A spin-polarized current source using nonmagnetic layered materials is promising for next-generation all-electrical spintronic science and technology. Here we electrically created spin polarization in a layered semimetal TaTe$_2$ via the charge-spin conversion process. Using a hybrid device of TaTe$_2$ in a van der Waals heterostructure with graphene, the spin polarization in TaTe$_2$ is efficiently injected and detected by nonlocal spin-switch, Hanle spin precession, and inverse spin Hall effect measurements. Systematic experiments at different bias currents and gate voltages in a vertical geometry prove the TaTe$_2$ as a nonmagnetic spin source at room temperature. These findings demonstrate the possibility of making an all-electrical spintronic device in a two-dimensional van der Waals heterostructure, which can be essential building blocks in energy-efficient spin-orbit technology.

DOI: 10.1103/PhysRevResearch.2.033204

I. INTRODUCTION

Spintronic technology was mainly governed by the generation of spin-polarized currents by using the exchange interaction of conduction electrons in magnetic materials, which require a magnetic field to control their spin orientation [1–4]. However, the demand for faster and smaller spintronic technologies for memory, logic, and artificial intelligence requires efficient and spontaneous spin-polarized current sources using nonmagnetic materials, where all the device operations can be controlled by electrical means [5,6]. Recently, the electronic generation of spin-polarized currents was realized in nonmagnetic materials via the spin Hall effect (SHE), Rashba-Edelstein effect (REE), and spin momentum locking (SML) phenomenon [7–9].

Due to their potential for spintronic applications, the SHE and REE were extensively studied in heavy metals [10,11], semiconductors, oxide heterostructures [7], and more recently, on transition metal dichalcogenides (TMDs) [12], Weyl semimetals [12,13], Rashba spin-orbit materials [14], and their heterostructures with graphene [12,13,15–18]. Topological insulators (TIs) were shown to possess SML characteristics in the Dirac surface states, which could be detected using potentiometric measurements [19–21] and the charge-spin conversion process [22–24]. However, the spin injection from TIs into graphene is so far restricted to very low temperatures due to contributions from trivial bulk states [25,26]. Utilizing the SHE in Pt metal thin films, spin injection and detection has been realized in a graphene channel [10,11]. However, the direct deposition of metallic layers on graphene can modify its electronic properties [27,28]. Recently discovered two-dimensional (2D) magnets can be potential candidates for spin injection into graphene; however, the low Curie temperature of the 2D magnets at this stage limits their room-temperature applications [29]. Therefore, finding a nonmagnetic layered material as a spin source in a van der Waals (vdW) heterostructure with graphene is necessary for newly emerging 2D spintronics science and technology [30].

Using our recently developed vertical measurement geometry [13], we demonstrate the electronic creation and injection of in-plane spin polarization using a layered semimetal tantalum ditelluride (TaTe$_2$) due to efficient charge-spin conversion processes. In a hybrid spintronic device, the spin polarization generated in TaTe$_2$ is efficiently injected into the graphene channel and subsequently detected by a ferromagnet using a sensitive nonlocal spin-valve and Hanle spin precession measurements. Detailed measurements using different bias currents and gate voltages provide insight into the current-induced spin polarization in TaTe$_2$ at room temperature.

II. RESULTS AND DISCUSSION

The choice of the layered monoclinic (1T') semimetal TaTe$_2$ is motivated by its high spin-orbit interaction (SOI) originating from 5d electrons along with the potential for use in charge-to-spin conversion technologies [7,31], and it can be exfoliated into thin 2D layers. Mainly, TaTe$_2$ is an excellent candidate for the generation of pure spin current due to SHE [7,32] and REE [9,33,34], as shown schematically in Fig. 1(a). Figure 1(b) shows the fabricated device picture, where a vdW heterostructure of TaTe$_2$ is prepared with a graphene channel to use its excellent spin transport properties [35,36] together with ferromagnetic Co/TiO$_2$ (FM) injector/detector tunnel contacts (see Appendix A for detailed fabrication processes). The characteristic Raman spectrum of a TaTe$_2$

The inset shows the NLSV measurement geometry.

flake is shown in Fig. 1(c) using a 638-nm laser, where three prominent peaks at 87, 116, and 135 cm⁻¹ are visible [31]. In the transport measurements, TaTe₂ shows semimetallic properties (see Appendix B) and a large magnetoresistance (MR % = \( \frac{R_{\text{B}} - R_0}{R_0} \times 100 \)) [Fig. 1(d)], showing MR \( \sim 30\% \) at room temperature and \( \sim 120\% \) at 25 K at a magnetic field of \(-0.8\) T [37].

Standard nonlocal (NL) spin-valve measurements were performed across the graphene-TaTe₂ heterostructure channel in different graphene-TaTe₂ interface resistance \( R_{\text{int}} \) conditions [Fig. 1(e)]. The spin-polarized electrons were injected and detected by FM contacts in the NL geometry while measuring a \( \frac{\Delta V_{\text{nl}}}{\Delta I} \) as a function of magnetic field sweep \( (B_x) \) to achieve the parallel and antiparallel magnetization of FM electrodes. As shown in Fig. 1(e), while a large spin transport signal \( \Delta R_{\text{nl}} \) of 272 mΩ was measured for high \( R_{\text{int}} \), for very low \( R_{\text{int}} \), tentatively \( < 100 \) Ω (see Appendix C), the \( \Delta R_{\text{nl}} \) drastically reduced to 16 mΩ due to strong spin absorption in the low-\( R_{\text{int}} \) regime.

First, the spin-to-charge conversion experiments [measurement geometry in Fig. 2(a)] were performed in TaTe₂ via the inverse spin Hall effect (ISHE), when the \( R_{\text{int}} \) is \( < 100 \) Ω (see Appendix C). In this condition, the spin current injected from a FM into the graphene channel is strongly absorbed by TaTe₂, as shown in Fig. 1(e). The spin current in TaTe₂ subsequently gives rise to a transverse charge current due to the efficient spin-charge conversion in TaTe₂, which is detected as a voltage signal \( V_{\text{nl}} \) across the TaTe₂ [Fig. 2(b)]. By sweeping an in-plane magnetic field along the \( x \) axis, \( B_x \), the \( V_{\text{nl}} \) varies antisymmetrically at low field and saturates at \( ±0.4\) T as the magnetization of the injector FM rotates completely toward the \( x \) axis. The saturation field range of the FM contacts for the \( B_x \) field sweep has been verified from the spin precession x-Hanle measurements in the graphene channel (see Appendix D). Considering the symmetry of the system with the spin current being absorbed from graphene into TaTe₂ along the \( z \) direction, spin polarization \( (\geq 0.4\, \text{T}) \) in the \( x \) direction and manifested orthogonal charge current \( I_x \) in the \( y \) direction can be due to the ISHE or the Edelstein effect (EE) in TaTe₂ [12]. The \( V_{\text{nl}} \) signal has been measured at different spin injection bias currents, which scales linearly [Fig. 2(c)] at room temperature.

We observed a large spin-charge conversion (SCC) signal at room temperature in TaTe₂ with signal amplitude \( \Delta R_{\text{SCC}} = \Delta V_{\text{nl}}/I_{\text{bias}} = -1.69\, \mu\text{V}/-20\, \mu\text{A} \sim 84\, \text{mΩ} \), which is about few times larger than in WTe₂ [12], MoS₂, and Pt in heterostructure with graphene [10,11,17], one order of magnitude larger than in graphene-MoTe₂ heterostructure [38], and a few orders of magnitude higher than in Pt/Cu heterojunction [39] but comparable to the graphene-TaS₂ heterostructure system [15]. Recently, spin-orbit torque experiments using a TaTe₂-ferromagnet heterostructure reported a dominating
Oersted field contribution by local measurements [40], which is avoided in our NL measurements. Form our data, it is not possible to calculate the exact spin Hall angle ($\theta_{\text{SH}}$) in TaTe$_2$, as the spin diffusion length $\lambda_{\text{TaTe}_2}$, is unknown. Furthermore, the larger width of a TaTe$_2$ flake (2.6 µm) compared to the spin diffusion length in graphene ($\sim 2.5$ µm) restrains the use of the available model [10–12]. An estimation of $\theta_{\text{SH}}$ was found to be in the range of 0.2–0.6 using a simple model and considering $\lambda_{\text{TaTe}_2} = 10–110$ nm and $R_{\text{int}}$ of 10–100 $\Omega$ (see Appendix E). Moreover, we have also approximately calculated the inverse Edelstein effect (IEE) of TaTe$_2$ through IEE length $\lambda_{\text{IEE}} = \theta_{\text{SH}} \ast \lambda_{\text{TaTe}_2}$, and we found $\lambda_{\text{IEE}} \approx 6–60$ nm (see Appendix E for more discussion) as a function of $\lambda_{\text{TaTe}_2}$ (10–110 nm).

Next, we focus on the observation of vertical spin injection (VSI) of in-plane spin polarization from TaTe$_2$ into a graphene channel at room temperature [see Fig. 2(d) for measurement geometry]. In the spin-switch experiment, we measured the spin signal $V_{\text{VSI}}$ as a function of an in-plane magnetic field $B_z$ sweep, which switches the magnetization of the FM detector contact from parallel to antiparallel orientation with respect to the in-plane injected spin polarization from TaTe$_2$ [Fig. 2(e)]. The amplitude ($\Delta V_{\text{VSI}} = \Delta V_{\text{VSI}}/R_{\text{bias}}$) of the spin-to-charge conversion signal for vertical spin injection is about 240 m$\Omega$. A confirmatory test of the in-plane spin polarization using a Hanle spin precession measurement was performed in the same NL geometry [Fig. 2(d)], where a perpendicular magnetic field ($B_x$) was swept while keeping the magnetization of the detector FM contact in the in-plane orientation. The $B_z$ field induces spin precession in addition to diffusion and dephasing, which results in a reduction of the spin signal as the detector probes only the projection of the spin orientation onto the FM contact. Figure 2(f) shows the Hanle data measured at room temperature while injecting spin from TaTe$_2$ into the graphene channel, and fitting with Eq. (F1), we estimate the spin lifetime $\tau_s = 195 \pm 26$ ps and spin diffusion length $\lambda_s = \sqrt{\tau_s D_s} = 1.98 \pm 0.3\mu$m, considering the channel length between the TaTe$_2$ and detector FM electrode $L = 3.75 \mu$m (distance between the center of the TaTe$_2$ flake to the center of the FM electrode). We found the spin polarization of the FM detector contact is about $P_{FM} \sim 6.13\%$ (Fig. 10). Subsequently, knowing the $P_{FM}$, the lower limit for the current-induced spin polarization of TaTe$_2$ is calculated to be about $P_{TaTe_2} = 1.34\% \pm 0.26\%$ (see Appendix F).

We further investigated the back-gate ($V_g$) dependence of the VSI spin-switch signal using TaTe$_2$ as the spin injector. Figure 3(a) shows a sketch of the graphene-TaTe$_2$ heterostructure and the change in the Fermi-level position in graphene with an application of $V_g$ from electron- to hole-doped regimes, whereas no change is expected in TaTe$_2$ due to its metallic state. The measured spin-switch signals ($V_{\text{VSI}}$) at various $V_g$ in the range from $-40$ to $40$ V are depicted in Fig. 3(b). The gate dependence of the magnitude of the spin signal $\Delta V_{\text{VSI}}(\Delta R_{\text{bias}} \approx 250–400$ m$\Omega$) is presented in Fig. 3(c) (top panel), which shows that the spin-switch signal direction remains unchanged in the hole and electron transport regime.
Measurement setup and the band diagram of TaTe$_2$ and graphene with an application of a back-gate voltage ($V_g$) across the Si/SiO$_2$ substrate. The measured NL spin-switch signals at various $V_g = -40$–$40$ V for both $n$- and $p$-doped graphene regime in device 3 with a bias current $I = -20 \mu$A at room temperature. The magnitude of the signal $\Delta V_{nl}$ as a function of $V_g$ (top panel). The $V_g$ dependence of the graphene-TaTe$_2$ heterostructure channel resistance (bottom panel) along with the Fermi-level position in the graphene band structure.

FIG. 3. Gate dependence of spin injection signal from TaTe$_2$. (a) Measurement setup and the band diagram of TaTe$_2$ and graphene with an application of a back-gate voltage ($V_g$) across the Si/SiO$_2$ substrate. (b) The measured NL spin-switch signals at various $V_g = -40$–$40$ V for both $n$- and $p$-doped graphene regime in device 3 with a bias current $I = -20 \mu$A at room temperature. (c) The magnitude of the signal $\Delta V_{nl}$ as a function of $V_g$ (top panel). The $V_g$ dependence of the graphene-TaTe$_2$ heterostructure channel resistance (bottom panel) along with the Fermi-level position in the graphene band structure.

To compare $\Delta V_{nl}$ with the heterostructure channel properties, the gate dependence of the graphene-TaTe$_2$ heterostructure channel resistance is presented in the bottom panel of Fig. 3(c), where the charge neutrality point ($V_{CND}$) is $\sim 10$ V with field-effect mobility of about 1074 cm$^2$ V$^{-1}$ s$^{-1}$. Similar gate dependence of the spin-switch signal is observed for device 1 (see Appendix G). These results rule out any contribution of the local Hall effect produced by the local fringe field from the FM detector contact edges on the graphene, since this effect should change its sign with carrier types in graphene [41].

Next, the electrical-bias-controlled switching of the spin injection from TaTe$_2$ was measured. Figure 4(a) shows the spin-switch signal ($V_{nl}$) with injection bias currents of $I = +/− 2 \mu$A at $V_g = 20$ V. Reversing the current direction creates opposite spin polarization in TaTe$_2$ and hence accumulation of opposite spins in the graphene channel, which results in the opposite direction of the hysteretic behavior of the measured spin-switch signal. A full bias-dependent measurement was carried out at larger biases to understand the detailed energy dependence of the spin injection mechanism at the graphene-TaTe$_2$ junction [see Figs. 4(b) and 4(c)]. In the $−I$ range, we observed an increase of $\Delta V_{nl}$ with bias currents, where the amplitude of the spin-to-charge conversion signal is about $\Delta R_{nl} = 300 \Omega$. However, for the $+I$, the $\Delta V_{nl}$ increases linearly for low biases up to $I = 8 \mu$A and disappears at larger bias within the measurement noise. One of the reasons for such bias dependence can be ascribed to the energy dependence of spin polarization in TaTe$_2$, or the availability of spin-polarized density of states near the Fermi level in TaTe$_2$. In contrast to local detection of the spin signal [42,43], as the measurements were performed in the NL geometry without any bias across the detector FM contact, any effects originating from the detector can be ruled out. This asymmetric feature of the bias-dependent spin injection effect in graphene-TaTe$_2$ heterostructure can be correlated to an electronic diode, where instead of controlling the charge current with bias in the conventional diode we control the spin injection in the heterostructure. To further examine the asymmetry of the bias dependence, we also checked the bias dependence of the graphene-TaTe$_2$ injector interface resistance ($R_{int}$) [see Fig. 4(d)]. Interestingly, $R_{int}$ is observed to be asymmetric with bias, which can be the origin of the asymmetry in the spin injection signal due to a conductivity mismatch issue between the TaTe$_2$ spin source and the graphene channel [35,44].

We discuss the possible mechanisms that engender the generation of current-induced in-plane spin polarization in the TaTe$_2$ in VSI geometry. First, like the ISHE measurements, we can also explain the VSI signal in TaTe$_2$ using the symmetry principle [see Appendix H, Figs. 12(a)–12(d)], that the generated field or spin ($s$) is perpendicular to the applied charge current ($I_c$) and spin current ($I_s$). As the TaTe$_2$ crystals have a relatively smaller thickness (70 nm) compared to their lateral width ($2.6−6$ µm), as well as a low resistance compared to the graphene and interface ($R_{int}$), this makes the electric field within TaTe$_2$ predominantly in plane. Moreover, considering the in-plane spin injection in graphene, the origin of spin polarization can be attributed to the bulk SHE of TaTe$_2$ due to an in-plane electric field in TaTe$_2$. Similarly, the surface or bulk states of TaTe$_2$, if present and spin polarized, can also inject in-plane spin into graphene due to the EE [13] (see Fig. 12). If we consider the lower symmetry of the TaTe$_2$ crystals [40], both SHE and EE can also give rise to in-plane spin polarization in the TaTe$_2$, as it does not have to follow the orthogonal rule between $s$, $I_c$, and $I_s$ [45]. On the other hand, proximity-induced SHE in graphene can be excluded as an origin of the signals, as it is expected to align spin in the out-of-plane direction [16–18,46]. Moreover, with the lack of gate-dependent sign change behavior of the spin-switching signal for electron and hole transport regimes, the contribution of proximity-induced REE in graphene can be ruled out [15,16,47–49]. Any contribution of spin polarization from the Te layer can also be ruled out because equal and opposite contributions from both Te surfaces within a single TaTe$_2$ layer will be canceled out [50].

III. CONCLUSION

In summary, we demonstrated efficient charge-spin conversion in semimetal TaTe$_2$ as an efficient spin injector in graphene-based spintronic devices at room temperature by using a vertical spin injection geometry. The advantage of using such a spin source is that the spin polarization direction can be controlled by an electrical bias instead of the magnetic field as conventionally achieved with ferromagnetic materials. Systematic bias and gate-dependent measurements of the spin injection signal indicate that the origin of spin polarization can be mainly because of the SHE or EE in TaTe$_2$ considering symmetric or low-symmetric spin-charge
conversion processes. Such a nonmagnetic spin source based on the charge-spin conversion effect shows great potential to replace the ferromagnetic injector in all-electrical 2D spintronic circuits and is suitable for spin-orbit technologies.

APPENDIX A: FABRICATION AND CHARACTERIZATION OF GRAPHENE-TaTe2 HETEROSTRUCTURE

To fabricate graphene-TaTe2 heterostructure spintronic devices, first a few layer graphene were mechanically exfoliated from highly ordered pyrolytic graphite (HOPG) onto SiO2 (300 nm)/n-doped Si substrate using the Scotch tape method. Later, TaTe2 flakes were exfoliated from bulk crystal (from Hq Graphene) on polydimethylsiloxane (PDMS) film and dry transferred onto the few-layer graphene flake under a microscope using a home-built micromanipulator-controlled transfer stage. Contacts to graphene and TaTe2 were defined by electron-beam lithography, electron-beam evaporation, and a lift-off process. For the preparation of ferromagnetic tunnel contacts to graphene, a two-step deposition of 0.5 nm of Ti at less than $3 \times 10^{-7}$ Torr and 30 min in situ oxidation at above 30 Torr was carried out, followed by 90 nm of Co deposition. The resistances of ferromagnetic tunnel contacts (TiO2/Co) on the graphene channel were in the range of 5–20 kΩs at room temperature. The spin injection measurements were performed in a vacuum cryostat with a magnetic field up to 0.8 T. All the measurements were performed at room temperature using a Keithley 6221 current source, a Keithley 2182A nanovoltmeter, and Keithley 2612B source meter for application of gate voltages.

Figures 5(a) and 5(b) show the optical microscopic picture and atomic force microscopic image of device 1 consisting of exfoliated TaTe2, graphene with Co/TiO2 tunnel contacts. The widths of the TaTe2 flake and graphene stripe are 2.6 μm and 1.8 μm, respectively. After bias-dependent measurements of the inverse spin Hall effect, the flake was damaged, presumably due to gate leakage. The thickness of the exfoliated TaTe2 flake is about 70 nm, scanned along the dotted orange line in the atomic force microscopy image. Figures 5(c) and 5(d) present the optical micrographs of
FIG. 5. (a, b) Optical microscopic picture and atomic force microscopic image of device 1 consisting of exfoliated 70 nm TaTe_2, graphene with Co/TiO_2 tunnel contacts. (c, d) Optical microscopic images of devices 2 and 3. The green color scale bar in the microscopic images is 6 µm.

devices 2 and 3, respectively, prepared by similar fabrication procedures. Dotted lines in the optical micrographs are to highlight the exfoliated multilayer graphene region below the TaTe_2 flake.

APPENDIX B: ELECTRIC AND MAGNETOTRANSPORT PROPERTIES OF TaTe_2

Figure 6(a) shows conventional four-terminal (4T) I-V characteristics of the TaTe_2 flake with channel resistance 120 Ω at room temperature (pink line) and 70 Ω at 25 K (green line). The resistivity (ρ = R^2/L) of TaTe_2 is approximated to be ∼300 × 10^{-8} Ωm at room temperature and is ∼60 × 10^{-8} Ωm at 25 K. The TaTe_2 channel length (L) is 13 µm and the width (w) is 11 µm; the thickness of TaTe_2 is about 30 nm.

We examined the magnetoresistance (MR%) of TaTe_2 with angle dependence measurements up to ±0.8 T from the perpendicular (⊥) to in-plane field (ⅰⅰ) with respect to the device plane at 300 K with I = −150 µA, as shown in Fig. 6(b). Figure 6(c) presents a maximum MR% at different angles at 0.8 T with a cosine fit. It can be seen [from Figs. 6(b) and 6(c)] that MR% is maximum with the out-of-plane field (Angle = 0) but turns to a minimum with an in-plane field.

APPENDIX C: INTERFACIAL RESISTANCE OF GRAPHENE-TaTe_2 HETEROSTRUCTURE

The graphene-TaTe_2 interfacial resistance (R_{int}) is estimated by two-terminal (2T) measurement geometry in device 1 [Fig. 7(a)]. At the start of the measurements, the 2T resistance was 35 kΩ [Fig. 7(b)], and the 4T R_{int} was about 16 kΩ [Fig. 4(d)]. In such a high-R_{int} condition, the spin transport in graphene is not much affected (without spin absorption). Such high resistance, in the beginning, can be due to the larger van der Waals gap between graphene and TaTe_2. After a few hours of measurement, we observed the 2T resistance to decrease and stabilize at ∼5 kΩ [Fig. 7(b)]. The 4T measurements could not be performed in the low-interface condition due to a lack of working contacts on both sides of the TaTe_2 flake. By considering the graphene channel and contact resistances, the low R_{int} is estimated to be less than 100 Ω. In this low-R_{int} condition, we observed a drastic reduction of the spin transport signal in graphene due to spin absorption by TaTe_2 [presented in Fig. 1(e)]. The inverse spin Hall effect measurements were performed in low-R_{int} and vertical spin injection measurements that were performed in high-R_{int} conditions.

APPENDIX D: x-FIELD HANLE IN GRAPHENE-TaTe_2 HETEROSTRUCTURE

Figure 8(a) shows a schematic of the measurement setup for nonlocal xHanle, where the magnetic field is applied in the planner perpendicular (x axis) to the magnetic easy axis (y axis) of the FM contacts [51]. Figure 8(b) shows the measured xHanle spin signal in a condition where TaTe_2 does not absorb the spin significantly. It can be seen that the magnetization of the FM becomes saturated at ±0.4 T along the x axis.

FIG. 6. Transport properties of TaTe_2. (a) Four-terminal (4T) I-V characteristics of TaTe_2 along with the measurement geometry. (b) Angle-dependent measurements of MR% in TaTe_2 from perpendicular (⊥) to the in-plane field (ⅰⅰ) at room temperature. (c) Maximum MR% at different angles at 0.8 T with cosine fit.
FIG. 7. Interfacial resistance in the graphene-TaTe$_2$ heterostructure. (a) Schematic of the 2T measurement geometry to measure I-V characteristics of the graphene-TaTe$_2$ heterostructure. (b) 2T I-V properties of the graphene-TaTe$_2$ heterostructure, where high resistance, 35 kΩ (orange line), and low resistance, 5 kΩ (blue line), stages are shown.

APPENDIX E: ESTIMATION OF SPIN HALL ANGLE

We have estimated the spin Hall angle ($\theta_{SH}$) in TaTe$_2$ by using the spin diffusion model [10–12]. The manifested inverse spin Hall effect (ISHE) signal can be represented using the following equation:

$$\Delta R_{ISHE} = \frac{2\theta_{SH} \rho_{TaTe2} X}{w_{TaTe2}} \left( \frac{I_i}{I_c} \right). \quad (E1)$$

Here, $\Delta R_{ISHE}$, $\theta_{SH}$, $\rho_{TaTe2}$, $X$, and $w_{TaTe2}$ are the ISHE signal amplitude ($\Delta R_{ISHE} = \Delta V_{ISHE}/I_{300\mu A} = 43 \text{ m}\Omega$), spin Hall angle, resistivity of TaTe$_2$ (300 $\mu$Ω cm), shunting factor (0.94), and width of TaTe$_2$ (2.6 µm). $I_i$ and $I_c$ are the effective spin current absorbed by TaTe$_2$ from the graphene channel due to the shunting effect and converted charge current due to ISHE in TaTe$_2$. The shunt factor ($X$) is estimated by considering the spin signal is in the linear regime with bias current, and from the spin signal presented in Fig. 1(e), $X = 1 - \frac{I_i}{I_c} = 0.94$, which alludes to 94% spin absorption by TaTe$_2$.

$$\frac{I_i}{I_c}$$ can be written as below.

| TABLE I. Parameters of graphene-TaTe$_2$ for device 3 to estimate the spin Hall angle in TaTe$_2$ to solve Eq. (E1). |
|-------------------|-------------------|-------------------|-------------------|-------------------|-------------------|-------------------|-------------------|-------------------|-------------------|
|                  | $D_i$ (m$^2$/s)   | $\tau_v$ (ps)    | $\lambda_{gr}$ ($\mu$m) | $w_{Gr}$ ($\mu$m) | $L_{SH}$ ($\mu$m) | $t_{TaTe2}$ (nm) | $w_{TaTe2}$ ($\mu$m) | $R_{os,Gr}$ ($\Omega$) | $\rho_{TaTe2}$ ($\mu$Ω cm) | $R_1$ (kΩ) | $R_2$ (kΩ) |
| Device 1         | 0.021             | 311              | 2.56                         | 1.8              | 2.5              | 70              | 2.6              | 339              | 300              | 20          | 15          |
diffusion length ($\lambda_{TaTe_2}$) in $TaTe_2$ by assuming $R_{in} = 20 \Omega$ [shown in Fig. 9(a)]. The spin Hall angle $\theta_{SH}$ decays exponentially with increasing $\lambda_{TaTe_2}$ according to Eq. (E1) and its simplified solution. We found $\theta_{SH}$ is 0.59 at $\lambda_{TaTe_2} = 10$ nm; 0.23 at $\lambda_{TaTe_2} = 30$ nm, and becomes saturated with 0.20. We can also approximately calculate the inverse Edelstein effect (IEE) of $TaTe_2$ through IEE length $\lambda_{IEE} = \theta_{SH} \times \lambda_{TaTe_2}$, and we found $\lambda_{IEE} \approx 6$–60 nm [see Fig. 9(b)] as a function of $\lambda_{TaTe_2}$ (10–110 nm) by considering $R_{in} = 20 \Omega$.

Overall, the calculated range of $\theta_{SH}$ for $TaTe_2$ seems to be consistent with Pt ($\theta_{SH, Pt} \approx 0.23$) [10,11], and other TMDs such as $MoTe_2$ ($\theta_{SH, MoTe_2} \approx 0.2$) [38]. $MoS_2$ ($\theta_{SH, MoS_2} \approx 0.1$) [17], but one order of magnitude higher compared to the lower limit of the $\theta_{SH, WTe_2}$ for $WTe_2$ ($\theta_{SH, WTe_2} = 0.01$) [12]. Interestingly, the estimated values of $\lambda_{IEE}$ are comparable to topological insulators [52] (2.1 nm), oxide interfaces [53] (6.4 nm), but it seems to be one order of magnitude higher than in heavy metals (0.1–0.4 nm) and other Rashba systems [33,54]. Figure 9(c) depicts $\theta_{SH}$ as a function of $R_{in}$ by considering spin diffusion length in $TaTe_2$, $\lambda_{TaTe_2} = 30$ nm at room temperature. The spin Hall angle, $\theta_{SH}$, shows a linear dependence on $R_{in}$ and ranges from 0.22 to 0.29 for $R_{in} = 1$–100 $\Omega$.

**APPENDIX F: SPIN TRANSPORT AND SPIN POLARIZATION IN GRAPHENE-$TaTe_2$ HETEROSTRUCTURE**

We characterized the spin transport properties in the graphene-$TaTe_2$ channel (without spin absorption) to estimate the spin polarization of the detector FM contact. Figure 10(a) shows the sketch of the measurement geometry for NL Hanle measurement, where the magnetic field is applied in the out-of-plane direction. The measured spin precession signal is fitted with the following Hanle precession Eq. (F1) to approximate the spin diffusion constant ($D_s$), spin diffusion length ($\lambda_s$), and lifetime ($\tau_s$):

$$\Delta R_{NL} \propto \int_0^\infty \frac{1}{\sqrt{4\pi D_s}} e^{-\frac{t^2}{4D_s}} \cos (\omega L t) e^{\frac{i}{\tau_s} t} dt.$$  \hspace{1cm} (F1)

Furthermore, the measured Hanle spin signal (purple circles) along with its fit (magenta line) to Eq. (F2) is shown in Fig. 10(b) to extract TiO$_2$/Co contact polarization:

$$\Delta R_{NL} = \pm \frac{P_R D_s}{W} \frac{\text{Re} \left\{ 1 - e^{-t/\tau_s} \sqrt{\frac{\omega L}{\Delta \omega}} \right\} }{2D_s \sqrt{\tau_s^2 - i\omega}}.$$ \hspace{1cm} (F2)

Here, $\omega$ depends on the frequency of spin flips and Larmor precession, $\eta_L = \frac{\eta}{\omega L_0} B_\perp$ is the Larmor frequency, where $B_\perp$ is an applied perpendicular magnetic field to the easy axis of the FM contacts, $g = 2$ is assumed. In equation (F1) and (F2), $D_s$ is the spin diffusion constant, and $\lambda_s$ ($2.56 \pm 0.14 \mu m$) and $\tau_s$ ($311 \pm 16 \text{ps}$) are the spin diffusion length and spin lifetime, respectively. In device 1, $R_{in} = 339 \Omega$ for multilayer exfoliated graphene at $V_g = 40 \text{ V}$ on Si/SiO$_2$ substrate. The distance between spin injection and spin detection electrodes is $L = 4.5 \mu m$, graphene width, $w = 1.8 \mu m$. Considering the spin polarization of the injector and detector to be equal ($P_i = P_d$), $P_{NL/TIO2}$ is estimated to be about $6.13\% \pm 0.9\%$.

To estimate the current-induced spin polarization in $TaTe_2$ in device 2, we have also used the same equation, Eq. (F2), to fit the Hanle signal, as shown in Fig. 2(f). In device 2, using the graphene channel resistance, $R_{in} = 1425 \Omega$, width...
FIG. 11. Spin injection from TaTe₂ into graphene and spin-switch signal in device 1. (a, b) Spin injection from TaTe₂ into graphene for the electron- and hole-doped regimes at gate voltages $V_g = 40$ and $-50$ V with $I = -40$ and $-30$ µA, respectively.

$w = 1.2$ µm, we found that

\[
\sqrt{P_{\text{TaTe}_2} P_{\text{Co/TiO}_2}} = 0.0287 \pm 0.0127
\]

\[
P_{\text{TaTe}_2} = \frac{0.0287^2}{P_{\text{Co/TiO}_2}} \pm \frac{0.0127^2}{P_{\text{Co/TiO}_2}} = 0.0134 \pm 0.0026.
\]

Now, using previously obtained $P_{\text{Co/TiO}_2} = 6.13\%$, the spin polarization is of TaTe₂ is approximated to be $P_{\text{TaTe}_2} = 1.34\% \pm 0.26\%$.

**APPENDIX G: SPIN INJECTION FROM TaTe₂ INTO GRAPHENE IN DEVICE 1**

The vertical spin injection results were reproducibly observed at room temperature in three different devices fabricated with similar methods, as presented in this manuscript. Figure 11 shows the spin injection from TaTe₂ into graphene and spin-switch signal in device 1. The possibility of spin transport contribution from the reference FM electrodes on the graphene channel in the injector and detector circuit can be ruled out, as it would have resulted in multiple switches in the measured signal (see Fig. 1(e), where both FM injector and detector contacts are involved in the conventional spin-valve measurements).

**APPENDIX H: CURRENT-INDUCED SPIN POLARIZATION IN SYMMETRIC AND LOW-SYMMETRIC CRYSTALS**

Here we discuss possible origins of in-plane spin polarization in TaTe₂ considering the crystal structure of TaTe₂. IT’-TaTe₂ is a centrosymmetric layered material at room temperature where spin current ($I_s$), charge current ($I_c$), and spin polarization ($s$) are perpendicular to each other for symmetric measurements of the spin Hall effect (SHE) or Edelstein effect (EE). To facilitate our discussion, three-dimensional (3D) axis directions are presented in Fig. 12(a), similar to the schematics shown in Figs. 2(a) and 2(d). Conventional ISHE in the symmetric 3D crystal of TaTe₂ is shown in Fig. 12(b), where $I_c$, $I_x$, and $s$ are perpendicular to each other in the $z$, $y$, and $x$ directions, respectively, and can explain the measurements depicted in Figs. 2(a)–2(c).

Interestingly, in-plane spin polarization along the $y$ axis in TaTe₂, presented in Figs. 2(d)–2(f), is possible while injecting charge current ($I_c$) can be along the $z$ axis [Fig. 12(c)] and $x$ axis [Fig. 12(d)], which needs to be perpendicular to the corresponding spin current ($I_s$) to maintain symmetry. These symmetries allow bulk and surface states to inject spin from bulk (via SHE) or surface states (via Edelstein effect) of TaTe₂. While charge current ($I_c$) and spin current ($I_s$) are along the $z$ axis and $x$ axis, respectively, the spins are accumulated at the edges of TaTe₂ [Fig. 12(c)]. However, the TaTe₂ crystals have a relatively smaller thickness (70–100 nm) and
negligible edge area in contact with graphene compared to the bottom surface area. Hence, in-plane (y-axis) spin injection into graphene from the accumulated spins at the TaTe$_2$ edges is improbable. On the other hand, considering charge current ($I_c$) and spin current ($I_s$) are along the x and z axis [Fig. 12(d)], where spin along the y axis can accumulate at the top and bottom surface of TaTe$_2$, this can explain our measurements of spin polarization in symmetric TaTe$_2$ crystal with lateral widths of 2.6–6 µm in contact with graphene and nanometer-range thickness.

However, in-plane spin polarization can also emerge in unconventional and lower symmetric TaTe$_2$ crystal [see Figs. 12(e) and 12(f)], where spin current and spin orientation can be parallel to each other and along the y axis ($s \parallel I_s$) but are perpendicular to the charge current ($I_c$), which could be in either $z$ or $x$ direction in our measurement geometry [45]. Again, considering $k$-dependent spin polarization and the lateral width of TaTe$_2$, which is considerably higher than the thickness, the latter situation is more likely to emanate in such a lower symmetric crystal because of SHE or EE.
