Introduction. Discretized photonic transport and light walks in non-Hermitian lattices show a wealth of interesting effects which have attracted a major relevance in the past few years. In particular, lattices with asymmetric hopping display rather generally a unidirectional flow of light, which is responsible for such phenomena as non-Hermitian Anderson delocalization transition [1–3] and non-Hermitian transparency [4], with interesting applications to e.g. robust light transport [5], reflectionless transmission [6], nonreciprocal photon transmission and amplification [7,8], topological lasers [9], laser array synchronization [10], non-Hermitian interferometry [11], funneling of light [12], and vortex microlaser control [13]. On a more fundamental viewpoint, non-Hermitian light walks provide a suitable platform to observe a wealth of recently discovered phenomena like the non-Hermitian skin effect (NHSE) [14–17], i.e. the accumulation of all eigenvectors in a finite-sized system toward the edges, the breakdown of the bulk-boundary correspondence based on Bloch-band topological invariants [14,16,18–21], non-Bloch and dynamic phase transitions [17,22–24]. While the impact of static spatial disorder in such systems has been investigated, with the prediction of important effects as non-Hermitian Anderson delocalization transition [1–3,12,25], non-Hermitian transparency [4] and Anderson skin effect [26], the role of temporal fluctuations of spatially homogeneous systems remains unexplored. Since fluctuations can induced transport in non equilibrium systems [27], it is of major relevance to understand the interplay between stochastic fluctuations, non-Hermitian transport and the skin effect.

In this Letter we disclose a rather counterintuitive photonic transport mechanism in a lattice with spatially-ordered but fluctuating hopping amplitudes, dubbed stochastic non-Hermitian skin effect, for which unidirectional light flow arises as a result of fluctuations solely. The effect is illustrated by considering funneling of light at an interface induced by stochastic fluctuations.

Discrete-time non-Hermitian light walk and the skin effect. In order to illustrate the main idea of the present work, let us consider the discrete-time non-Hermitian light walk on a one-dimensional lattice with asymmetric hopping $J_{L,R}$ described by the following map

\[
-i\alpha^{(m+1)}_n = J_{R}^{(m)}_{n-1} + J_{L}^{(m)}_{n+1} \tag{1}
\]

where $\alpha^{(m)}_n$ is the light field amplitude at the site $n$ of the lattice and at the discrete time $m$. This model, earlier introduced in [28], can be implemented in a fiber optics setup [Fig.1(a)], where periodic circulation of optical pulses in fiber loops realizes a synthetic mesh lattice [29–34], and can be regarded as a discrete-time version of the Hatano-Nelson model [Fig.1(b)]. Like the Hatano-Nelson model [1–4,26], for asymmetric hopping $J_L \neq J_R$ distinct quasi-energy spectra are found for a lattice with periodic (PBC) or open (OBC) boundary conditions. In the former case the quasi energy spectrum describes a closed loop complex plane and unidirectional light flow is observed in the bulk of the lattice, while in the latter case the quasi energy describes an arc and all eigenstates are squeezed toward the edge of the lattice (skin effect). In fact, the quasi-energy spectrum $\mu$ is obtained by introducing the Ansatz $\alpha^{(m)}_n = \exp(-i\mu n) A_n$ in Eq.(1), where $\mu$ and corresponding eigenvectors $A_n$ are obtained from the Hatano-Nelson eigenvalue problem

\[
\exp(-i\mu - i\pi/2)A_n = J_R A_{n-1} + J_L A_{n+1} \tag{2}
\]

with appropriate boundary conditions. Under PBC, $A_n = \exp(ikn)$ where $-\pi < k \leq \pi$ is the Bloch wave number, and the quasi-energy spectrum reads

\[
\mu(k) = -\frac{\pi}{2} + i \log \{ J_L \exp(ik) + J_R \exp(-ik) \} \tag{3}
\]

Note that the largest growth rate, i.e. largest imaginary part of $\mu$, is given by $\log(J_L + J_R)$ and is attained at $k = 0, \pi$. The corresponding group (drift) velocity

\[
v_g = \left( \frac{\partial \text{Re}(\mu)}{\partial k} \right)_{0,\pi} = \frac{J_R - J_L}{J_R + J_L} \tag{4}
\]
both in arms of length \( L \) propagating in the main fiber loop is periodically splitted and recombined in an interferometer with unbalanced velocities. We might naively expect that, for a fluctuating hopping amplitude \( J_R \) such that on average the left/right hopping amplitudes are equal, nothing will change. However, such a prediction is not correct and, rather counterintuitively, a fluctuation can produce a unidirectional light flow and the skin effect despite the hopping is symmetric on average. In fact, let us consider an infinitely extended lattice, all eigenstates condensate near \( n = 0 \) and an arbitrary initial excitation of the system is pulled toward the interface (Fig.3), an effect dubbed light funneling [12].

**Stochastic non-Hermitian skin effect and light funneling.** Let us now consider a lattice in which one of the two hopping amplitudes, for example \( J_R \), changes stochastically at successive time steps \( m \) in such a way that, on average, \( J_L = J_R = J \), i.e. let us assume in Eq.(1)

\[
J_L = J , \quad J_R = J(1 + \xi^{(m)})
\]

where \( J \) is the (symmetric) hopping amplitude in the absence of fluctuations and \( \xi^{(m)} \) is a set of independent random variables with the same probability density distribution \( f(\xi) \) of zero mean, i.e. \( \langle \xi \rangle = \int \xi f(\xi) d\xi = 0 \). Clearly, in the absence of fluctuations there is not unidirectional light flow on the lattice (the drift velocity \( v_g \) vanishes) and the skin effect is absent (since \( h = 0 \)). One might naively expect that, for a fluctuating hopping amplitude \( J_R \) such that on average the left/right hopping amplitudes are equal, nothing will change. However, such a prediction is not correct and, rather counterintuitively, a fluctuation can produce a unidirectional light flow and the skin effect despite the hopping is symmetric on average.

\[
A_n = \sin(nk_l) \exp(hn)
\]

are squeezed toward either the left \( h < 0 \) or right \( h > 0 \) edge of the lattice. A typical behavior of quasi-energies for either PBC or OBC is shown in Fig 2. The skin effect can be observed in the infinite lattice when an interface is introduced at site \( n = 0 \) by flipping left and right hopping amplitudes in two half-lines, as shown in Fig 1(c). For \( J_R > J_L \), all eigenstates condensate near \( n = 0 \) and an arbitrary initial excitation of the system is pulled toward the interface (Fig.3), an effect dubbed light funneling [12].

Fig. 1. (Color online) (a) Schematic of the fiber loop that realizes a synthetic mesh lattice [28]. An optical pulse propagating in the main fiber loop is periodically splitted and recombined in an interferometer with unbalanced arms of length \( L \pm \Delta L \). Two acousto-optic modulators (AOMs) provide controllable loss in the two arms, while a semiconductor optical amplifier (SOA) in the main loop controls the overall gain per transit. The evolution of pulse amplitudes \( a_n^{(m)} \) at successive transits \( m \) in the loop is described by Eq.(1). The values of \( J_R \) and \( J_L \) can be tailored both in \( n \) (fast time) and \( m \) (slow time) by judicious control of loss rates in the two AOMs and gain in the SOA. (b) Schematic of a translational-invariant lattice with asymmetric hopping \( J_{L,R} \). The continuous-time light walk on the lattice realizes the Hatano-Nelson model. Light flows unidirectionally for asymmetric hopping \( J_L \neq J_R \). (c) Principle of light funneling based on the NHSE. An interface at \( n = 0 \) is created by flipping left and right hopping amplitudes in the two half lines. For \( J_R > J_L \), any initial excitation in the system flows toward the interface due to the skin effect.

Fig. 2. (Color online) (a) Quasi-energy spectrum (real and imaginary parts of the quasi energy \( \mu \)) of the discrete system (1) for \( J_L = 1 \), \( J_R = 1.3 \) and for (a) PBC, and (b) OBC.
at successive time steps \( m \) read

\[
a_n^{(m)} = \int_{-\pi}^{\pi} F(k) \exp \{i kn - i \mu_m(k) m \}
\]

where we have set

\[
\mu_m(k) = -\frac{\pi}{2} + \frac{i}{m} \sum_{l=0}^{m-1} \log \left[ J \exp(ik) + J(1 + \xi^{(l)}) \exp(-ik) \right].
\]

In the long time limit \( m \rightarrow \infty \), \( \mu_m(k) \) converges to the stationary value (Lyapunov exponent)

\[
\mu(k) = -\frac{\pi}{2} + i \int_{-\infty}^{\infty} \xi f(\xi) \log \left[ J \exp(ik) + J(1 + \xi) \exp(-ik) \right] d\xi,
\]

which provides a generalization of the concept of quasi energy \( \mu(k) \) [Eq.(3)] to the time-dependent (fluctuating) case. For example, assuming that \( \xi^{(m)} \) is uniformly distributed in the range \((-\Delta, \Delta)\), one obtains

\[
\mu(k) = -\frac{\pi}{2} + k + i(\log J - 1)
\]

\[
+ \frac{i}{2\Delta} \left[ 1 + \Delta + \exp(2ik) \right] \log[1 + \Delta + \exp(2ik)]
\]

\[
- \frac{i}{2\Delta} \left[ 1 - \Delta + \exp(2ik) \right] \log[1 - \Delta + \exp(2ik)].
\]

A typical behavior of the real and imaginary parts of the Lyapunov exponent \( \mu(k) \) versus \( k \) is shown in Fig.4(a). The stochastic skin effect is clearly revealed after computation of the Lyapunov exponents in a finite lattice with OBC [Fig.4(b)]. Like in the time-independent case, the Lyapunov exponent under PBC is point-gapped and describes a closed loop in complex plane, indicating the topological origin of the stochastic skin effect as measured by the non-vanishing winding number \( w = (1/2\pi) \int d\log (\det(\mu(k) - E_B)) \) for any base energy \( E_B \) inside the loop [3,35]. However, under OBC the Lyapunov exponents collapse along a segment. Under PBC, the largest growth rate is attained ay \( k = 0, \pi \), with a corresponding non-vanishing and negative value of the drift velocity \( v_g = (d\text{Re}(\mu)/dk) \), given by

\[
v_g = 1 - \frac{\log(2 + \Delta) - \log(2 - \Delta)}{\Delta}.
\]

Note that \( v_g \rightarrow 0 \) as \( \Delta \rightarrow 0 \), i.e. as the fluctuations vanish, indicating that the drift is driven by the stochastic term. The asymptotic behavior of \( a_n^{(m)} \) at large values of \( m \) is dominated by the spectral components with wave numbers near \( k = 0, \pi \) showing the largest growth rate, corresponding to a non-vanishing drift velocity. Hence, fluctuation-induced unidirectional light flow is expected,
even thought on average the left/right hopping amplitudes remain equal. An example of stochastic-induced unidirectional light flow, as obtained for a general realization of the stochastic process $\xi^{(m)}$, is shown in Fig.5. The direction of the drift can be reversed by just considering the fluctuation in $J_R$ rather than in $J_L$, i.e. by assuming [compare with Eq.(6)]

$$J_R = J, \ J_L = J(1 + \xi^{(m)}). \tag{13}$$

We mention that above results hold for other distributions $f(\xi)$ of the stochastic process $\xi^{(m)}$, for example for a normal distribution or even for the simplest case of the Bernoulli distribution, where $\xi^{(m)}$ can assume only two values.

In the presence of a lattice boundary or an interface where the direction of the drift is reversed in the two half-lines, we expect accumulation of light excitation at the boundary or at the interface, an effect that can be referred to as stochastic non-Hermitian skin effect. However, it should be noted that, since we are dealing with a time-dependent system with stochastic dynamics, the concept of eigenvectors cannot be introduced and thus in our case the skin effect refers to accumulation of excitation at the edges or interfaces in the dynamics, rather than condensation of eigenvectors. To illustrate the concept of stochastic non-Hermitian skin effect, let us consider an interface separating two half-lines with different fluctuations, namely

$$J_L = J, \ J_R = J(1 + \xi^{(m)}) \ n \geq 0 \tag{14}$$

$$J_R = J, \ J_L = J(1 + \xi^{(m)}) \ n < 0 \tag{15}$$

so that the drift velocity $v_g$ changes direction in the two half-lines and pushes any initial light excitation toward the interface. This effect realizes the stochastic version of light funneling shown in Fig.3 and recently demonstrated in [12]. Figure 6 shows an example of stochastic light funneling for two different initial conditions, clearly indicating the condensation of light excitation at the interface induced by the fluctuations.

Conclusions In this work we predicted a kind of non-Hermitian skin effect which is driven solely by stochastic temporal fluctuations in the system. Such a counterintuitive effect has been illustrated by discussing funneling of light pulses in fiber mesh lattices. While on average left and right hopping in the lattice remains symmetric, fluctuations can still induce unidirectional flow of excitation and its accumulation at system edges or interfaces. Like for the ordinary skin effect, the stochastic skin effect is rooted in the point-gap topology of the Lyapunov exponents under PBC. As we limited to consider skin effect in lattices induced by temporal fluctuations that maintain discrete translational spatial invariance, a similar effect is expected to arise when considering spatial fluctuations in the system, which destroy translational invariance [26]. Our results shed new light on stochastic non-Hermitian transport and non-Hermitian skin effect, and are expected to motivate further investigations in different areas of physics.
