteron wave function gives only a small contribution and can be savely neglected. This was demonstrated in Ref. [8] for the case of the reaction \( \vec{p}d \rightarrow Mn \) where the same structure integrals (4) for \( \pi, \rho \) and \( \omega \) exchanges occur. Note that the property \( \hat{M}_\pi(\vec{p}_1) = -\hat{M}_\pi(-\vec{p}_1) \) ensures the correct behaviour of the amplitude (1) under permutations of the initial nucleons. The amplitude should be symmetric in the isoscalar state.

Near threshold only the S-wave part of the amplitude of the elementary reaction \( \pi N \rightarrow MN \) should be of relevance for the production amplitude \( T_{pn \rightarrow dM} \). It can be obtained from the experimental S-wave cross section through the relation

\[
|A_{\pi^0 N \rightarrow MN}(s_1, t)|^2 = |A_{\pi^0 N \rightarrow MN}(s_1, u)|^2 = 8\pi s_1 \frac{P^M_{\text{cm}}}{P^M \sigma_{\pi p \rightarrow Mn}} \sigma_{\pi^0 N \rightarrow MN}(s_1, t) \frac{P^M_{\text{cm}}}{P^M \sigma_{\pi p \rightarrow Mn}} (6)
\]

where \( s_1 \) is the square of the c.m. energy in the \( Mn \) system. The values of these S-wave cross sections that we used in our calculation are

\[ \sigma_{\pi p \rightarrow \eta n} = (21.2 \pm 1.8)\mu b \text{ and } \sigma_{\pi \rightarrow \eta' n} = (0.35 \pm 0.03)\mu b \]

(\( P^M \) in MeV/c). They are extracted from the data given in Ref. [12].
The total cross sections resulting from the $\pi$-exchange contribution (with $\Lambda_\pi = 0.8$ GeV/c) are shown in Figs. 2 and 3 (dashed curves) as a function of the c.m. excess energy $Q = \sqrt{s} - m_3 - m_4$. The data points for $\eta$ production (Fig. 2) are taken from [1,2].

Evidently pion exchange alone cannot describe the $\eta$-production cross-section data. Of course, we could have simply adjusted the cutoff mass in the pion form factor in such a way that we reproduce the data. But it goes without saying that the exchange of heavier mesons should also be considered as well as effects of the initial- and final-state interactions.

In order to obtain a direct estimate of the contributions from the $\rho$ and $\omega$ exchanges we calculated them in the framework of the TSM using the vector-dominance model (VDM) prediction for the amplitude $\rho N \rightarrow \eta(\eta')N$ and assuming that $A_{\omega N \rightarrow \eta(\eta')N} \approx A_{\rho N \rightarrow \eta(\eta')N}$. We derive the S-wave $\gamma N \rightarrow \eta N$ amplitude from the Mainz data at $E_\gamma = 716$ MeV [13] where the differential cross section of the reaction $\gamma p \rightarrow \eta p$ is isotropic. In the case of $\eta'$ we take the $\gamma p \rightarrow \eta' p$ cross section of about 1 – 1.5 $\mu$b at $E_\gamma = 1.5$ GeV from Ref. [14]. According to Ref. [14] the differential cross section of the reaction $\gamma p \rightarrow \eta' p$ at this energy is almost isotropic. In the actual evaluation of the amplitudes we use the coupling constants $\gamma_\rho$ and $\gamma_\omega$ of Ref. [15]. The $VN \rightarrow MN$ amplitudes for longitudinal polarization of the vector mesons $V$ are taken to be the same as the transversal ones. Defining the cross section averaged over the $V$-meson polarizations as $d\sigma/d\Omega = (p^{\text{cm}}_f/p^{\text{cm}}_i)|f|^2$ we obtain the values $|f|^2 = 720 \mu$b/sr and 60 – 90 $\mu$b/sr for the reactions $\rho^0 p \rightarrow \eta p$ and $\rho^0 p \rightarrow \eta' p$, respectively. Those numbers should be compared with 360 and 9.8 $\mu$b/sr for the reactions $\pi^0 p \rightarrow \eta p$ and $\pi^0 p \rightarrow \eta' p$, respectively.

The amplitudes for the vector-meson exchanges can be written in the form (treating again the nucleons in the deuteron nonrelativistically)

$$A_{pn\rightarrow dM}(s, t) = \frac{G_V}{2m} \phi_{\lambda_1}(\vec{p}_2) (\vec{\sigma}_f \cdot \vec{\epsilon}_d - i \vec{\sigma}_d) \cdot \phi_{\lambda_1}(\vec{p}_1), \quad (7)$$

$$A_{pn\rightarrow dM}(s, u) = \frac{G_V}{2m} \phi_{\lambda_1}(\vec{p}_1) (\vec{\sigma}_f \cdot \vec{\epsilon}_d - i \vec{\sigma}_d) \cdot \phi_{\lambda_2}(\vec{p}_2), \quad (8)$$

where

$$\vec{M}_1^V(\vec{p}_1) = \sqrt{2m} \int \left[ (\vec{k} - \vec{p}_1) + \frac{\vec{k}^2 - \vec{p}_1^2}{m_V^2}(\vec{k} + \vec{p}_1) + 2(1 + \kappa_V)(\vec{k} + \vec{p}_1) \right] \times$$
\[ \Phi_V(\vec{k}, \vec{p}_1) \Psi_d(\vec{k}) \frac{d^3k}{(2\pi)^{3/2}} \]  

(9)

and

\[ M_2^V(\vec{p}_1) = \sqrt{2m} \int \left[ (\vec{k} - \vec{p}_1) + \frac{\vec{k}^2 - \vec{p}_1^2}{m_V^2} (\vec{k} + \vec{p}_1) \right] \times \]

\[ \Phi_V(\vec{k}, \vec{p}_1) \Psi_d(\vec{k}) \frac{d^3k}{(2\pi)^{3/2}}. \]  

(10)

\[ \Phi_V(\vec{k}, \vec{p}_1) \] is defined by Eq. (5) where \( m^2_\pi \) should be substituted by \( m^2_\rho \) etc. \( G_V \) is the vector coupling constant and \( \kappa_V \) is the ratio of the tensor and vector couplings. For these coupling constants and for the corresponding vertex form factors we use the values from the full Bonn NN potential [16], i.e. \( G_\rho^2/4\pi = 0.84, \kappa_\rho = 6.1, G_\omega^2/4\pi = 20, \kappa_\omega = 0 \) and \( \Lambda_\rho = 1.4 \text{ GeV/c}, \Lambda_\omega = 1.5 \text{ GeV/c}. \) Note that the amplitudes (7)–(8) should also be multiplied by the isospin factor 3 in the case of \( \rho \) exchange.

As far as the initial state interaction (ISI) is concerned it would be, of course, desirable to calculate its effect by means of a realistic model of the \( NN \) interaction. However, there are basically no \( NN \) potentials available in the literature that are still valid in the energy range where \( \eta \) and, in particular, \( \eta' \) production occurs. Therefore we decided to introduce an overall normalization constant which effectively accounts for the expected reduction of the production cross sections due to the ISI. This constant is adjusted to the data on the reaction \( pn \rightarrow d\eta \) and then used for calculating predictions for the reaction \( pn \rightarrow d\eta' \). The latter step is based on the reasonable assumption that the ISI does not change that much in the energy range from the \( \eta \)- to the \( \eta' \)-production threshold.

Alternatively, we employ an estimate for the effect of the ISI that has been presented recently in Ref. [17]. It is based on the assumption that, at the large energies required for the production of heavier mesons, the \( NN \) \( t \)-matrices are basically constant for (off-shell) momenta not too far away from the on-shell point. In this case the effect of the ISI can be expressed by a simple reduction factor \( \lambda \) that depends only on the \( NN \) phase shifts and inelasticities, i.e. [17]

\[ \lambda(T_{NN}) = \eta_L(T_{NN}) \cos^2(\delta_L(T_{NN})) + 1/4 [1 - \eta_L(T_{NN})]^2. \]  

(11)

In our case the initial \( pn \) system is in the \(^1P_1\) state. The corresponding phase shifts and inelasticity parameters near the thresholds of \( \eta \) and \( \eta' \) production can be taken from the VA phase-shift analysis [18]. The values at \( T_{\text{lab}} \approx 1250 (2400) \text{ MeV} \) are \( \delta_L(p_1) = -29^\circ (-21^\circ) \) and \( \eta_L(p_1) = 0.54(0.828) \). This yields a reduction factor of \( \lambda_{\text{ISI}} = 0.46(0.83) \).
Since the relative phases of the different contributions are not known we calculate the cross section of the reaction \( pn \rightarrow dM \) as the incoherent sum

\[
\sigma_{pn \rightarrow dM} = N[\sigma^{(\pi)} + \sigma^{(\rho)} + \sigma^{(\omega)}].
\] (12)

The dash-dotted curve in Fig. 2 represents the sum \( \sigma^{(\pi)} + \sigma^{(\rho)} + \sigma^{(\omega)} \) without correcting for the ISI. This result clearly overestimates the empirical cross section. In order to achieve agreement with the data for the reaction \( pn \rightarrow d\eta \) at \( Q > 10 \text{ MeV} \) the theoretical cross section has to be multiplied by a normalization constant \( N \) of 0.68 (see the solid curves in Fig. 2). It is remarkable that this reduction factor is not very different from the value obtained from the estimation of ISI effect based on Eq. (11). We see that as a confirmation of the physics contained in our model being basically correct.

Comparing the dash-dotted with the dashed curve makes clear that we get significant contributions from the exchanges of vector mesons. We want to emphasize that those contributions are primarily due to the \( \rho \) exchange. The \( \omega \)-exchange term is negligibly small and the result without its contribution would be indistinguishable from the full result shown in the figure. As a matter of fact, the magnitude of the \( \rho \)-exchange term is even larger than the \( \pi \)-exchange contribution. This is not unreasonable. Actually, recently C. Wilkin has argued [7] that a large \( \rho \) exchange might be favourable for explaining the observed large cross section ratio \( \sigma_{\gamma p \rightarrow \eta'p}/\sigma_{pp \rightarrow \eta p} \) [19]. We would like to stress that the dominance of the \( \rho \) exchange over \( \pi \) exchange in our model is not due to the soft form factor used for the latter. Even with a value of \( \Lambda_{\pi} = 1.3 \text{ GeV} \) as used in the full Bonn model \( \rho \) exchange would still dominate.

The predictions for the reaction \( pn \rightarrow d\eta' \) are shown in Fig. 3. The dashed curve shows the cross section when only \( \pi \) exchange is taken into account. The solid and dash-dotted lines include the contributions from \( \rho \) and \( \omega \) exchange. Like in case of \( \eta \) production the \( \omega \) exchange gives only a rather small contribution. Thus the difference between the dash-dotted and the dashed curves is entirely due to the \( \rho \)-exchange contribution. Since there is still a large uncertainty in the experimental value of the \( \gamma p \rightarrow \eta'p \) cross section (1 \( \mu b - 1.5 \mu b \)) [14] on which the \( \rho \) exchange contribution is based we present calculations employing the lower and upper bounds. The corresponding results (lower and upper solid and dash-dotted curves in Fig. 3) reflect this uncertainty in the input of our model. In any case, the \( \rho \) exchange increases the cross section of the reaction \( pn \rightarrow d\eta' \) by almost a factor of 20–40. This strong enhancement is caused by the rather large \( \rho N \rightarrow \eta'N \) S-wave amplitude extracted from the experimental \( \gamma p \rightarrow \eta'p \) cross section. There are indications that the latter reaction is dominated by an \( S_{11}(1890) \) resonance, cf. Ref. [14].

Admittedly, the ambiguity involved in the \( \rho \) exchange introduce fairly large variations in the predicted cross section. But still one can conclude from our
model calculation that the cross section for the reaction $pn \rightarrow \eta'd$ for $Q \approx 30$ MeV should be about 1 $\mu$b or even more, and therefore should be measurable at new accelerator facilities such as COSY in Jülich.

Note that the results shown by the solid curves in Fig. 3 were obtained by using the same reduction factor 0.68 for the ISI as in the reaction $pn \rightarrow d\eta$. Estimate (11) suggests a slightly smaller reduction of the $pn \rightarrow d\eta'$ cross section ($\lambda_{\text{ISI}} = 0.83$).

In Fig. 3 we show also the data for the reaction $pp \rightarrow pp\eta'$ which are from [20] (open circles) and [21] (filled circles) for comparison. Evidently, near threshold the cross section predicted for the reaction $pn \rightarrow d\eta'$ is significantly larger than the cross section of the reaction $pp \rightarrow pp\eta'$. This is similar to the case of $\eta$ production near threshold (see, e.g. [1]) and can be explained by a more favourable isospin factor as well as by the larger phase space in the reaction $pn \rightarrow dM$ as compared with the reaction $pp \rightarrow ppM$.

It can be seen from Fig. 2 that the experimental cross section for very small excess energies lies above the calculated cross section. In order to demonstrate this more clearly we have divided the data points by the result of our model (solid curve in Fig. 2) and present this ratio in Fig. 4. Then the enhancement of the cross section close to threshold is rather obvious. It is generally believed that this enhancement of the cross section at small excess energies is due to a strong and attractive interaction of the $\eta$ meson with the nucleons in the final state [2] (a similar enhancement has been also found in the reaction $pp \rightarrow pp\eta$ [22]). Therefore, in the following we want to discuss the effect of this final-state interaction (FSI) on the reaction $pn \rightarrow d\eta$.

Evidently the enhancement occurs only for $Q \leq 10$ MeV which corresponds to characteristic momenta of $p_3 = p^m_\eta$ below 50 MeV/c. This indicates that the enhancement should be mainly due to the coherent final-state interaction. Therefore one can safely assume that the range of the FSI is much larger than the range of the interaction that is responsible for the production of the $\eta$ meson. In this case the (S-wave) production amplitude and the (S-wave) FSI can be factorised [23] and the FSI can be taken into account by multiplying the production cross section calculated above with a so-called enhancement factor [23] resulting from the long range $\eta d$ interaction.

In the simplest version of this approach the enhancement factor depends only on the $\eta d$ scattering length $A_{\eta d}$ (see, e.g., Ref. [24]). Values for this scattering length can be readily found in the literature [25,26]. In the present investigation, however, we adopt the original prescription of Goldberger and Watson [23] where also the $\eta d$ wave function in the continuum, $\psi_{p_3}(\vec{r})$, is required. Furthermore, we apply two different approaches for the calculation of the enhancement factor for the reaction $pn \rightarrow d\eta$: The optical potential (OP)
method and the Foldy-Brueckner adiabatic approach based on the multiple
scattering (MS) formalism (see also Ref. [23]). Note that both these methods
have already been used for the calculation of the enhancement factor for the
reaction \(pd \rightarrow ^3He \eta\) (see Refs. [24] and [27], respectively).

Let us first describe the OP method. The optical potential in momentum space
can be expressed through the single \(\eta d\)-scattering term

\[
V_{\text{opt}}(\vec{q}) = -\frac{2\pi}{\mu} \frac{m_d}{m_\eta + m_d} \left[ t_{\eta p}(k_{\eta p}) + t_{\eta n}(k_{\eta n}) \right] \rho_d(\vec{q}) .
\]

(13)

Here \(\mu\) is the \(\eta d\) reduced mass, and \(t_{\eta N}\) the \(\eta N\) t-matrix which is related to
the scattering amplitude \(f_{\eta N}\) by \(t_{\eta N}(k_{\eta N}) = (1 + \frac{m_\eta}{m}) f_{\eta N}(k_{\eta N})\). Note that
we use the scattering length approximation for the latter, i.e.
\(f_{\eta N}(k_{\eta N}) = (\frac{a_{\eta N}}{i k_{\eta N}}) - 1\). \(k_{\eta N}\) is the modulus of the relative \(\eta N\) momentum and
\(\rho_d(\vec{q})\) the deuteron form factor,

\[
\rho_d(\vec{q}) = \int d^3 r \exp \left( i \frac{\vec{q} \cdot \vec{r}}{2} \right) |\Psi_d(\vec{r})|^2 .
\]

(14)

In the \(\eta d\) c.m. system \(\vec{k}_{\eta N}\) is given by

\[
\vec{k}_{\eta N} = \frac{m}{m + m_\eta} \vec{p}_\eta - \frac{m_\eta}{m + m_\eta} \frac{\vec{p}_d}{2} = \frac{m + m_\eta/2}{m + m_\eta} \vec{p}_3 .
\]

(15)

The optical potential (13) is transformed into coordinate space and then the
Schrödinger equation is solved numerically yielding the continuum wave function \(\psi_{p_3}(\vec{r}_{\eta d})\) as well as the \(\eta d\)-scattering length. The enhancement factor is
simply given by \(\lambda_{\text{FSI}}^{\text{OP}}(p_3) = |\psi_{p_3}(0)|^2\) [23].

In the multiple scattering formalism we use the Foldy-Brueckner adiabatic
approximation and start from the \(\eta d\) wave function defined at fixed coordinates
of the proton (\(\vec{r}_p\)) and the neutron (\(\vec{r}_n\)) (see Ref. [23] for details):

\[
\psi_k(\vec{r}_\eta, \vec{r}_p, \vec{r}_n) = \exp \left( i \vec{k}_{\eta N} \cdot \vec{r}_\eta \right) + \frac{t_{\eta p}}{D} \frac{\exp \left( i k_{\eta p} \vec{r}_p \right)}{r_p} \left( \exp \left( i \vec{k}_{\eta N} \cdot \vec{r}_p \right) + t_{\eta n} \frac{\exp \left( i k_{\eta n} \vec{r}_n \right)}{r_n} \right) \\
\psi_k(\vec{r}_\eta, \vec{r}_p, \vec{r}_n) = \exp \left( i \vec{k}_{\eta N} \cdot \vec{r}_\eta \right) + \frac{t_{\eta n}}{D} \frac{\exp \left( i k_{\eta n} \vec{r}_n \right)}{r_n} \left( \exp \left( i \vec{k}_{\eta P} \cdot \vec{r}_n \right) + t_{\eta p} \frac{\exp \left( i k_{\eta p} \vec{r}_p \right)}{r_p} \right) ,
\]

where

\[
D = \left( 1 - t_{\eta p} t_{\eta n} \frac{\exp \left( 2 i k_{\eta P} \vec{r}_n \right)}{r_{pn}^2} \right) .
\]

(16)
Here $\vec{r}_{pn} = \vec{r}_p - \vec{r}_n$ and $\vec{k} = \vec{p}$, and $k, r_{pn},$ etc., are the moduli of these vectors. $t_{\eta N}$ is defined in Eq. (13). Then the $\eta$-$d$-scattering length and the enhancement factor follow from

$$A_{\eta d}^{\text{MS}} = \frac{m_d}{m_\eta + m_d} \frac{2t_{\eta N}(k_{\eta N} = 0)}{1 - t_{\eta N}(k_{\eta N} = 0)/r},$$

$$\lambda_{\text{FSI}}^{\text{MS}}(p_3) = |\langle \psi_{p_3}(\vec{r}_\eta = 0, \vec{r}_p = \vec{r}/2, \vec{r}_n = -\vec{r}/2) \rangle|^2.$$

The resulting enhancement factors $\lambda_{\text{FSI}}(p_3)$ are plotted in Fig. 4 (upper panel for the multiple scattering formalism and lower panel for the optical potential) for different values of the $\eta N$-scattering lengths given in Table 1. In this Table we also present the calculated values of $A_{\eta d}^{\text{OP}}$ and $A_{\eta d}^{\text{MS}}$ and compare them with the results of Ref. [26]. Of course, the optical potential model is a questionable approximation for the $\eta d$ system. It only gives reasonable values for the $\eta d$ scattering length if $a_{\eta N}$ is small so that the first iteration is dominant. For larger $a_{\eta N}$ it might still give a reasonable estimate of $A_{\eta d}$ provided that there is a cancelation between different higher-order iterations.

Nevertheless, it is expected that the multiple scattering approach gives a more reliable estimation for $A_{\eta d}$. It is known that the Foldy-Brueckner approach describes the $\pi d$-scattering amplitude at low energies quite well (see, e.g., Ref. [32]). The $\eta$-meson is certainly somewhat heavier than the pion but its interaction with the nucleons is likewise considerably weaker than the forces in the $NN$ system. Therefore the adiabatic approximation might still be quite reasonable also in the case of $\eta d$ scattering. For example, we see from Table 1 that within the MS approach an attractive $\eta N$ interaction never yields spurious repulsive results for the $\eta d$ system — as it happens for the optical potential and for the first approach used by Green et al. [26]. We want to point out that our results are in rather good agreement with the second approach of Ref. [26] for a wide range of $a_{\eta N}$ values.

The solid curves in Fig. 4 show our results based on the $\eta N$ scattering $a_{\eta N} = 0.291 + i 0.360$ fm derived from $\eta$ photo-production data [29]. Evidently, they describe the enhancement of the cross section rather well. The dashed and dotted curves correspond to the values $a_{\eta N} = 0.3 + i 0.3$ fm and $a_{\eta N} = 0.476 + i 0.279$ fm proposed in Refs. [24] and [27], respectively. The former curve which corresponds to the smaller value of $a_{\eta N}$ still agrees satisfactorily with the data, while the latter one overshoots them. The dash-dotted curve based on $a_{\eta N} = 0.717 + i 0.263$ fm from a recent analysis of Batinić et al. [31] overestimates the data at $Q \leq 10$ MeV by more than a factor 2. Thus, we conclude that our analysis of the reaction $pn \rightarrow d\eta$ close to threshold favours fairly small $\eta N$-scattering lengths, $\text{Re } a_{\eta N} \leq 0.3$ fm. The $\eta d$ scattering length corresponding to these values are $A_{\eta d} \approx 0.4 + i 1.2$ fm, cf. Table 1. We would like to point out that the above $\eta N$ scattering lengths are considerably below the lowest
value, $\text{Re } a_{\eta N} \approx 0.7$ fm, for which an $\eta d$ bound state is expected to exist [26]. Finally, we want to call attention to the fact that both employed approaches give very similar results for the enhancement factor. Furthermore, we would like to remark that a recent Faddeev-type calculation of the $\eta d$ system testifies that the MS approach is quite reliable for small values of $\text{Re } a_{\eta N}$ like those supported by our analysis [33].

In summary, using the two-step model we calculated the cross sections of the reactions $pn \rightarrow d\eta$ and $pn \rightarrow d\eta'$ near the threshold including $\pi$, $\rho$ as well as $\omega$ exchange. The $\omega$ contribution is found to be rather small. The contribution of the $\rho$ exchange is of comparable magnitude to the one from $\pi$ exchange in the case of $\eta$ production and might be even more important for $\eta'$ production due to the presence of a possible $S_{11}(1980)$ resonance for which the SAPHIR collaboration found strong evidence in the photo production of $\eta'$ mesons near threshold. Our results agree with the experimental data on $\eta$ production if we take into account effects from the initial state interaction. We considered also the influence of the final-state interaction using the optical-potential and multiple-scattering approaches. Both methods yield similar results for the enhancement factor. Agreement with the data could be obtained only for $\eta N$ interactions with small $\eta N$-scattering lengths, $\text{Re } a_{\eta N} \leq 0.3$ fm, i.e. values that are considerable below the lowest value, $\text{Re } a_{\eta N} \approx 0.7$ fm, for which an $\eta d$ bound state is expected to exist.

We are grateful to H. Ströher for useful discussions.

Fig. 1. Diagrams describing the two-step model (TSM). Note that besides the $\pi$-exchange contribution also diagrams involving the exchange of the $\rho$ and $\omega$ mesons are taken into account.
Fig. 2. Cross section of the reaction $pn \rightarrow d\eta$ as a function of the c.m. excess energy. The dashed curve shows the result from the $\pi$-exchange contribution alone whereas the dash-dotted curve is the sum of $\pi$, $\rho$, and $\omega$ exchange. The solid curve represents the results including all contributions ($\pi$, $\rho$, $\omega$) multiplied with a normalization factor $N = 0.68$ in order to take into account effects from the initial state interaction (see text). The data points for are taken from Refs. [1] (open circles) and [2] (filled circles).
Fig. 3. Cross section of the reaction $pn \rightarrow d\eta'$ as a function of the c.m. excess energy. The dashed curve shows the result from the $\pi$-exchange contribution alone whereas the dash-dotted curves are the sum of $\pi$, $\rho$, and $\omega$ exchange. The solid curves represent the results including all contributions ($\pi$, $\rho$, $\omega$) multiplied with a normalization factor $N = 0.68$ in order to take into account effects from the initial state interaction (see text). The upper and lower solid and dash-dotted curves are the results obtained using the maximal and minimal values of the $\rho^0 p \rightarrow \eta' p$ S-wave amplitudes. The data points are from Refs. [20] (open circles) and [21] (filled circles), respectively.
Fig. 4. The enhancement factors $\lambda_{FSI}(p_3)$ for different values of the $\eta N$-scattering lengths as a function of the c.m. excess energy. The solid curves correspond to the $\eta N$ scattering length $a_{\eta N} = 0.291 + i 0.360$ fm derived from $\eta$ photo-production data [29]. The dashed and dotted curves correspond to the values $a_{\eta N} = 0.3 + i 0.3$ fm and $a_{\eta N} = 0.476 + i 0.279$ fm proposed in Refs. [24] and [27], respectively. The dash-dotted curve is the result for $a_{\eta N} = 0.717 + i 0.263$ fm, found in a recent analysis of Batinić et al. [31].
