ABSTRACT

Secondary contributions to the anisotropy of the Cosmic Microwave Background (CMB), such as the integrated Sachs-Wolfe (ISW) effect, the thermal Sunyaev-Zel’dovich effect (tSZ), and the effect of gravitational lensing, have distinctive non-Gaussian signatures, and full descriptions therefore require information beyond that contained in their power spectra. The Minkowski Functionals (MF) are well-known as tools for quantifying any departure from Gaussianity and are affected by noise and other sources of confusion in a different way from the usual methods based on higher-order moments or polyspectra, thus providing complementary tools for CMB analysis and cross-validation of results. In this paper we use the recently introduced skew-spectra associated with the MFs to probe the topology of CMB maps to probe the secondary non-Gaussianity as a function of beam-smoothing in order to separate various contributions. We devise estimators for these spectra in the presence of a realistic observational masks and present expressions for their covariance as a function of instrumental noise. Specific results are derived for the mixed ISW-lensing and tSZ-lensing bispectra as well as contamination due to point sources for noise levels that correspond to the Planck (143 GHz channel) and EPIC (150 GHz channel) experiments. The cumulative signal to noise ration $S/N$ for one-point generalized skewness-parameters can reach an order of $O(10)$ for Planck and two orders of magnitude higher for EPIC, i.e. $O(10^3)$. We also find that these three spectra skew-spectra are correlated, having correlation coefficients $r \sim 0.5-1.0$; higher $l$ modes are more strongly correlated. Though the values of $S/N$ increase with decreasing noise, the triplets of skew-spectra that determine the MFs become more correlated; the $S/N$ ratios of lensing-induced skew-spectra are smaller compared to that of a frequency-cleaned tSZ map.

1 INTRODUCTION

All-sky multi-frequency Cosmic Microwave Background (CMB) missions, such as the completed WMAP1, ongoing Planck2 and future (proposed) Experimental Probe of Inflationary Cosmology (EPIC) survey (Bock et al. 2008, 2009; Baumann et al. 2009) or ESAs Cosmic Origin Explorer (CoREx, The CoREx Collaboration 2012) are major sources of information about the properties of the primordial density fluctuations that seeded the process of galaxy formation in the Universe as well as other key aspects of cosmological theory, including the global isotropy (Copi et al. 2007; Hoftuft et al. 2009; Hanson & Lewis 2009) and topology of the Universe (Luminet et al. 2003; Roukemia et al. 2004).

The study of non-Gaussianity in the CMB fluctuations can provide valuable and detailed information regarding the physics of the early Universe of the inflationary epoch. In the standard slow-roll paradigm, the scalar field responsible for inflation fluctuates with a minimal amount of self interaction which ensures that any non-Gaussianity generated during the inflation through self-interaction is expected to be small (Salopek & Bond 1990, 1991; Falk et al. 1993; Gangui et al. 1994; Acquaviva et al. 2003; Maldacena 2003): see Bartolo, Matarrese & Riotto (2006) for a review. Variants of the simple inflationary model such as multiple scalar fields, features in the inflationary potential, non-adiabatic fluctuations, non-standard kinetic terms, warm inflation, or deviations from Bunch-Davies vacuum can however all lead to higher level of primordial non-Gaussianity (Chen 2010).

However, the detection of departure from Gaussianity in the CMB can be due to either primary or secondary effects (or both), as well as the mode-coupling effects of secondaries and gravitational lensing along the observer’s light cone. Secondary anisotropies resulting from the formation of struc-
ture are known to dominate at smaller angular scales, are highly non-Gaussian in nature (Cooray 2001; Cooray & Hu 2004; Verde & Spergel 2002) and are arguably as interesting as their primary counterpart. One of the prominent contributions to the secondary non-Gaussianity is due to the mode-coupling of weak gravitational lensing and sources of secondary contributions such as the thermal Sunyaev-Zel’dovich effect (Goldberg & Spergel 1999; Cooray & Hu 2000). Although weak lensing of the CMB produces its own characteristic signature in the angular power spectrum, its detection has proved to be difficult using the CMB power spectrum alone. Non-Gaussianity imprinted by lensing into the primordial CMB remains below the detection level of current experiments, although with Planck the situation is likely to improve. Nevertheless, cross-correlating CMB data with external tracers means lensing signals can be probed at the level of the mixed bispectrum. After the first unsuccessful attempt to cross-correlate WMAP against SDSS, recent efforts by Smith, Zahn & Dore (2007) have found a clear signal of weak lensing of the CMB, by cross-correlating WMAP against NVSS. Their work also underlines the link between three-point statistical estimators and the estimators for weak lensing effects on CMB. The understanding of secondaries are not only important in their own right, but also from the perspective of their impact on estimation of cosmological parameters (Smith et al. 2010).

The study of non-Gaussianity is usually primarily focused on the bispectrum, as this saturates the Cramér-Rao bound (Babich 2005; Kamionkowski, Smith & Heavens 2011) and is therefore in a sense optimal, however in practice it is difficult to probe the entire configuration dependence in harmonic space contained within the bispectrum using noisy data (Munshi & Heavens 2010). The cumulant correlators are multi-point correlators collapsed to encode two-point statistics. These were introduced in the context of analyzing galaxy clustering by (Szapudi & Szalay 1995), and were later found to be useful for analyzing projected surveys such as the APM galaxy survey (Munshi, Melott & Cole 2000). Being two-point statistics they can be analyzed in multipole space by defining an associated power-spectrum. Recent studies by Cooray (2006) and Cooray, Li & Melchiorri (2008) have demonstrated their wider applicability including, e.g., in 21cm studies. In more recent studies the skew- and kurt-spectra were found to be useful for analysing temperature (Munshi & Heavens 2010) as well as polarization maps (Munshi et al. 2011) from CMB experiments and in weak lensing studies (Munshi et al. 2011).

In addition to studies involving lower order multi-spectra, MFs have been extensively developed as a statistical tool for non-Gaussianity in a cosmological setting for both 2-dimensional (projected) and 3-dimensional (redshift) surveys. Analytic results are known certain properties of the MFs of a Gaussian random field making them suitable for identifying non-Gaussianity. Examples of such studies include CMB data (Schmalzing & Górski 1998; Novikov, Schmalzing and Mukhanov 2000; Hikage et al. 2008; Natoli et al. 2010); weak lensing (Matsubara and Jain 2001; Sato et al. 2001); Taruya et al. (2002); Munshi et al. (2012a), large-scale structure (Gott et al. 1988; Coles 1988; Gott et al. 1989; Melott 1990; Gott et al. 1990; Moore et al. 1992; Gott et al. 1992; Canaveses et al. 1998; Sahni, Sathyaprakash & Shandarin 1998; Schmalzing & Diaferio 2000; Kerscher et al. 2001; Hikage et al. 2002; Park et al. 2005; Hikage et al. 2008), 21cm (Gleser et al. 2006), frequency cleaned Sunyaev-Zel’dovich (SZ) maps (Munshi et al. 2012b) and N-body simulations (Schmalzing & Diaferio 2000; Kerscher et al. 2001). The MFs are spatially-defined topological statistics and, by definition, contain statistical information of all orders in the moments. This makes them complementary to the poly-spectra methods that are defined in Fourier space. It is also possible that the two approaches will be sensitive to different aspects of non-Gaussianity and systematic effects although in the weakly non-Gaussian limit it has been shown that the MFs reduce to a weighted probe of the bispectrum (Hikage, Komatsu & Mastubara 2006).

The skew-spectrum is a weighted statistic that can be tuned to a particular form of non-Gaussianity, such as that which may arise either during inflation at an early stage or from structure formation at a later time. The skew-spectrum retains more information about the specific form of non-Gaussianity than the (one-point) skewness parameter alone. This allows not only the exploration of primary and secondary non-Gaussianity but also the residuals from galactic foreground and unresolved point sources. The skew-spectrum is directly related to the lowest order cumulant correlator and is also known as the two-to-one spectra in the literature (Cooray 2001a). In a series of recent publications the concept of skew-spectra was generalized to analyse the morphological properties of cosmological data sets or in particular the MFs by Munshi, Smidt & Cooray (2010; Munshi et al. 2012a; Pratten & Munshi 2012). The first of these three spectra, in the context of secondary-lensing correlation studies, was introduced by Munshi et al. (2011b) and was subsequently used to analyse data release from WMAP by Calabrese et al. (2010).

The primary aim of this paper is to consider the entire set of generalised skew-spectra resulting from the mode-coupling of secondary anisotropies and lensing of the CMB and the contribution thereof to non-Gaussian morphology of the CMB maps. We will be considering three different secondary-lensing correlation bispectra. The secondaries that we consider are the Integrated Sachs-Wolfe effect (ISW) that dominates at large angular scales (Cooray 2002) and the thermal Sunyaev-Zel’dovich (tSZ) effect that dominates at smaller angular scales (Birkinshaw 1999). In addition we consider a foreground, namely the contribution from unresolved point sources. We will consider two experimental setups, the ongoing Planck satellite and the the proposed EPIC satellite mission discussed above.

The layout of the paper is as follows. In §2 we briefly outline the bispectrum corresponding to lensing-secondary mode-coupling. Next, in §3 we review the formalism underlying the Minkowski Functionals and in §4 we introduce the generalised skew-spectra associated with the MFs. In §5 we present the estimators for these spectra and their covariances. Finally, in §6 we discuss our results and comment on future implementation.

Throughout we will use the parameters of a WMAP cosmology (Larson et al. 2011).

2 MODE COUPLING INDUCED BY LENSING - SECONDARY CROSS-CORRELATION AND THE RESULTING BISPECTRUM

The bispectrum of primary anisotropies encodes information that can be used to constrain the inflationary dynamics but, as discussed in the previous section, the primary contribution to non-Gaussianity is expected to be negligible in the simplest realisations of the generic inflationary scenario.

The secondary bispectrum provides valuable information regarding the low-redshift Universe and constrains structure formation scenarios. The secondaries can be broadly divided into three different types:
Secondary Anisotropies and Minkowski Functionals

Figure 1. The cross-spectra $\beta_l$ for various secondaries and lensing are plotted as a function of the harmonics $l$. From left to right different panels correspond to cross-correlation of lensing potential and SZ, ISW and PS contribution. The cross-spectra $\beta_l$ is being used in Eq. (5) for the construction of mixed bispectrum $B^{PLS}_{1123}$. It is defined in Eq. (7). Various estimators for the skew-spectra that we will use, associated with the three MFs, will be defined using the mixed bispectra. A background $\Lambda$CDM cosmology is assumed. The details of these calculations, which relies on halo model prescriptions, can be found in Cooray (2001a).

(i) Gravitational secondaries, caused by evolution in the gravitational potential along the observer’s past light cone including the well-known integrated Sachs-Wolfe (ISW) effect (Kofman & Starobinsky 1985, Martinez-González, Sanz, Silk 1990, Mukhanov, Feldman & Bandenberger 1992, Kaminkowski & Spergel 1994, Munshi, Souradeep & Starobinsky 1995, Mollerach et al. 1995, Boughn & Crittenden 2004) as well as the Rees-Sciama (RS) effect.

(ii) Scattering secondaries, such as the thermal Sunyaev-Zel’dovich (tSZ) effect (Birkinshaw 1999), kinetic Sunyaev Zel’dovich (kSZ) effect and the Ostriker-Vishniac effect (see e.g. Castro et al. (2004)). These effects are caused by the interaction of the CMB photons with the intervening free-electron population.

(iii) Lensing secondaries caused by the propagation of photons through large scale structures.

Contributions to secondary bispectra can also arise from terms involving the cross-correlation of gravitational lensing and the effects of intervening material, such as the tSZ effect due to inverse Compton scattering of CMB photons from hot gas in the intervening clusters. The decay of the peculiar gravitational potential along the line of sight in $\Lambda$CDM cosmology, introduced above as the Integrated Sachs-Wolfe or ISW effect, is correlated to the lensing potential due to the power, can also generate an additional contribution to the secondary bispectrum in a similar fashion; see e.g. Cooray & Seth (2002) for a detailed discussion of various secondaries in the context of halo model. The contribution to secondaries due to reionization of the Universe are detailed in Hu, Scott & Silk (1994). Foregrounds, such as unresolved point sources (PS), can also contribute to the secondary bispectrum through their cross-correlation with the lensing of CMB.

On a different note, we comment that while the study of secondary anisotropies is important in its own right, they are also important in their effect on the calculation of error covariances in cosmological parameter estimation (Joudaki et al. 2010). Understanding the detailed statistical properties of secondary anisotropies like those we discuss here is therefore is of the utmost importance in the era of precision cosmology.

We will be dealing with the secondary bispectrum involving the lensing of both primary anisotropies and other secondaries. Following Goldberg & Spergel (1999a), Goldberg & Spergel (1999b) and Cooray & Hu (2000) we start by expanding the observed temperature anisotropy in terms of the primary contribution $\Theta_P(\hat{\Omega})$, the secondary contribution $\Theta_S(\hat{\Omega})$ and lensing of the primary $\hat{\Theta}_L(\hat{\Omega})$: $\hat{\Omega}(\hat{\Omega}) = \Theta_P(\hat{\Omega}) + \Theta_L(\hat{\Omega}) + \Theta_S(\hat{\Omega}) + \cdots$. Here $\hat{\Omega} = (\theta, \phi)$ is the angular position on the surface of the sky. Expanding the respective contribution in terms of spherical harmonics $Y_{lm}(\hat{\Omega})$ we can write:

$$\Theta_P(\hat{\Omega}) \equiv \sum_{lm} (\Theta_P)_{lm} Y_{lm}(\hat{\Omega}); \quad \Theta_L(\hat{\Omega}) \equiv \sum_{lm} [\nabla \psi(\hat{\Omega}) \cdot \nabla \Theta_P(\hat{\Omega})]_{lm} Y_{lm}(\hat{\Omega}); \quad \Theta_S(\hat{\Omega}) \equiv \sum_{lm} (\Theta_S)_{lm} Y_{lm}(\hat{\Omega}).$$

(2)

Here $\psi(\hat{\Omega})$ is the projected lensing potential (Goldberg & Spergel 1999a,b). The secondary bispectrum for the CMB takes contributions from products of P, L and S terms with varying order. The bispectrum $B^{PLS}_{1123}$ are defined as follows (see Bartolo et al. 2004 for generic discussion on the bispectrum and its symmetry properties):

$$B^{PLS}_{1123} \equiv \sum_{m_1 m_2 m_3} \left( l_1 \ m_1 \ l_2 \ m_2 \ l_3 \ m_3 \right) \int \left( \Theta_P(\hat{\Omega}_1) \Theta_L(\hat{\Omega}_2) \Theta_S(\hat{\Omega}_3) \right) Y_{l_1 m_1}^* (\hat{\Omega}_1) Y_{l_2 m_2}^* (\hat{\Omega}_2) Y_{l_3 m_3}^* (\hat{\Omega}_3) d\Omega_1 d\Omega_2 d\Omega_3;$$

$$\equiv \sum_{m_1 m_2 m_3} \left( l_1 \ m_1 \ l_2 \ m_2 \ l_3 \ m_3 \right) \langle (\Theta_P)_{1 m_1} (\Theta_L)_{2 m_2} (\Theta_S)_{3 m_3} \rangle.$$

(3)
The angular brackets represent ensemble averages. The matrices denote 3j symbols (Edmonds 1968) and the asterisks denote complex conjugation. It is possible to invert the relation assuming isotropy of the background Universe:

$$
\langle (\Theta_P)_{l_1 m_1}(\Theta_P)_{l_2 m_2}(\Theta_S)_{l_3 m_3} \rangle = \left( \begin{array}{ccc}
 l_1 & l_2 & l_3 \\
 m_1 & m_2 & m_3
 \end{array} \right) B_{l_1 l_2 l_3}^{\text{PLS}},
$$

(4)

Finally the bispectrum $B_{l_1 l_2 l_3}^{\text{PLS}}$ is expressed in terms of the un-lensed primary power spectrum $C_l = \langle (\Theta_P)_{l m} (\Theta_P)_{l m} \rangle$ and the cross-spectra $\beta_l$ (to be defined below) as follows:

$$
B_{l_1 l_2 l_3}^{\text{PLS}} = - \left\{ \beta_{l_1} C_{l_1} \frac{l_2 (l_2+1) - l_1 (l_1+1) - l_3 (l_3+1)}{2} + \text{cyc. perm.} \right\} I_{l_1 l_2 l_3} \equiv B_{l_1 l_2 l_3}^{\text{PLS}}; 
$$

(5)

$$
I_{l_1 l_2 l_3} = \frac{\sqrt{(2l_1+1)(2l_2+1)(2l_3+1)}}{4\pi} \left( \begin{array}{ccc}
 l_1 & l_2 & l_3 \\
 0 & 0 & 0
 \end{array} \right).
$$

(6)

(see Goldberg & Spergel 1999a, Goldberg & Spergel 1999b for a derivation). The reduced bispectrum above is denoted $B_{l_1 l_2 l_3}$. To simplify the notation for the rest of this paper, we henceforth drop the superscript PLSS form the bispectrum $B_{l_1 l_2 l_3}$. The cross-spectrum $\beta_l$ introduced above represents the cross-correlation between the projected lensing potential $\psi(\hat{\Omega})$ and the secondary contribution $\Theta_S(\hat{\Omega})$:

$$
\langle \psi(\hat{\Omega}) \Theta_S(\hat{\Omega}') \rangle = \frac{1}{4\pi} \sum_{l=0}^{l_{\text{max}}} (2l+1) \beta_l P_l (\hat{\Omega} \cdot \hat{\Omega}').
$$

(7)

The cross-spectra $\beta_l$ take different forms for ISW-lensing, RS-lensing or SZ-lensing correlation and we assume a zero primordial non-Gaussianity. The reduced bispectrum $B_{l_1 l_2 l_3}$ defined above using the notation $I_{l_1 l_2 l_3}$ is useful in separating the angular dependence from the dependence on power spectra $C_l$ and $\beta_l$. We will use this to express the topological properties of the CMB maps. The $\beta_l$ parameters for lensing secondary correlations are displayed in Figure 1. The left, middle and right panels in Figure 1 display SZ-lensing, ISW-lensing and point source lensing correlations. These results are based on halo model calculations performed using the halo model (Cooray 2001a).

The beam $b_l(\theta_b)$ and the noise of a specific experiment are characterised by the parameters $\sigma_{\text{beam}}$ and $\sigma_{\text{rms}}$:

$$
b_l(\theta_b) = \exp[-l(l+1)\sigma_{\text{beam}}^2]; \quad \sigma_{\text{beam}} = \frac{\theta_b}{\sqrt{8\ln(2)}}, \quad n_l = \sigma_{\text{rms}}^2 \Omega_{\text{pix}}; \quad \Omega_{\text{pix}} = \frac{4\pi}{N_{\text{pix}}},
$$

(8)

where $\sigma_{\text{rms}}$ is the rms noise per pixel that depends on the full width at half maxima or FWHM of the beam $\theta_b$. The number of pixel $N_{\text{pix}}$ required to cover the sky determines the size of the pixels $\Omega_{\text{pix}}$. To incorporate the effect of experimental noise the beam we have to replace $C_l \rightarrow C_l b_l^2(\theta_b) + n_l$, and the normalization of the skew-spectra that we will introduce later will be affected by the experimental beam and noise. The computation of scatter will also depend on these parameters. We will consider two different experimental setups: Planck and EPIC. The parameters of these experiments are tabulated in Table 1.

The optimal estimators for lensing-secondary mode-coupling bispectrum have been recently discussed by Munshi et al. (2011a). The estimators that we propose here are relevant in the context of constructing the MFs.

3 MINKOWSKI FUNCTIONALS

Integral geometry provides a natural framework within which to define the set of morphological descriptors for a random field. These descriptors are intrinsically defined in the spatial domain where they take into account all n-point correlators up to arbitrary order. Hadwiger’s characterization theorem shows that a linear combination of these $d+1$ functionals will provide a complete morphological description of the morphology of d-dimensional objects; see Hadwiger (1959) for a formal treatment. These functionals are more commonly referred to as the Minkowski functionals. The Minkowski Functionals are usually calculated using volume-weighted curvature integrals for which the analytical results for a Gaussian random field are known (Adler 1981; Tomita 1986; Gott et al. 1990). More recently the analytical values for weakly non-Gaussian fields have been calculated as a function of skewness parameters by using a perturbative approach based on the Edgeworth expansion (Matsubara 1994; Matsubara & Yokohama 1996, Matsubara 2002; Hikage, Komatsu & Mastubara 2006). This approach allows us to use the MFs as a test of non-Gaussianity in the weakly perturbed regime as constrained by observation and predicted by models for inflation.

In 2 dimensions the MFs $V_0(\omega)$, $V_1(\omega)$ and $V_2(\omega)$ correspond respectively to the area of a set $\Sigma$, length of the perimeter of the set and the integrated curvature along its boundary. The MF $V_2(\omega)$ can be related to the well-known genus $g$ and the Euler characteristic $\chi$:

$$
V_0(\omega) = \int_{\Sigma} da; \quad V_1(\omega) = \frac{1}{4} \int_{\partial\Sigma} dl; \quad V_2(\omega) = \frac{1}{2\pi} \int_{\partial\Sigma} n dl.
$$

(9)

Here $dl$ and $da$ represent the length and surface element respectively. In our analysis we consider a smoothed random field $\Theta(\hat{\Omega})$ with mean $\langle \Theta(\hat{\Omega}) \rangle = 0$ and variance $\sigma^2(\theta_b) = \langle \Theta^2(\hat{\Omega}) \rangle$. For a generic 2-dimensional weakly non-Gaussian random field $\Theta$ on the surface of the sky, the spherical harmonic decomposition using $Y_{lm}(\Theta)$ as basis functions $\Theta(\hat{\Omega}) = \sum_{lm} \Theta_{lm} Y_{lm}(\hat{\Omega})$ can be used to define the power spectrum $C_l$ which is sufficient to characterize an isotropic Gaussian field $\langle \Theta_{lm} \Theta_{lm}^* \rangle = C_l \delta_{ll} \delta_{mm'}$.

Secondary Anisotropies and Minkowski Functionals

Figure 2. The variances \( \sigma_0(\theta_b) \) and \( \sigma_1(\theta_b) \), defined in Eq. (12), are plotted as a function of the FWHM \( \theta_b \). The left panel corresponds to an experimental setup such as EPIC and the right panel corresponds to Planck-type experiment. See Table 1 for detail specifications regarding the noise level and beam.

We will be studying the MFs defined over the surface of the celestial sphere but equivalent results can be obtained in 3D using a Fourier decomposition (Pratten & Munshi 2012). The MFs for a 3D random Gaussian field are well known and are given by Tomita’s formula (Tomita 1986).

For a non-Gaussian field the higher order statistics such as bi- or tri-spectrum can describe the resulting mode-mode coupling. Alternatively topological measures such as the MFs (including the Euler characteristic or genus) can be employed to quantify deviations from Gaussianity. Indeed it can be shown that the information content in both descriptions is equivalent in that, at leading order, the MFs can be constructed completely from the knowledge of the bispectrum alone.

The notations and analytical results in this section are being kept generic however they will be specialized to the case of CMB sky in subsequent discussions.

The MFs denoted as \( V_k(\nu) \) for a threshold \( \nu = \Theta / \sigma_0 \), where \( \sigma_2^2(\theta_b) = (\Theta^2) \) are perturbatively expressed as:

\[
V_k(\nu) = \frac{1}{(2\pi)^{(k+1)/2} \omega_2 \omega_k} \exp \left( -\frac{\nu^2}{2} \right) \left( \frac{\sigma_1}{\sqrt{2}\sigma_0} \right)^k \left[ V_k^{(2)}(\nu)\sigma_0(\theta_b) + V_k^{(3)}(\nu)\sigma_0^2(\theta_b) + V_k^{(4)}(\nu)\sigma_0^3(\theta_b) + \cdots \right]
\]

\[
V_k^{(2)}(\nu) = \left[ \frac{1}{6} S^{(0)}(\theta_b)H_{k+2}(\nu) + \frac{k}{3} S^{(1)}(\theta_b)H_{k}(\nu) + \frac{k(k-1)}{6} S^{(2)}(\theta_b)H_{k-2}(\nu) \right]
\]

\[
\sigma_0^2(\theta_b) = \frac{1}{4\pi} \sum_{l} (2l+1)[(l+1)!]^2 C_l b_l^2(\theta_b)
\]

The constant \( \omega_k \) introduced above is the volume of the unit sphere in \( k \) dimensions. \( w_k = \pi^{k/2}/\Gamma(k/2 + 1) \) in 2-dimension we will only need \( \omega_0 = 1, \omega_1 = 2 \) and \( \omega_2 = \pi \). Here \( \Gamma \) is the the gamma function. The lowest-order Hermite polynomials \( H_k(\nu) \) are listed below.

\[
H_{-1}(\nu) = -\sqrt{\frac{\pi}{2}} \exp \left( \frac{\nu^2}{2} \right) \operatorname{erfc} \left( \frac{\nu}{\sqrt{2}} \right) ; \quad H_0(\nu) = 1, \quad H_1(\nu) = \nu,
\]

\[
H_2(\nu) = \nu^2 - 1, \quad H_3(\nu) = \nu^3 - 3\nu, \quad H_4(\nu) = \nu^4 - 6\nu^2 + 3,
\]

\[
H_n(\nu) = (-1)^n \exp \left( \frac{\nu^2}{2} \right) \frac{d^n}{d\nu^n} \exp \left( -\frac{\nu^2}{2} \right).
\]

The expression consists of two distinct contributions. The part that does not depend on the three different skewness parameters \( S^{(0)}(\theta_b), S^{(1)}(\theta_b), S^{(2)}(\theta_b) \) and signifies the MFs for a Gaussian random field. The other contribution \( \delta V_k(\nu) \) represents the departure from the Gaussian statistics and depends on the generalized skewness parameters defined in Eq. (13) - Eq. (17). Various second-order moments \( \sigma_j(\theta_b) \) defined in Eq. (12) appear in Eq. (10) and Eq. (11) can be expressed in terms of the power spectra \( C_l \) and the observational beam \( b_l(\theta_b) \), assumed Gaussian with a full width at half maximum \( \theta_b \); see Eq. (8) for definition. The moment \( \sigma_0(\theta_b) \) is a special case which relates to the variance of the field. The quantities \( \sigma_1(\theta_b), \sigma_2(\theta_b) \) are natural generalization of this variance, putting greater weight on higher-order harmonics; the variances that appear most frequently henceforth are \( \sigma_0^2(\theta_b) = (\Theta^2) \) and \( \sigma_1^2(\theta_b) = (\langle \nabla \Theta \rangle^2) \).

Real space expressions for the triplets of skewness \( S^{(i)}(\theta_b) \) are given below. These are natural generalizations of the ordinary skewness \( S^{(0)}(\theta_b) \) that is used in many cosmological studies. They are all cubic statistics but are constructed from different cubic combinations.

\[
S^{(0)}(\theta_b) = \frac{S^{(0)}(\theta_b)}{\sigma_0^2(\theta_b)} = \frac{(\Theta^3)}{\sigma_0^3(\theta_b)}, \quad S^{(1)}(\theta_b) = \frac{3 S^{(2)}(\Theta^2 \Theta^2)}{4 \sigma_0^4(\theta_b) \sigma_1^2(\theta_b)} = -3 \frac{\langle \Theta^2 \nabla^2 \Theta \rangle}{4 \sigma_0^2(\theta_b) \sigma_1^2(\theta_b)},
\]

\[
S^{(2)}(\theta_b) = -3 \frac{S^{(3)}(\Theta^3 \Theta^3 \Theta)}{\sigma_1^4(\theta_b)} = -3 \frac{(\langle \nabla \Theta \rangle^3 (\nabla \Theta) (\nabla^2 \Theta))}{\sigma_1^4(\theta_b)}.
\]
we have studied. The parameter cross-correlation of point sources and lensing (right-panel). The parameter as indicated. An experimental set up which is same as EPIC was considered. See Table-1 for detailed specifications regarding level of noise and beam. The bispectrum parameters remain positive for the entire range of FWHM probed.

Notice that a knowledge of the skewness parameter $S^{(i)}(\theta_b)$ changes sign near $\theta_b \sim 10^\circ$ as before. $S^{(0)}(\theta_b)$ is negative for all three effects. The other parameters remain positive for the entire range of FWHM probed.

Notice that a knowledge of the $S^{(i)}(\theta_b)$ parameters completely specifies the $V^{(2)}(\nu)$ parameters which characterize the lowest order departure from Gaussianity. The expressions in the harmonic domain are more useful in the context of CMB studies where these skewness parameters can be recovered from a masked sky using analytical tools that are commonly used for power spectrum analysis. The skewness parameter $S^{(1)}(\theta_b)$ is constructed from the product field $[\Theta^2]$ and $[\nabla^2 \Theta]$, whereas skewness parameter $S^{(2)}(\theta_b)$ relies on the combination of $[\nabla \Theta \cdot \nabla \Theta]$ and $[\nabla^2 \Theta]$. By construction, the skewness parameter $S^{(3)}(\theta_b)$ has the highest weight for high $l$ modes and $S^{(0)}(\theta_b)$ has the lowest weight from high $l$ modes.

The expressions in terms of the bispectrum $B_{i_1,i_2,i_3}$ (see Eq.9 for definition) take the following form:

$$S^{(\nu \nu \nu)}(\theta_b) = \frac{1}{4\pi} \sum_{i_1,i_2=2}^{l_{\max}} B_{i_1,i_2,i_3} B_{i_1}(\theta_b) B_{i_2}(\theta_b) B_{i_3}(\theta_b),$$  

$$S^{(\nu \nu \nabla^2)}(\theta_b) = -\frac{1}{12\pi} \sum_{i_1,i_2=2}^{l_{\max}} \left[ l_1(l_1+1) + l_2(l_2+1) + l_3(l_3+1) \right] B_{i_1,i_2,i_3} B_{i_1}(\theta_b) B_{i_2}(\theta_b) B_{i_3}(\theta_b),$$  

$$S^{(\nabla \Theta \cdot \nabla \Theta)}(\theta_b) = \frac{1}{4\pi} \sum_{i_1,i_2=2}^{l_{\max}} \left[ l_1(l_1+1) + l_2(l_2+1) - l_3(l_3+1) \right] B_{i_1,i_2,i_3} B_{i_1}(\theta_b) B_{i_2}(\theta_b) B_{i_3}(\theta_b).$$

Notice that a knowledge of the $S^{(i)}(\theta_b)$ parameters completely specifies the $V^{(2)}(\nu)$ parameters which characterize the lowest order departure from Gaussianity. The expressions in the harmonic domain are more useful in the context of CMB studies where these skewness parameters can be recovered from a masked sky using analytical tools that are commonly used for power spectrum analysis. The skewness parameter $S^{(1)}(\theta_b)$ is constructed from the product field $[\Theta^2]$ and $[\nabla^2 \Theta]$, whereas skewness parameter $S^{(2)}(\theta_b)$ relies on the combination of $[\nabla \Theta \cdot \nabla \Theta]$ and $[\nabla^2 \Theta]$. By construction, the skewness parameter $S^{(3)}(\theta_b)$ has the highest weight for high $l$ modes and $S^{(0)}(\theta_b)$ has the lowest weight from high $l$ modes.

The expressions in terms of the bispectrum $B_{i_1,i_2,i_3}$ (see Eq.9 for definition) take the following form:

$$S^{(\nu \nu \nu)}(\theta_b) = \frac{1}{4\pi} \sum_{i_1,i_2=2}^{l_{\max}} B_{i_1,i_2,i_3} B_{i_1}(\theta_b) B_{i_2}(\theta_b) B_{i_3}(\theta_b),$$  

$$S^{(\nu \nu \nabla^2)}(\theta_b) = -\frac{1}{12\pi} \sum_{i_1,i_2=2}^{l_{\max}} \left[ l_1(l_1+1) + l_2(l_2+1) + l_3(l_3+1) \right] B_{i_1,i_2,i_3} B_{i_1}(\theta_b) B_{i_2}(\theta_b) B_{i_3}(\theta_b),$$  

$$S^{(\nabla \Theta \cdot \nabla \Theta)}(\theta_b) = \frac{1}{4\pi} \sum_{i_1,i_2=2}^{l_{\max}} \left[ l_1(l_1+1) + l_2(l_2+1) - l_3(l_3+1) \right] B_{i_1,i_2,i_3} B_{i_1}(\theta_b) B_{i_2}(\theta_b) B_{i_3}(\theta_b).$$
and do not assume any specific form of non-Gaussianity. However, to arrive at specific expressions we will ignore the primordial non-Gaussianity.

The dependence of the skew-spectra is not uncorrelated. The cross-correlation among various skew-spectra are displayed in Figure 11 for EPIC and Figure 10 for Planck. The three skew-spectra corresponding to the three MFs \( S^{(0)}(\theta_b) \) (left-panel), \( S^{(1)}(\theta_b) \) (middle-panel) and \( S^{(2)}(\theta_b) \) (right-panel) are plotted for the mixed secondary bispectrum of SZ\times\text{Lensing} as a function of the harmonics \( l \). A background \( \Lambda \text{CDM} \) cosmology is assumed. The skew-spectra are defined in Eq.15, Eq.16 and Eq.17 respectively. All other sources of non-Gaussianity are ignored. Four different Gaussian-beams are considered. The curves from left to right correspond to \( \theta_b = 10', 25', 50', 100' \) in each panel. The normalization of the skew spectra is somewhat arbitrary and do not affect the signal to noise ratios. We have ignored the presence of noise, as defined in Eq.(12), in our calculation of \( \sigma_2(\theta_b) \) and \( \sigma_1(\theta_b) \) respectively. Notice that for a given \( \theta_b \) higher order skew-spectra peak at a higher \( l \). The signal to noise of the skew-spectra associated with SZ effect are plotted in Figure 11 for EPIC and Figure 10 for Planck noise level respectively. The skew-spectra are not uncorrelated. The cross-correlation among various skew-spectra are displayed in Figure 11 for EPIC and Figure 10 for Planck.

The dependence of the skew spectra \( S^{(i)}(\theta_b) \) and the beam \( b_1(\theta_b) \) on the smoothing angular scale \( \theta_b \) is being suppressed for brevity.

The angular bispectrum \( B_{\ell_1\ell_2\ell_3} \) contains all the information at the level of the three-point angular correlation function. These results are generic and do not assume any specific form of non-Gaussianity. However, to arrive at specific expressions we will ignore the primordial non-Gaussianity, known to be sub-dominant, and concentrate on secondary non-Gaussianity. There is a family of one-point statistics, namely the well-known skewness \( \theta \) and Eq(17) respectively. All other sources of non-Gaussianity are ignored. Four different Gaussian-beams are considered. The curves from left to right correspond to \( \theta_b = 10', 25', 50', 100' \) in each panel. The normalization of the skew spectra is somewhat arbitrary and do not affect the signal to noise ratios. We have ignored the presence of noise, as defined in Eq.(12), in our calculation of \( \sigma_2(\theta_b) \) and \( \sigma_1(\theta_b) \) respectively. Notice that for a given \( \theta_b \) higher order skew-spectra peak at a higher \( l \). The signal to noise of the skew-spectra associated with SZ effect are plotted in Figure 11 for EPIC and Figure 10 for Planck noise level respectively. The skew-spectra are not uncorrelated. The cross-correlation among various skew-spectra are displayed in Figure 11 for EPIC and Figure 10 for Planck.

The series expansion for the MFs can be extended beyond the leading order at the level of the bispectrum to the next-to-leading order which involves the trispectrum of the temperature field. The lensing induced trispectrum of the CMB will constitute the main next-to-leading order contribution. It is also important to realize that measurements of skewness parameters \( S^{(0)}(\theta_b) \), \( S^{(1)}(\theta_b) \) and \( S^{(2)}(\theta_b) \) will not be independent but correlated with one another; the level of correlation depends on the noise and beam profile.

In Figure 2 we have plotted the variance parameters \( \sigma_2^2(\theta_b) \) and \( \sigma_1^2(\theta_b) \) for various smoothing beams (assumed Gaussian). The four different FWHM that are considered are \( \theta_b = 10', 25', 50' \) and \( 100' \) respectively. The parameter values only depend on the underlying CMB power spectra and the beam as well as the noise. They are used as a normalization parameters while constructing the MFs from the generalized skewness parameters. Two different beam and noise levels are considered EPIC (left-panel) and Planck (right-panel). The one-point generalised skewness parameters are depicted in Figure 3 for Planck and Figure 4 for EPIC. The background cosmology is that of \( \Lambda \text{CDM} \).

In Figure 2 the one-point skewness parameters \( S^{(0)}(\theta_b) \), \( S^{(1)}(\theta_b) \) and \( S^{(2)}(\theta_b) \) (solid, short-dashed and long dashed lines respectively) are plotted as a function of smoothing scale \( \theta_b \). These parameters are defined in Eq.(14). The panels correspond to contributions from different types of secondary non-Gaussianity: cross-correlation of lensing and Sunyaev-Zel’dovich effect (left-panel), cross-correlation of ISW and lensing (middle-panel); cross-correlation of point source and lensing (right-panel). An experimental set up which is same as EPIC was considered. See Table 1 for detail specifications regarding level of noise and beam. The bispectrum used in our calculation is given in Eq.5 and the cross-spectra is plotted in Figure 5.

The skew-spectra resulting from cross-correlating these parameters introduced above, or pseudo-collapsed three-point function (Hinsaw et al. 1995), as well as the equilateral configuration statistics (Ferreira, Magueijo & Gorski 1998) which can all be expressed as linear combinations of the bispectrum terms. The generalized skewness parameters introduced above are also all linear combinations of the bispectrum weights but with varying weights. Using one-point statistics has the advantage of higher signal to noise but the price we pay is in terms of reduced power to discriminate individual contributions.

The triplet of skew-spectra and lowest order corrections to Gaussian MFs

The skew-spectrum has been studied previously in various cosmological contexts (Cooray 2001a), e.g. to estimate the bispectrum resulting from lensing-SZ correlation. The skew-spectra are cubic statistics constructed by cross-correlating two different fields. One of the fields used is a composite field (map) typically a product of two maps either in its original form or constructed by means of applying relevant differential operators. Example of such derived maps that we will consider are \( [\Theta^2(\Omega)] \), \( [\nabla \Theta(\Omega) \cdot \nabla \Theta(\Omega)] \) and \( [\nabla^2 \Theta(\Omega)] \). The skew-spectra resulting from cross-correlating these maps are known as the \textit{generalised} skew spectra and are related to the three \textit{generalised} skewness parameters introduced above. At the lowest order, the MFs themselves can be constructed using these generalized skewness parameters and contain equivalent information.

The detection of each individual mode of the primary or secondary bispectrum is still considered challenging. This is primarily due to the low signal-to-noise associated with each individual modes. All available information is therefore typically compressed into a single number - the skewness. This drastic data compression leads to a significant degradation of the power of the statistic to discriminate between models.
The skew-spectra $S^{(0)}_l(\theta_b)$, $S^{(1)}_l(\theta_b)$ and $S^{(2)}_l(\theta_b)$ for ISW×Lensing is plotted as a function of the harmonics $l$. Notice that skew-spectra corresponding to ISW are dominant at smaller $l$s while the ones corresponding to SZ dominate at larger $l$ values. The skew-spectra, being integrated measures, depend on the entire harmonic range of the bispectra. The shape of the skew-spectra can play an important role in separating individual contributions of secondary non-Gaussianity.

The first of the skew-spectra that we will study is the one introduced by [Cooray 2001a] and later generalized Munshi & Heavens (2010). It is related to sometimes known as the two-to-one power spectrum and is constructed by cross-correlating the squared map $|\Theta(\hat{\Omega})|^2$ with the original map $\Theta(\Omega)$. The second skew-spectrum is constructed by cross-correlating the squared map $|\nabla^2 \Theta(\Omega)|^2$ with $|\nabla \Theta(\Omega)|$. Analogously the third skew-spectrum represents the cross-spectra that can be constructed using $[\nabla \Theta(\Omega) \cdot \nabla \Theta(\Omega)]$ and $[\nabla^2 \Theta(\Omega)]$ maps.

$$S^{(0)}_l(\theta_b) \equiv \frac{1}{12 \pi \sigma^2_{b \hat{\Omega}}(\theta_b)} S^{(\Theta^2, \Theta^2)}_l(\theta_b) = \frac{1}{12 \pi \sigma^2_{b \hat{\Omega}}(\theta_b)} \frac{1}{2l+1} \sum_{m} \text{Real}(\Theta[\hat{\Omega}]_m[\Theta^2]_m) = \frac{1}{12 \pi \sigma^2_{b \hat{\Omega}}(\theta_b)} \sum_{l_1 l_2} B_{l_1 l_2} J_{l_1 l_2} b_i(\theta_b) b_i(\theta_b) b_i(\theta_b), \tag{18}$$

$$S^{(1)}_l(\theta_b) \equiv \frac{1}{16 \pi \sigma^2_{b \hat{\Omega}}(\theta_b) \sigma^2_\Theta(\theta)} S^{(\Theta^2, \nabla^2 \Theta^2)}_l(\theta_b) = \frac{1}{16 \pi \sigma^2_{b \hat{\Omega}}(\theta_b) \sigma^2_\Theta(\theta)} \frac{1}{2l+1} \sum_{m} \text{Real}(\nabla^2 \Theta[\hat{\Omega}]_m[\nabla^2 \Theta]_m) = \frac{1}{16 \pi \sigma^2_{b \hat{\Omega}}(\theta_b) \sigma^2_\Theta(\theta)} \sum_{l_1} \left[(l+1) + (l_1 + l_1) + (l_2 + l_2)ight] B_{l_1 l_2} J_{l_1 l_2} b_i(\theta_b) b_i(\theta_b) b_i(\theta_b), \tag{19}$$

$$S^{(2)}_l(\theta_b) \equiv \frac{1}{8 \pi \sigma^2_{b \hat{\Omega}}(\theta_b)} S^{(\nabla \Theta, \nabla \Theta, \nabla^2 \Theta)}_l(\theta_b) = \frac{1}{8 \pi \sigma^2_{b \hat{\Omega}}(\theta_b)} \frac{1}{2l+1} \sum_{m} \text{Real}(\nabla \Theta \cdot \nabla \Theta[\hat{\Omega}]_m[\nabla^2 \Theta]_m) = \frac{1}{8 \pi \sigma^2_{b \hat{\Omega}}(\theta_b)} \sum_{l_1} \left[(l+1) + (l_1 + l_1) - (l_2 + l_2) + cyc. \perm.\right] B_{l_1 l_2} J_{l_1 l_2} b_i(\theta_b) b_i(\theta_b) b_i(\theta_b), \tag{20}$$

$$= \frac{J_{l_1 l_2 l_3}}{2l_3 + 1} = \frac{(l_2 + l_2 + 1)(2l_1 + 1)}{(2l_1 + 1)4\pi} \left( \begin{array}{ccc} l_1 & l_2 & l_3 \\ 0 & 0 & 0 \end{array} \right), \tag{21}$$

$$S^{(3)}_l(\theta_b) = \sum_{l}(2l+1)S^{(3)}_l(\theta_b). \tag{22}$$

Each of these spectra probes the same bispectrum $B_{l_1 l_2}$ but with different weights. Each triplet of modes specifies a triangle in the harmonic domain and the skew-spectra sum over all possible configuration of the bispectrum keeping one of its sides $l$ fixed.

The extraction of skew-spectra from data is relatively straightforward. The procedure consists of the construction the relevant maps in real space either by algebraic or differential operations and then cross-correlating them in multipole space. Issues related to mask and noise will be dealt with in later sections. We will show that even in the presence of a mask the computed skew spectra can be inverted to give a unbiased estimate of all-sky skew-spectra; presence of noise will only affect the scatter. We have explicitly displayed the experimental beam $b_i$ in all our expressions.

In Figs. 5, 6 we have presented the three different skew-spectra $S_l$ as a function of the harmonics $l$. The skew-spectra for a generic bispectrum is defined in Eq. (18), Eq. (19) and in Eq. (20). In Figure 5 we present the skew-spectra corresponding to the SZ effect cross-correlated to lensing. The Figure 6 we present the skew-spectra for the ISW effect and Figure 7 shows the skew-spectra for unresolved point sources. The skew spectra are sensitive to the beam $b_i(\theta_b)$ moreover the skew-spectra at a given $l$, i.e $S_l^{(i)}(\theta_b)$ depend on the bispectrum $B_{l_1 l_2 l_3}$ defined over the entire range of modes specified by all possible $l$ values that are being probed. The distinct shape of these individual spectra can be used to study the nature of their origin (i.e. primordial or secondary). Specific models of primary non-Gaussianity such as local or equilateral too will have distinct shapes for the $S_l^{(i)}(\theta_b)$ parameters though such contributions will be subordinate for currently allowed levels of primordial non-Gaussianity.

It is important to stress that these three skew-spectra do not contain completely independent information; the errors associated with them are correlated. We next turn to a detailed derivation of signal-to-noise level of these estimators and the level of cross-correlation among these spectra for a given observational strategy. The derivations are accurate for near all-sky coverage; for more accurate modeling a computationally expensive but conceptually straightforward Monte-Carlo analysis is required.

resolution
channels using raw as well as frequency-cleaned maps (Calabrese et al. 2010). These studies used the KQ75 mask and were limited by the WMAP

Table 1. Parameters used to compute the skew-spectra and the associated scatter for the two different experiments, ongoing Planck [Planck Collaboration 2008] and EPIC [Baumann et al. 2009].

| Mission | \( \theta_b \) | \( \sigma_{\text{pix}} \) | \( \Omega_{\text{pix}} \) | Frequency |
|---------|------------|----------|----------|----------|
| Planck  | 7.1'       | 2.2 \times 10^{-6} | 0.0349   | 143 (GHz) |
| EPIC    | 5.0'       | 8.0 \times 10^{-9} | 0.002    | 150 (GHz) |

Using the estimator Eq. (18) previous studies have focused towards a detection of lensing-secondary correlation for individual WMAP frequency channels using raw as well as frequency-cleaned maps (Calabrese et al. 2010). These studies used the KQ75 mask and were limited by the WMAP resolution \( N_{\text{side}} = 512 \) and an \( l_{\max} = 600 \). No significant evidence for a non-Gaussian signal from the lensing-secondary correlation was found in any of the individual bands, 2\( \sigma \) and 3\( \sigma \) evidence were obtained both for lensing-ISW and lensing-SZ signals in the foreground cleaned Q-band maps, respectively. They also found that the point source amplitude at the bispectrum level to be consistent with previous measurements. With higher resolution maps available from Planck as well as other future missions such as EPIC it will be possible not only to achieve a cross validation using multiple skew spectra, but it should also be possible to reconstruct the topological properties and compare them with the ones obtained in the pixel domain.

A great deal of attention has recently been focused on designing optimal estimators. Indeed this is true that for current generation of experiments (WMAP) the mere detection of non-Gaussianity remains a challenging task because of the low ratio of signal to noise. Optimality of an estimator may not be a crucial issue for high resolution data from experiments such as Planck, at least for the detection of secondaries, as very high level of signal to noise is expected. Attention then will shift to the characterization of non-Gaussianity (primordial and secondary) and provide the level of contamination from foregrounds such as point sources. The skew-spectra associated with MFs can play a valuable role in this direction. The main advantage of computing the skew-spectra being a direct estimator which can deal with issues that are related to the presence of a mask and(possibly inhomogeneous) noise. Partial sky coverage introduces mode-mode coupling based on the Pseudo-\( C_l \) method devised by Hivon et al. (2002) for power spectrum analysis and later developed by Munshi et al. (2011a) for analyzing the skew spectra and the kurt-spectrum (Munshi et al. 2011c).

Consider two generic fields \( A(\Omega) \) and \( B(\Omega) \) and denote their harmonic decompositions in the presence of a mask \( w(\Omega) \) as \( \tilde{A}_{lm} \) and \( \tilde{B}_{lm} \). Notice that the mask is completely general and our results do not depend on any specific symmetry requirements such as the azimuthal symmetry. The fields \( A \) and \( B \) may correspond to any of the fields we have considered above. In a generic situation \( A \) and \( B \) will denote composite fields and the harmonics \( \tilde{A}_{lm} \) and \( \tilde{B}_{lm} \) will correspond to any of the harmonics listed in Eq. (22) i.e., \( \Theta^2 \), \( \nabla \cdot \nabla \Theta \), and \( \nabla^2 \Theta \):

5 ESTIMATOR, SKY COVERAGE AND ERROR ANALYSIS

The results derived above correspond to a situation in which an all-sky map is available which is free from noise. However, in reality often we have to deal with issues that are related to the presence of a mask and (possibly inhomogeneous) noise. Partial sky coverage introduces mode-mode coupling in the harmonic domain in such a way that individual masked harmonics become linear combinations of all-sky harmonics. The coefficients for this linear transformation depend on specific choice of mask through its own harmonic coefficients. We will devise a method that can be used to correct for this mode-mode coupling based on the Pseudo-\( C_l \) (PCL) method devised by Hivon et al. (2002) for power spectrum analysis and later developed by Munshi et al. (2011a) for analyzing the skew spectra and the kurt-spectrum (Munshi et al. 2011c).

Notice that the mask is completely general and our results do not depend on any specific symmetry requirements such as the azimuthal symmetry. The fields \( A \) and \( B \) may correspond to any of the fields we have considered above. In a generic situation \( A \) and \( B \) will denote composite fields and the harmonics \( \tilde{A}_{lm} \) and \( \tilde{B}_{lm} \) will correspond to any of the harmonics listed in Eq. (22) i.e., \( \Theta^2 \), \( \nabla \cdot \nabla \Theta \), and \( \nabla^2 \Theta \):

Figure 7. The skew-spectra \( S_l^{(0)}(\theta_b) \), \( S_l^{(1)}(\theta_b) \) and \( S_l^{(2)}(\theta_b) \) for Point-Source \( \times \) Lensing is plotted as a function of the harmonics \( l \). The similarity of the underlying bispectrum for unresolved point-sources and the SZ effect means the shape of resulting skew-spectra are similar.
\[ \hat{A}_{lm} = \int d\Omega \ Y_{lm}^*(\hat{\Omega}) \left[ w(\hat{\Omega}) \ A(\hat{\Omega}) \right]; \]  
\[ \hat{A}_{lm} = \sum_{l_{i1}l_{i2}} (-1)^m I_{l_{i1}l_{i2}} \left( \begin{array}{ccc} l_1 & l_2 & l \\ m_1 & m_2 & -m \end{array} \right) w_{l_1m_1} A_{l_2m_2}. \]  
(23)  
(24)

Similar expressions holds for \( B \). The above expression relates the masked harmonics denoted by \( \hat{A}_{lm} \) and \( \hat{B}_{lm} \) with their all-sky counterparts \( A_{lm} \) and \( B_{lm} \), respectively. In their derivation we use the Gaunt integral to express the overlap integrals involving three spherical harmonics in terms of the 3j symbols. The matrix \( I_{l_{i1}l_{i2}} \) encodes the overlap integral defined in Eq. (25). The expressions also depend on the harmonics of the mask \( w_{lm} \). If we now denote the (cross) power spectrum constructed from the masked harmonics and denote it by \( \tilde{S}_i(\theta) \) and its all-sky counterpart by \( S_i(\theta) \) we can write:

\[ \tilde{S}_i^{AB}(\theta_b) = \frac{1}{2l+1} \sum_{m} A_{lm} B^*_{lm}; \quad \hat{S}_i^{AB}(\theta_b) = \sum_{l_{i1}l_{i2}} M_{l_{i1}l_{i2}} S_l^{AB}(\theta_b); \quad M_{l_{i1}l_{i2}} = \frac{1}{2l+1} \sum_{l_{i1}l_{i2}} I_{l_{i1}l_{i2}} |w_{lm}|^2; \]
(25)

\[ \delta \tilde{S}_i^{AB}(\theta_b) = \langle \delta \tilde{S}_i^{AB}(\theta_b) \rangle - \hat{S}_i^{AB}(\theta_b); \quad \{ A, B \} \in \{ \Theta, \Theta^2, (\nabla \Theta \cdot \nabla \Theta), \nabla^2 \Theta \}. \]
(27)

The two-to-one estimators are from a family of non-Gaussian estimators. The three-to-one estimator probes the four-point correlation function or equivalently the (angular) trispectrum. The three-to-one estimator probes the four-point correlation function or equivalently the (angular) trispectrum.

\[ \langle \delta \tilde{S}_i^{AB}(\theta_b) \rangle = \frac{1}{2l+1} \left[ S_l^{AB}(\theta_b) + S_l^{AB}(\theta_b) \right]^2; \]

\[ \langle \delta \tilde{S}_i^{AB}(\theta_b) \rangle = \frac{1}{2l+1} \left[ S_l^{AB}(\theta_b) + S_l^{AB}(\theta_b) \right]^2; \]

\[ \{ A_1, A_2, B_1, B_2 \} \in \{ \Theta, \Theta^2, (\nabla \Theta \cdot \nabla \Theta), \nabla^2 \Theta \}. \]

In the next section we will provide detailed explicit expressions for various choices of estimators.

6 Explicit Expressions for Covariances

As we have already stressed, the estimators we have introduced for the skew-spectra are correlated and do not carry independent information. Their correlation structure depends on the experimental beam, noise and sky-coverage. Just as with non-Gaussianity, partial sky coverage also introduces mode-mode coupling. However using the mode-mixing matrix defined in Eq. (25) it is possible to deconvolve the convolved skew-spectra \( \tilde{S}_i \). In this section, we list the expressions for the co-variance of various estimators for skew-spectra. The variances or the scatter of the skew-spectra defined in
Eq. (27) take the following forms:

\[
\langle \delta S_l^{\Theta^2 \Theta} (\Theta_b) \rangle = \langle (S_l^{\Theta^2 \Theta} (\Theta_b))^2 \rangle - \langle S_l^{\Theta^2 \Theta} (\Theta_b) \rangle^2 = \frac{f_{\text{sky}}}{2l+1} \left[ S_l^{\Theta^2 \Theta} (\Theta_b) S_l^{\Theta^2 \Theta} (\Theta_b) + [S_l^{\Theta^2 \Theta} (\Theta_b)]^2 \right],
\]

which are derived without any specific assumption about the shape of the bispectrum. The rest of the expressions are generic, in that they are derived using Wick’s theorem to simplify the resulting expressions.

\[
\langle \delta S_l^{\Theta^2 \Theta} (\Theta_b) \rangle = \frac{f_{\text{sky}}}{2l+1} \left[ S_l^{\Theta^2 \Theta} (\Theta_b) S_l^{\Theta^2 \Theta} (\Theta_b) + [S_l^{\Theta^2 \Theta} (\Theta_b)]^2 \right],
\]

\[
\langle \delta S_l^{\Theta^2 \Theta} (\Theta_b) \rangle = \frac{f_{\text{sky}}}{2l+1} \left[ S_l^{\Theta^2 \Theta} (\Theta_b) S_l^{\Theta^2 \Theta} (\Theta_b) + [S_l^{\Theta^2 \Theta} (\Theta_b)]^2 \right],
\]

\[
\langle \delta S_l^{\Theta^2 \Theta} (\Theta_b) \rangle = \frac{f_{\text{sky}}}{2l+1} \left[ S_l^{\Theta^2 \Theta} (\Theta_b) S_l^{\Theta^2 \Theta} (\Theta_b) + [S_l^{\Theta^2 \Theta} (\Theta_b)]^2 \right].
\]

The final expressions that we derive are applicable to near-all-sky surveys. When a small portion of the sky is covered a sky patch version of our calculations can be performed using two dimensional Fourier analysis instead of the spherical harmonic analysis that we use here. Some of the terms appearing in these expressions can be expressed in terms of the bispectrum. If we assume that the instrumental noise is Gaussian then there is no contribution from noise in these expressions.

\[
S_l^{\Theta^2 \Theta} (\Theta_b) = - \sum_{l_1, l_2} l(l+1) B_{l_1, l_2} J_{l_1, l_2} b_{l_1} b_{l_2},
\]

\[
S_l^{\Theta^2 \Theta} (\Theta_b) = \sum_{l_1, l_2} l(l+1) B_{l_1, l_2} J_{l_1, l_2} [l(l+1) + l_1(l_1+1) - l_2(l_2+1)] b_{l_1} b_{l_2},
\]

\[
S_l^{\Theta^2 \Theta} (\Theta_b) = - \sum_{l_1, l_2} l(l+1) [l(l+1) + l_1(l_1+1) - l_2(l_2+1)] b_{l_1} b_{l_2}.
\]

Notice that these expressions are generic, in that they are derived without any specific assumption about the shape of the bispectrum. The rest of the terms can be expressed in terms of the power spectrum alone. As is common practice in the literature these results ignore all higher order correlation beyond the bispectrum.

\[
S_l^{\Theta^2 \Theta} (\Theta_b) = \frac{1}{2l+1} \sum_{l_1=2}^{l_{\text{max}}} \left( \begin{array}{ccc} l_1 & l_2 & l \\ 0 & 0 & 1 \end{array} \right)^2 T_{l_1} T_{l_2} [l(l+1) + l_1(l_1+1) - l_2(l_2+1)] (C_{l_1} b_{l_1}^2 + n_{l_1}) (C_{l_2} b_{l_2}^2 + n_{l_2}),
\]

\[
S_l^{\Theta^2 \Theta} = \frac{2}{2l+1} \sum_{l_1=2}^{l_{\text{max}}} \left( \begin{array}{ccc} l_1 & l_2 & l \\ 0 & 0 & 1 \end{array} \right)^2 T_{l_1} T_{l_2} (C_{l_1} b_{l_1}^2 + n_{l_1}) (C_{l_2} b_{l_2}^2 + n_{l_2}),
\]

\[
S_l^{\Theta \Theta \Theta} = \frac{2}{2l+1} \sum_{l_1=2}^{l_{\text{max}}} \left( \begin{array}{ccc} l_1 & l_2 & l \\ 0 & 0 & 1 \end{array} \right)^2 T_{l_1} T_{l_2} [l(l+1) + l_1(l_1+1) - l_2(l_2+1)]^2 (C_{l_1} b_{l_1}^2 + n_{l_1}) (C_{l_2} b_{l_2}^2 + n_{l_2}).
\]

The remaining terms are scaled input power-spectra:

\[
S_l^{\Theta^2 \Theta} = -l(l+1)(C_{l_1} b_{l_1}^2 + n_{l_1}); \quad S_l^{\Theta^2 \Theta} = l^2(l+1)^2 (C_{l_2} b_{l_2}^2 + n_{l_2}); \quad S_l^{\Theta \Theta} = (C_{l_1} b_{l_1}^2 + n_{l_1})
\]

The derivation of these results follow the same general principle that is outlined in [3]. These expressions are used to compute the cross-correlation coefficient among various spectra which are defined below:

\[
r_{ij}^{(l)} (\Theta_b) = \langle \delta S_l^{(i)} (\Theta_b) \delta S_l^{(j)} (\Theta_b) \rangle / \sqrt{\langle \delta S_l^{(i)} (\Theta_b)^2 \rangle} \sqrt{\langle \delta S_l^{(j)} (\Theta_b)^2 \rangle}; \quad i, j \in \{0, 1, 2\}.
\]
several previous studies on extraction of the MFs from the CMB data that rely either on simplification of radiative transfer using the Sachs-Wolfe
analysis and later developed by Munshi et al. (2011a) for analyzing the skew spectra and the kurt-spectrum (Munshi et al. 2011c). and the cross-
in Figure 9 for EPIC as well as for Planck in Figure (8). The cumulative signal-to-noise as expected is higher for EPIC due to higher sensitivity. The
signal to noise for ISW decreases sharply at higher
their cross-correlation coefficient provides a succinct measure of this lack of dependence.

As before, throughout we have ignored the mode-mode coupling. The coefficients of cross-correlation r_{ij} are independent of the sky-coverage f_{sky}.
The signal to noise for individual modes for a given spectrum on the other hand can be expressed as:

$$\frac{S}{N}^{(i)}(\theta_b) = \sqrt{\frac{\langle |S|^{(i)}(\theta_b) \rangle^2}{\langle |\delta S|^{(i)}(\theta_b) \rangle^2}} \quad i \in \{0, 1, 2\}. \quad (46)$$

The cumulative $\frac{S}{N} = \sum_{l=2}^{\text{max}} [\frac{S}{N}]^{(i)}$ is tabulated for individual experiments in Table 1 for Planck and EPIC.

We have also computed the signal to noise ratio for individual modes using these expressions for various skew spectra. These results are plotted in Figure 8 for EPIC as well as for Planck in Figure 9. The cumulative signal-to-noise as expected is higher for EPIC due to higher sensitivity. The signal to noise for ISW decreases sharply at higher l and peak at lower l on the other hand the signal to noise for SZ and unresolved point sources peak at a much higher angular frequency. Among the three skew-spectra we have considered, the skew spectra $S_1^{(i)}(\theta_b)$ was found to have higher signal to noise compared to $S_0^{(i)}(\theta_b)$ and $S_2^{(i)}(\theta_b)$. While the lowest order skew-spectra $S_0^{(i)}(\theta_b)$ is dominated mostly by cosmic variance the other skew-spectra, $S_2^{(i)}(\theta_b)$ is maximally affected by the instrumental noise. The information content is not independent for the different skew-spectra; their cross-correlation coefficient provides a succinct measure of this lack of dependence.

To correct for the effect of a mask and the noise we will follow the Pseudo-CF (PCL) method devised by Hivon et al. (2002) for power spectrum analysis and later developed by Munshi et al. (2011a) for analyzing the skew spectra and the kurt-spectrum (Munshi et al. 2011a) and the cross-

The signal to noise of estimates of one-point generalised skewness parameters $S^{(i)} = \sum_{l=2}^{\text{max}} (2l + 1) S_l^{(i)}$ is given by

$$\left[ \sum_{l=2}^{\text{max}} (2l + 1)^2 \frac{\langle |\delta S|^{(i)} / S^{(i)} \rangle^2}{\langle |\delta S|^{(i)} / S^{(i)} \rangle^2} \right]^{-1/2}. \quad \text{The corresponding numbers for Planck and EPIC are presented in Table 3.}$$

It is possible to introduce a filter function $w_{ij}$ in the definition of the skew-spectra. Choices include, sharp cutoff in the l space to avoid the
affect of noise at high l, or optimal filters that maximizes the signal to noise for a given resolution $l_{\text{max}}$. Clearly such option will invariably improve the statistical significance. The filter functions can be of further interest if the bispectrum is more pronounced for certain triangular configurations. Another potentially useful application of a filter function is to filter out a specific configuration.

7 CONCLUSION AND DISCUSSION

Non-Gaussianity is in itself a poorly defined concept, in that there is no unique approach that can be adopted to describe or parametrize an arbitrary
form of non-Gaussianity in a complete manner. In order to quantify non-Gaussianity as fully as possible it is therefore essential to deploy a battery
of complementary approaches each of which exploits different statistical characteristics. Each such technique will have a unique response to real
world issues such as the sky-coverage (observational mask), beam and instrumental noise. Any robust detection therefore will have to involve a
simultaneous cross-validation of results obtained from independent methods. The most common characterizations of non-Gaussianity involve
studying the bispectrum, which represents the lowest-order departure from Gaussianity; higher order non-Gaussianity can be studied using its higher
order analogues i.e. the multi-spectra.

By contrast the topological estimators (MFs) that we have studied here carry information to all orders, though in a collapsed (one-point) form. Analytical results for MFs for a Gaussian field are well understood, and form the basis of non-Gaussianity studies (Tomita 1986). There have been several previous studies on extraction of the MFs from the CMB data that rely either on simplification of radiative transfer using the Sachs-Wolfe
The MFs are completely specified by the knowledge of the bispectrum. Our results are most naturally defined in the harmonic domain. Comparison of MFs extracted using harmonic approach can be cross-compared with more traditional approach in the real space as an useful consistency check.

Our primary aim in this work has been to study how well we can probe the secondary signals from mode coupling using morphological descriptors. Effects such as gravitational lensing (Goldberg & Spergel 1999a,b; Cooray & Hu 2000). Among various sources of non-Gaussianity, Exploiting the perturbative expansion of the MFs, we showed that at the leading order of non-Gaussianity, the MFs have also been studied using elaborate computer-intensive non-Gaussian simulations (Komatsu et al. 2003; Spergel et al. 2007). Most of these studies were done using a specific model of non-Gaussianity, namely the local model of primordial non-Gaussianity which is parametrized by the well known parameter $f_{NL}$.

The main motivation behind the present study has been to extend such methods to secondary non-Gaussianities which have not been studied before in the context of morphological statistics analytically. The increase in sensitivity of CMB experiments and near all-sky coverage along with wide frequency range means the study of non-Gaussianities will be feasible in the very near future. Moreover, in the currently favoured adiabatic CDM models it is expected that the contribution from primordial non-Gaussianity is negligible and the main contribution to non-Gaussianities comes from secondaries. The secondary non-Gaussianity signal are associated with large scale structure contributions and through various mode coupling effects such as gravitational lensing (Goldberg & Spergel 1999a,b; Cooray & Hu 2000). Our primary aim in this work has been to study how well we can probe the secondary signals from mode coupling using morphological descriptors.

One of the main difficulties faced by one-point estimators $S^{(i)}(b_0)$, that also affects the MF-based estimators $V_{k}(N)$, is their inability to differentiate among various sources of non-Gaussianity. The triplets of skew-spectra $S_{l}^{(i)}(b_0)$ that we have introduced can be used to separate out contributions from various secondaries as well as to probe and constrain any foreground residuals left from the component separation step of the data analysis chain. Generalizing Munshi & Heavens (2010) we have introduce a set of triplets of skew-spectra which can be extracted from any realistic data. These skew-spectra do not compress the available information from a bispectrum to a single number, and their shape can help to distinguish among various sources of non-Gaussianity. Exploiting the perturbative expansion of the MFs, we showed that at the leading order of non-Gaussianity the MFs are completely specified by the knowledge of the bispectrum. Our results are most naturally defined in the harmonic domain. Comparison of MFs extracted using harmonic approach can be cross-compared with more traditional approach in the real space as an useful consistency check.

The methods based on the skew-spectra that we have presented are simple to implement once the derivative fields $\nabla \Theta$ or $\nabla^{2} \Theta$ are constructed. We have shown that this can be implemented in a model-independent way. Our method is based on a Pseudo-$C_{l}$ approach (Hivon et al. 2002) and can handle arbitrary sky coverage and inhomogeneous noise distributions. The Pseudo-$C_{l}$ approach is well understood in the context of power spectrum studies, and its variance or scatter can be computed analytically. We provide generic analytical results for the computation of scatter around individual estimates. We also provide detailed predictions on how they are cross-correlated. In our method, it is possible indeed to go beyond the lowest level in non-Gaussianity to include the contribution from trispectrum. The main contributions in frequency-cleaned CMB maps will be from lensing of the CMB, though it is expected that such corrections will be sub dominant at least in the context of CMB data analysis.

We conclude by pointing out that the MFs do not probe the full bispectrum, but involve only weighted sums of modes and are thus equivalent to the three generalised skewness parameters we have used. We have also defined three generalized skew-spectra associated with each of these skewnesses.

Parameters used to compute the skew-spectra and the associated scatter for the two different experiments, ongoing Planck (Planck Collaboration 2008) and EPIC (Baumann et al. 2009). We have assumed \( f_{\text{sky}} = 1 \) in our calculations.

![Planck Cross-correlation](image)

**Figure 10.** Same as the previous Figure but for Planck noise. The expression for scatter Eq. (32)-Eq. (34) and cross-correlation Eq. (35)-Eq. (37) has two contributions. In each of these expressions there are terms which depend on the bispectrum and there are terms which can constructed from power spectrum alone. For Planck noise we found that the expressions for the scatter as well as the cross-correlation are entirely dominated by the terms which depend only on the power spectrum thus making the coefficient \( r_{ij} \) independent of the type of underlying bispectrum.

In this sense, the study of these skew-spectra can replace the study of MFs. The skew-spectra we have introduced can all be probed for arbitrary mask and noise. Unbiased estimators can also be constructed which can work in the presence of partial sky coverage and inhomogeneous noise. Their variance can also be computed analytically, thereby avoiding the use of non-Gaussian Monte-Carlo simulations completely. Finally, the MFs can be constructed from the knowledge of generalized skew-spectra and can be compared with the results from real space analysis. The triplets of generalized skew-spectra can be used to separate individual components of NGs using their shape information. From our analytical results of cross-correlation, we find that in the absence of noise, e.g. experiments such as EPIC, the skew-spectra are highly correlated, more so for higher \( l \) parameters.

![EPIC Cross-correlation](image)

**Figure 11.** The information content of the skew-spectra are not completely independent. The level of cross-correlation among various estimator is encoded in the coefficient of cross-correlations \( r_{ij} \) defined in Eq. (45). The cross-correlation coefficient \( r_{01}, r_{02} \) and \( r_{12} \) are plotted as a function of harmonics \( l \). The noise level correspond to that of EPIC (see Table 1). The correlation structure refelects the underlying spectra \( \beta_l \) as well as the level of noise. The cross-correlation is similar for SZ and PS.
values. The correlation coefficients are typically in the range $r = 0.5 - 1$ for a Planck type experiment. The cumulative signal-to-noise ratio, in a Planck type experiment, for bispectrum corresponding to the ISW and SZ and lensing cross-correlation reaches $O(10)$. An improvement of about two orders of magnitude can be expected with experiments such as EPIC.

Throughout we have ignored the presence of primordial non-Gaussianity which is expected to be subdominant. Nevertheless, it can be incorporated. Individual skew-spectra from different underlying bispectrum can essentially be combined to construct the total skew-spectra which means that our results can straightforwardly be generalised to incorporate specific models of primordial non-Gaussianity.

The generic results derived here are also applicable to other areas in cosmology and have indeed been explored recently. Examples include the analysis of galactic redshift surveys (Pratten & Munshi 2012), weak lensing surveys (Munshi et al. 2012) and the frequency cleaned SZ maps (Munshi et al. 2012b). The results presented here can be extended beyond the analysis of temperature maps, e.g. to analyze polarisation maps, by extending the spin-0 calculations to spin-2. Such results can furnish useful probes for the characterization of morphology of reionization in three dimensions.

A few comments are in order about the comparison of our estimators with the so-called optimal estimators. The motivation to construct an optimal estimator is to improve the signal-to-noise of detection which is important in case of weak signals such as the primordial non-Gaussianity. The main motivation in this paper has been to reconstruct the topological properties of the CMB map going beyond Gaussianity, in the harmonic domain; in particular due to the contributions from secondary lensing cross-correlation which will be detected with high signal to noise with the proposed CMB surveys such as EPIC.

In addition to the primary and secondary non-Gaussianity, cosmic defects such as textures or cosmic strings (Albrecht, Battye & Robinson 1999; Cruz et al. 2007; Regan & Shellard 2010) also leave non-Gaussian footprints in CMB maps which can be detected by the change in topological nature of the maps. The estimators we have presented here may have relevance in such investigations. A detailed study will be presented elsewhere.

At the level of the bispectrum the effect of lensing can only be studied through its cross-correlation with other secondaries. However weak lensing is also independently responsible for a next order correction to MFs through its effect on the trispectrum; the signal-to-noise is expected to be low.

The signal-to-noise of the skew-spectra for secondary-lensing cross-correlation bispectrum is comparable to that of the skew-spectra of frequency-cleaned SZ maps (Munshi et al. 2012b). However the secondary skew-spectra are much higher compared to skew-spectra associated with primary skew-spectra unless we assume a rather high value for the $f_{NL}$.

8 ACKNOWLEDGEMENTS

DM and PC acknowledges support from STFC standard grant ST/G002231/1 at the School of Physics and Astronomy at Cardiff University where this work was completed. DM would like to thank Joseph Smidt, Geraint Pratten, Asantha Cooray, Shahab Joudaki and Erminia Calabrese for very useful discussions.

APPENDIX A: SPHERICAL HARMONICS

The completeness relationship for the spherical harmonics \( Y_{lm}(\hat{\Omega}) \) is given by:

\[
\sum_{lm} Y_{lm}(\hat{\Omega}) Y_{lm}^*(\hat{\Omega}') = \delta_{2D}(\hat{\Omega} - \hat{\Omega}').
\] (A1)

The orthogonality relationship is as follows:

\[
\int d\hat{\Omega} \ Y_{lm}(\hat{\Omega}) Y_{l'm'}^*(\hat{\Omega}) = \delta^K_{lm} \delta^K_{l'm'}.
\] (A2)

Here \( \delta_{2D} \) and \( \delta^K \) represents the Dirac’s 2-dimensional delta function and Kroneker’s Delta function respectively.

APPENDIX B: 3J SYMBOLS

The following properties of \( 3j \) symbols were used to simplify various expressions.

\[
\sum_{l_3 m_3} (2l_3 + 1) \begin{pmatrix} l_1 & l_2 & l_3 \\ m_1 & m_2 & m_3 \end{pmatrix} \begin{pmatrix} l_1' & l_2' & l_3' \\ m_1' & m_2' & m_3' \end{pmatrix} = \delta^K_{m_1 m_1'} \delta^K_{m_2 m_2'};
\] (B1)

\[
\sum_{m_1 m_2} \begin{pmatrix} l_1 & l_2 & l_3 \\ m_1 & m_2 & m_3 \end{pmatrix} \begin{pmatrix} l_1' & l_2' & l_3' \\ m_1' & m_2' & m_3' \end{pmatrix} = \delta^K_{l_3 l_3'} \delta^K_{m_3 m_3'} \frac{1}{2l_3 + 1};
\] (B2)

\[
(-1)^m \begin{pmatrix} l & m & l' \\ m & -m & 0 \end{pmatrix} = \frac{(-1)^l}{\sqrt{(2l + 1)}} \delta^K_{l'0};
\] (B3)

\[
\int d\hat{\Omega} Y_{lm}(\hat{\Omega}) Y_{l'm'}(\hat{\Omega}) Y_{LM}(\hat{\Omega}) = \sqrt{\frac{(2l + 1)(2l' + 1)(2L + 1)}{4\pi}} \begin{pmatrix} l & l' & L \\ m & m' & M \end{pmatrix} \begin{pmatrix} l & l' & L \\ 0 & 0 & 0 \end{pmatrix}.
\] (B4)
