Serologic Markers of Gluten Sensitivity in a Healthy Population from the Western Region of Saudi Arabia

Yasir M. Khayyat

ABSTRACT

Background/Aim: To identify the prevalence of gluten sensitivity in a healthy adult Saudi population within a low endemic area of celiac disease using IgA tissue transglutaminase antibody. The study was conducted as a prospective pilot study for Saudi attendees of a blood donation centre at King Faisal Specialist Hospital & Research Centre in Jeddah, Saudi Arabia.

Patients and Methods: Individuals were invited to participate in the study and screened for gluten sensitivity using immunoglobulin A tissue transglutaminase antibody (IgA TTG) along with serum IgA level. Descriptive data was presented and expressed as mean value; correlation between variables was estimated using Pearson correlation, and nonparametric data using Pearson rho correlation (level of $P$ value <0.05 is considered to be statistically significant).

Results: Two hundred and four individuals (122 males and 82 females, mean age 35 years) attending the blood donation centre were screened. Three individuals tested positive for IgA TTG showing normal IgA level (1 female and 2 males) with a 1.5% prevalence in the cohort.

Conclusions: Positive celiac screening is present at a low prevalence rate in our adult population, in which the individuals’ age and their serum IgA levels are not associated with the positivity level. A study on a larger scale with the application of histologic confirmation of positive cases is needed.

Key Words: Celiac, duodenal, gluten, tissue transglutaminase antibody

Celiac disease (CD) prevalence, often considered uncommon outside the western hemisphere, tends to be misdiagnosed or underdiagnosed. Interestingly, even in high-prevalence areas, a large survey revealed CD as underdiagnosed by primary care physicians compared with gastroenterologists (11% vs 65%). Furthermore, the manifestations of the disease were deemed uncommon (32%) in adulthood. Most often, CD presents with nongastroenterological features; therefore, sound knowledge of the diversity of the disease and its prevalence in the region is essential. This pilot study would explore the prevalence of this disease in a silent group or asymptomatic individuals.

PATIENTS AND METHODS

Between April and July 2010, Saudi attendees of the Blood Donation Centre of King Faisal Specialist Hospital and Research Centre, Jeddah, were assessed by the principal investigator for their current medical issues and possible coexisting manifestations of CD using a short self-administered questionnaire. Subsequently, the purpose of this study was explained and informed consent obtained from all the participants. Blood samples were drawn to screen for CD using tissue transglutaminase antibody immunoglobulin A (TTG IgA) and immunoglobulin A (IgA) to rule out IgA deficiency. TTG is measured using the commercial enzyme-linked immunosorbent assay (ELISA, QUANTA lite, Inova Diagnostics, San Diego, CA, USA) Positive TTG IgA is defined at a level above 20.00 units. Serum IgA is measured using immunoturbidimetric assay (COPAS INTEGRA® 400 plus, Roche, Mannheim, Germany). The reference range of serum IgA is 0.70–4.00 g/L. Sample size calculation for determination of the desired sample in consideration to the reported prevalence in the middle eastern area showed that 300 individuals are needed to be included to determine the...
prevalence. This study is approved and monitored by the Institutional Review Board of King Faisal Specialist Hospital and Research Centre, Jeddah.

RESULTS

Two hundred and four individuals (122 males and 82 females) attending the blood donation center were screened [Table 1]. Based on the screening questionnaire, no individual was found to have features to suggest CD. No short stature was identified in the cohort (defined as a standing height more than 2 standard deviations (SDs) below the mean (or below the 2.5 percentile) for gender). Three individuals tested positive for TTG IgA revealing normal IgA level (1 female and 2 males); their values are as follows: A 22-year-old female, 22 units; a 31-year-old male, 32 units; and a 33-year-old male, 40 units, with the prevalence rate in the cohort being 1.5%. No IgA-deficient individuals were reported. A significant association was found to exist between serum IgA and anti-TTG levels (P=0.0001) and serum IgA levels and the age of the individuals (P=0.010). A non significant association was noted between age and the TTG IgA level (P=0.554) as well as between serum IgA level and TTG status (P=0.153).

DISCUSSION

CD is an autoimmune disorder prevalent in patients with hypersensitivity to a gluten component and its derivatives in agricultural crops, most typically observed in European descendants; however, the current evolutionary data showed that in areas of the fertile crescent in Iraq, Syria, and Iran, this component is present and has been consumed by the locals over several centuries,[2] and therefore, the possibility of CD development is at present due to the continuous exposure to this antigen. Various studies have shown, in fact, that CD prevalence is reaching those in developing countries with a prevalence rate in the adult population with tissue transglutaminase antibody IgA of 1.5%, over a wide representative population age range. TTG IgA was chosen for this study because of its high specificity, above 95% and sensitivity of 90%–96%. The common presence of IgA deficiency estimated at 1:500–700, and particularly in those with CD, the reported incidence being 2%–3%,[3] the IgA value in this study was mandated for each patient. No IgA-deficient individual was detected. Considering the limitations imposed by reporting the prevalence of CD in this study, including those not biopsied or who had declined biopsy, the prevalence in the western populations appears to be approximately 1:100 (1%) with a range of 1:80–1:140 (1.25%–0.71%).[10] The question that arises is whether the diagnosis of CD was satisfactorily arrived at, based on serology alone or in combination with duodenal biopsy? Also, could serology alone be done to discuss the prevalence of CD? The answer has been addressed in several prior studies. Sanders and colleagues reported through a decision tool applied to a large group that had undergone upper endoscopy and duodenal biopsy, that in a given positive TTG of a high-risk group, based on the referral symptoms, have a sensitivity, specificity, positive predictive value, and negative predictive value for a positive antibody result to diagnose CD are 90.9%, 90.9%, 28.6%, and 99.6%, respectively.[11] When two tests are employed together, such as TTG and DPG (deaminated gliadin peptide), it will be possible to reach or rule out a diagnosis of CD without biopsy in 92% of cases in pretest populations of low- and high-risk individuals for CD, with better results in the high-risk individuals.[12] Higher levels of TTG IgA antibodies in conjunction with serum total IgA levels are associated with the increased likelihood of a diagnosis of CD.[13] The observations in this study also showed a statistically significant association between serum IgA and TTG IgA levels that would support the importance of serum IgA measurement.

Table 1: Summary of celiac disease screening

| Table 1: Summary of celiac disease screening | Range | Mean±SD |
|--------------------------------------------|-------|---------|
| Age (years)                                | 14–78 | 34.97±12.73 |
| TTG IgA (units)                             | 3–40  | 6.75±4.19 |
| IgA (g/L)                                  | 0–8   | 2.75±1.28 |
Limitations of this study stem from it being a small sample coupled with the inability to confirm the positive serologic cases with a corresponding duodenal histology. This will provide a more appropriate representation of the prevalence and support the statistical conclusions regarding the presence of CD in the silent population.

CONCLUSION

In conclusion, the prevalence of CD compares favourably with the low-prevalent regions within the neighbouring countries, and in the areas having a higher disease incidence, duodenal biopsy is needed for confirmation of the disease, especially in individuals with low serology titres, particularly in the low-prevalence areas. With increased serology titres the precision and accuracy to diagnose CD improve, with probably a lesser need to perform duodenal biopsy.
