ABSTRACT: Designing and manufacturing multifunctional nanoparticles (NPs) are of considerable interest for both academic and industrial research. Among NPs used in this field, iron oxide NPs show low toxicity compared to metallic ones and are thus of high interest for biomedical applications. In this work, superparamagnetic Fe$_3$O$_4$-based core/shell NPs were successfully prepared and characterized by the combination of different techniques, and their physical properties were investigated. We demonstrate the efficiency of the layer-by-layer process to graft polyelectrolytes on the surface of iron oxide NPs. The influence of the polyelectrolyte chain configuration on the magnetic properties of the Fe$_3$O$_4$/polymer core/shell NPs was enlightened. The simple and fast process described in this work is efficient for the grafting of polyelectrolytes from surfaces, and thus, derived Fe$_3$O$_4$ NPs display both the physical properties of the core and of the macromolecular shell. Finally, the cytotoxicity toward the human THP-1 monocytic cell line of the core/shell NPs was assessed. The results showed that the polymer-capped Fe$_3$O$_4$ NPs exhibited almost no toxicity after 24 h of exposure at concentrations up to 25 μg mL$^{-1}$. Our results show that these smart superparamagnetic nanocarriers with stealth properties are promising for applications in multimodal cancer therapy, including drug delivery.

INTRODUCTION

Owing to their numerous and promising applications, superparamagnetic iron oxide NPs (SPIONs) have attracted the interest of many research groups worldwide.$^{1−5}$ In the medical field, their development was shown to be of particular interest as their superparamagnetic behavior guarantees a high magnetization when submitted to a magnetic field, whereas no magnetic remanence can be observed after their exposure to the magnetic field. $^5$

The use of SPIONs in the medical field requires their full stability in biological fluids to take advantage of their physical properties. Indeed, when bare iron oxide NPs are dispersed in complex media like physiological fluids, their surface can be altered and the release of Fe$^{2+}$ ions leads to the loss of their physical properties and to the increase of their cytotoxicity. $^7$ Thus, strategies such as the preparation of core/shell NPs were developed to graft a surrounding layer on the NPs to prevent the adsorption of undesirable molecules or proteins that may alter NP physical properties.$^{6,8}$ Moreover, the shell can ensure the passivation of the NP surface for the full preservation of their magnetic properties.$^{3,6,9}$ Finally, it is possible to synthesize NPs with new physical and colloidal properties such as magnetic and optical that could not be obtained if each nanomaterial was used separately.$^6$ Among these strategies, the most commonly used consists of the synthesis of inorganic/inorganic core/shell NPs in which the core is surrounded by a shell composed of at least one layer.$^8,10−14$ For example, these new nanomaterials could display magnetic and luminescence properties, or if the shell is composed of a porous silica layer,$^{15−17}$ drugs could be loaded and released in the cell environment.$^{14,18}$ Another method consists of grafting a...
polymer layer at the surface of SPIONs to enhance their stealth properties in the body\cite{15,19-21} or to combine the magnetic properties of the core and polymer chain physicochemical properties to elaborate responsive NPs that exhibit high potential as drug carriers for cancer therapy.\cite{12,22,23} The previously described strategy leads to very promising nanomaterials especially for cancer therapy by combining imaging and drug release properties. However, the synthetic processes developed to obtain such NPs are time-consuming, and for the more sophisticated ones, the ease of implementation required by industries is hindered.

To overcome the synthetic process limitations, the layer-by-layer (LbL) assembly of charged molecules has shown interesting features.\cite{24} This method consists of the alternative adsorption of charge macromolecules (mainly polyelectrolytes) onto surfaces.\cite{24} It has been shown three decades ago that the process can be versatile, controlled at the nanometer scale, and could eventually lead to structured surfaces with high potential for biological applications.\cite{25}

To the best of our knowledge, the LbL process is usually used for the encapsulation of drugs,\cite{26-30} silica nanostructures,\cite{31-35} or iron oxide NPs\cite{36,37-38} but the synthesis of core/shell NPs was rarely reported.\cite{13,39-42} Palomec-Garfias et al. synthesized magnetic core/shell NPs composed of a γ-Fe₂O₃ core on which were layer-by-layer assembled poly(styrene sulfonate) (PSS) followed by either poly(allylamine hydrochloride) (PAH) or chitosan (Chi).\cite{13} The authors have focused their studies on the influence of the pH on the shell shape, which is directly related to the pH-responsive behavior of the PAH or Chi, which are weak polyelectrolytes.\cite{43} However, the influence of the polyelectrolyte multilayer films on the magnetic properties was not evidenced. In another work devoted to biomedical applications, Mancarella et al. have assembled on Fe₃₋₈O₄ surfaces biocompatible and biodegradable polymers, that is, poly-L-lysine and dextran, to obtain magnetic curcuma nanocarriers.\cite{13} Biocompatible and biodegradable polymers, that is, poly-L-lysine (PLL) or chitosan (Chi), assembled poly(styrene sulfonate) (PSS) followed by either poly(allylamine hydrochloride) (PAH) or chitosan (Chi).\cite{13} As et al. synthesized magnetic core/shell NPs composed of a γ-Fe₂O₃ core on which were layer-by-layer assembled poly(styrene sulfonate) (PSS) followed by either poly(allylamine hydrochloride) (PAH) or chitosan (Chi).\cite{13}

To study the efficiency of the LbL assembly of polyelectrolytes at the surface of the Fe₃₋₈O₄@NH₃⁺, we have combined complementary characterization methods to study the microstructures of the core/shell NPs and their colloidal stability after the LbL assembly of PSS and PDADMAC (Figure 1).

**Core/Shell NP Microstructure.** To ensure that the process does not damage the crystallinity of the NP core, X-ray diffraction (XRD) experiments were performed. The characteristic diffraction peaks at 2θ = 30.10, 35.60, 43.14, 53.49, 57.11, and 62.88° remain unchanged after the functionalization process and match with the characteristic diffraction (220), (311), (400), (422), (511), and (440) planes of the magnetite Fe₃O₄ phase (JCPDS PDF No. 00-019-0629) (Figure S1 in the Supporting Information).

High-resolution TEM micrographs show the spherical shape of Fe₃₋₈O₄@PSS/PDADMAC) NPs (Figure 2). The core displays an average diameter of 10 ± 1.5 nm as determined from TEM images (Figure 2c). The diameter range size of these NPs is well compatible with the expected superparamagnetic behavior at room temperature.\cite{45}

To study the influence of the shell on the physical and colloidal properties of the core/shell NPs and on their cytotoxicity, the coverage of the core by the polyelectrolyte film is necessary. To demonstrate the efficiency of our process, Energy-Filtered TEM analyses were conducted, and an amorphous layer essentially composed of carbon (see the C mapping, Figure 3c) at the surface and at the interspace between particles was observed (Figure 3a–c). The C mapping (carbon is essentially derived from the polyelectrolyte multilayered film) demonstrates that the LbL process enables a full and homogeneous coverage of the core/shell NPs by the polyelectrolytes. Moreover, HR-TEM images show the layered nanostructure of the PSS/PDADMAC) film as can be seen in the inset of Figure 3d. A final thickness of the polyelectrolyte multilayered film after 6 deposition cycles of about 2.2 nm was calculated from HR-TEM images, which is close to the thickness determined when the process is
conducted on flat surfaces. This indicates that the curvature of the surface does not have an impact on the LbL process.

The toxicity of NPs relies on different factors such as size, surface charge, composition, impurities, and specific surface area. NP size plays a key role as it affects their uptake by cells, their interaction with organelles, the death mechanism, and their clearance. Indeed, when considering cancer therapeutic nanosystems, it has been shown that NPs have to display sizes between 10 and 200 nm to accumulate into tumors while avoiding healthy tissues owing to their enhanced permeability and retention effect.

The average hydrodynamic diameters ($D_H$) of NPs were measured at each two adsorbed (PSS/PDADMAC) bilayers by dynamic light scattering (DLS) as presented in Figure 4. As expected, the NP hydrodynamic diameters increase with the number of bilayers; that is, Fe$_3$O$_4$@(PSS/PDADMAC)$_2$, Fe$_3$O$_4$@(PSS/PDADMAC)$_4$, and Fe$_3$O$_4$@(PSS/PDADMAC)$_6$ display diameters of 35, 75, and 120 nm, respectively. The increase in capsule shell thickness after the deposition of six PDADMAC/PSS bilayers is ~50 nm, a value that is in good agreement with the data related to the thickness of polyelectrolyte layers adsorbed onto a latex particle determined by single-particle light scattering. Due to their sizes varying between 35 and 120 nm, Fe$_3$O$_4$@(PSS/PDADMAC) NPs are well suited for antitumor treatment.

Iron oxide NPs with diameters below 50 nm exhibit almost no cytotoxicity, like ferumoxytol, which is already FDA-approved as an iron supplement. When adding the first layer of PSS, the ζ potential becomes negative and reaches ~27 mV, confirming the successful adsorption of the polyanion. The PDADMAC polycation was subsequently assembled onto the negatively charged NPs and leads to the charge inversion of the polarity to +40 mV. As shown in Figure 5, alternating the polycation and polyanion layers induces ζ potential oscillation better cell uptake than negatively charged ones (cationic iron oxide NPs can be more easily ingested by macrophages more easily than anionic ones).

The LbL process is well known to conduct a charge inversion of the substrate at each deposited layer on flat surfaces and will thus lead to changes of NP surface charge. The ζ potential of positively charged Fe$_3$O$_4$@NH$_3$ NPs at pH 4 is +25 mV (Figure 5). When adding the first layer of PSS, the ζ potential becomes negative and reaches ~27 mV, confirming the successful adsorption of the polyanion. The PDADMAC polycation was subsequently assembled onto the negatively charged NPs and leads to the charge inversion of the polarity to +40 mV. As shown in Figure 5, alternating the polycation and polyanion layers induces ζ potential oscillation

![Figure 2. Bright-field TEM micrographs of (a) Fe$_3$O$_4$ NPs, (b) Fe$_3$O$_4$@Silane, and (c) Fe$_3$O$_4$@(PSS/PDADMAC)$_6$. The insets show the size distributions as measured by TEM.](image1)

between negative and positive values. The high ζ potential values (up to 40 mV) combined to the HR-TEM measurement, which are close to the thickness measured for the polyelectrolyte layer on their stretched conformation, indicate that the polymer chains keep their complete stretched conformation while assembling on the NP surface. These characteristics make these NPs good candidates for drug or gene delivery for cancer therapy.

**Magnetic Measurements.** The magnetic properties of the Fe₃₋ₓO₄ SPIONs and of the Fe₃₋ₓO₄@(PSS/PDADMAC)ₙ NPs were evaluated at 5 and 300 K (Figure 6). Superparamagnetic behavior of the Fe₃O₄ SPIONs was observed at 300 K with a saturation magnetization around 70 emu/g. At 5 K, a hysteresis cycle can be observed due to the transition to a low-temperature blocked state, with a saturation magnetization of 80 emu/g and a coercive field around 270 Oe.

The saturated magnetization values (per gram of Fe₃₋ₓO₄ content) of Fe₃₋ₓO₄@(PSS/PDADMAC)₂, Fe₃₋ₓO₄@(PSS/PDADMAC)₄, and Fe₃₋ₓO₄@(PSS/PDADMAC)₆ NPs are 40, 20, and 9 emu g⁻¹, respectively. These values are lower than those of the native Fe₃₋ₓO₄@NH₂ NPs (60 emu g⁻¹) (Figure 6b). This originates from a decrease in the magnetic interaction due to the diamagnetic coating according to previous reports.³⁻⁹ Nevertheless, the NPs quickly interact with a magnet (Figure 7). The remanence (M_r) and coercivity (H_c) for Fe₃₋ₓO₄@(PSS/PDADMAC) NPs were close to zero, which is typical for superparamagnetic NPs.¹⁷,¹⁸

To confirm the superparamagnetic behavior of NPs, field-cooling (FC) and zero-field-cooling (ZFC) experiments were performed. The magnetization-dependent temperature was studied at an applied field of 75 Oe in the temperature range between 5 and 400 K (the graphs are depicted in the Supporting Information). The gradual increase of the magnetization for the ZFC and FC curves until their intersection at the blocking temperature (T_B) is linked to the progressive rotation of the magnetization of the blocked magnetic NPs toward the field direction.⁵⁶ Above T_B, the core/shell NPs display then superparamagnetic behavior at the room temperature.

The magnetic separation and redispersion process of Fe₃₋ₓO₄@(PSS/PDADMAC)₆ NPs is illustrated in Figure 7. The black particles were readily attracted to the bottom of the flask within 10 s by the magnet, and the color of the Fe₃₋ₓO₄@(PSS/PDADMAC)₆ solution quickly turned from black to transparent. The particles can be well dispersed again by stirring and ultrasonic vibration.

To envision the applications of these NPs in biological application, cytotoxicity studies were carried out toward THP-1 cells.

**Cytotoxicity Study.** THP-1 cells are well known to induce an inflammatory reaction when exposed to a drug.⁵⁷,⁵⁸ To evaluate the toxicity of the NPs toward THP-1 cells, cytotoxicity studies of Fe₃₋ₓO₄@(PSS/PDADMAC)₆ NPs were conducted by the conventional WST-1 assays. Figure 8 displays the THP-1 viability results after 5 and 24 h of exposure to NPs. Cytotoxicity appears only at 50 μg mL⁻¹ and higher doses, and the inhibitory concentration IC₅₀ calculated...
at 24 h was higher than 100 μg mL⁻¹. This result suggests that iron oxide NP toxicity is low on THP-1 cells and that their induced inflammatory response is limited.⁵⁷ According to our results, cell death was less important at 24 h. It may be linked to a mechanism of cell adaptation or to the aggregation of NPs after 24 h, which mitigate their toxicity. However, the cell death observed at high concentrations may originate from the release of reactive oxygen species, which will induce mitochondrial dysfunctions leading to an increase of the swelling and cell permeability and finally to DNA damage.⁵⁹,⁶⁰ However, these NPs still exhibit a favorable low cytotoxicity, which makes them of high interest for biomedical applications.

**CONCLUSIONS**

In this work, we have provided a novel simple method to encapsulate Fe₃₋₄O₄ SPIONs by using the LbL approach. The shell construction was followed at each step of the multilayered film formation. The cytotoxic tests toward human cancer THP-1 cells of the core/shell NPs showed that these functional nanomaterials exhibited almost no toxicity at concentrations up to 25 μg mL⁻¹. The techniques reported in this work could be transposed to the LBL of biobased macromolecules like poly-β-l-lysine and hyaluronic acid for its well-known targeting properties. This work paves the way for the elaboration of new core/shell NPs with promising biomedical properties.

**EXPERIMENTAL SECTION**

**Chemicals.** All reagents were purchased from Sigma-Aldrich, except for (3-aminopropyl)trimethoxysilane (Gelest, >95%), poly(sodium 4-styrenesulfonate) (PSS), and poly-(diallyldimethylammonium chloride) (PDADMAC), and were used as received.

**Synthesis of Fe₃₋₄O₄ SPIONs.** A coprecipitation method was used to synthesize the superparamagnetic Fe₃₋₄O₄ nanocrystals. 5 mL of a 28% (v/v) aqueous ammonia solution was added to 40 mL of an aqueous mixture of FeCl₃·6H₂O (6 mmol; 1.622 g) and FeSO₄·7H₂O (5 mmol; 1.39 g). The mixture was stirred and heated at 90 °C under an argon atmosphere. To stabilize the NPs, 15 mL of a 1 M solution of sodium citrate (chosen as the ligand) was added dropwise, and the mixture was stirred for 30 min. The final solution turned black. The SPIONs were recovered by magnetic separation and washed several times with ethanol to remove the unreacted reagents.

**Synthesis of (3-Aminopropyl)trimethoxysilane-Coated Fe₃₋₄O₄ NPs (Fe₃₋₄O₄@NH₂).** (3-Aminopropyl)-trimethoxysilane (0.2 mmol, 49.1 μL) was injected to 10 mL of a homogeneous oxygen-free solution of Fe₃₋₄O₄ SPIONs (50 mg). After stirring the solution for 2 min, 1 mL of an ethanolic solution of tetramethylammonium hydroxide pentahydrate (TMH) (0.2 M) was added, and the mixture was further stirred under argon for 15 min at 50 °C. The mixture was then cooled, and Fe₃₋₄O₄ SPIONs were separated by centrifugation and washed two times with toluene. After the dispersion of the silanized Fe₃₋₄O₄ SPIONs in 10 mL of toluene, 2 mL of an ethanolic solution of TMH (36.25 mg) was injected in the media. The mixture was stirred under argon pressure for 30 min at 50 °C. Afterward, the reactor was cooled in a water bath, and Fe₃₋₄O₄ SPIONs were separated by centrifugation and washed two times with toluene.

**Synthesis of Fe₃₋₄O₄@PSS/PDADMAC NPs.** After the silanization step, Fe₃₋₄O₄@NH₂ SPIONs were obtained. Because the layer-by-layer assembly is mainly driven by electrostatic interactions, the pH of the Fe₃₋₄O₄@NH₂ solution was adjusted to 4 in order to have a highly positively charged surface (Fe₃₋₄O₄@NH₄⁺). The LbL process could then be conducted as follows: the Fe₃₋₄O₄@NH₄⁺ NPs were stirred for 10 min in 10 mL of 10⁻² M solution of PSS followed by ultracentrifugation. The as-synthesized Fe₃₋₄O₄@PSS was redispersed in Milli-Q water, stirred for 5 min to remove the physisorbed molecules, and ultracentrifuged, and the supernatant was discarded. The rinsing process was repeated three times. Afterward, the solution of the negatively charged Fe₃₋₄O₄@PSS NPs was dispersed in 10 mL of PDADMAC, and the mixture was also stirred for 10 min, ultracentrifuged, and washed three times following the same process as presented below. The sample is then named Fe₃₋₄O₄@PSS/PDADMAC (the subscript 1 indicates that one bilayer of PSS/PDADMAC is deposited at the surface of the Fe₃₋₄O₄@NH₄⁺). This process was repeated as many times as the desired number of bilayers (PSS/PDADMAC)ᵢ, where n is the number of bilayers in the shell.

**Characterization.** DLS was performed at room temperature using a Malvern Zetasizer HSa instrument with a He–Ne laser (4 × 10⁻³ W) at a wavelength of 633 nm. NP aqueous solutions were filtered through Millipore membranes (0.2 mm pore size). Data were analyzed by the CONTIN method to obtain the hydrodynamic diameter and size distribution for each aqueous dispersion of NPs. The crystallographic structure of the NPs was identified by XRD using a Philips PW3710 diffractometer with Cu Kα radiation. For TEM observations, one drop of a dispersed solution of NPs was deposited on holey carbon grids and imaged. A transmission electron microscope used was a JEM - ARM 200F Cold FEG TEM/STEM operating at 200 kV and equipped with a spherical aberration (Cs) probe and image correctors. The magnetic properties of the core/shell NPs were studied by a superconducting quantum interference device SQUID-VSM combined to a vibrating sample magnetometer.

**Biological Characterization.** Cell Culture. The THP-1 human monocytic leukemia cell line (ATCC CRL2192; Manassas, USA) was grown in Dulbecco’s modified Eagle medium high-glucose (DMEM; Sigma-Aldrich, St. Louis, USA) medium supplemented with 15% fetal bovine serum (FBS), 1% penicillin–streptomycin, 2% l-glutamine, and 0.25 μg mL⁻¹ amphotericin B (Sigma-Aldrich, St. Louis, USA). Cells were grown at 37 °C under a 5% CO₂ atmosphere and were passed every 3 days.
**Cell Treatment.** Cells were seeded in 96 well plates with $5 \times 10^3$ cells per well. After overnight incubation, plates were centrifuged (800 x g, 10 min), and the medium with FBS was removed. A fresh medium without FBS and with 0, 1.5, 3.125, 6.25, 12.5, 25, 50, and 100 $\mu$g mL$^{-1}$ each CNM was added, and cells were incubated for 24 and 72 h. Six wells were used per culture condition, and experiments were repeated four times.

**WST-1 Assay.** The tetrazolium salt 2-(4-iodophenyl)-3-(4nitrophenyl)-5-(2,4-disulfophenyl)-2H-tetrazolium, monosodium salt, better known as WST-1 (Roche; Boulorge; France), was used to measure cell viability by detecting the mitochondrial dehydrogenase activity as previously described. Briefly, after treatment, 5 $\mu$L of WST-1 was added and incubated for 2 h at 37 °C. Absorbance was measured at 450 nm with a reference wavelength of 690 nm, using an iMark Microplate Reader (Bio-Rad Laboratories, Osaka, Japan). Inhibitory concentration IC$_{50}$ was calculated by the Reed–Muench formula.

The Supporting Information is available free of charge at https://pubs.acs.org/doi/10.1021/acsomega.9b02963.

The presence of characteristic diffraction peaks at 20 = 30.10, 35.60, 43.14, 53.49, 57.11, and 62.88° at each step of the functionalization process, confirming that the process used for the LbL deposition of the polyelectrolyte did not alter the crystalline structure of the core of the nanoparticles (Figure S1). The complete dispersion of the polyelectrolyte functional nanoparticulate system was confirmed by DLS measurement, and the size (and its polydispersity via the PDI) is illustrated (Figure S2). The superparamagnetic behavior of the NPs was confirmed by ZF-ZFC measurements of NPs at each step of modification. The blocking temperature found to be 270 K (around −3 °C) is higher than those reported for other iron oxide NPs with close sizes, which suggested that the NPs can be slightly aggregated in the physiological media (Figure S3) (PDF).
