Solving the Euler equation which corresponds to the energy minimum of a density functional expressed in orbital-free form involves related but distinct computational challenges. One is the choice between all-electron and pseudo-potential calculations and, if the latter, construction of the pseudo-potential. Another is the stability, speed, and accuracy of solution algorithms. Underlying both is the fundamental issue of satisfactory quality of the approximate functionals (kinetic energy and exchange-correlation). We address both computational issues and illustrate them by some comparative performance testing of our recently developed modified-conjoint generalized gradient approximation kinetic energy functionals. Comparisons are given for atoms, diatomic molecules, and some simple solids.

PACS numbers:

I. INTRODUCTION

Investigation of orbital-free density functional theory (OF-DFT)\cite{OF-DFT}, including development of approximate orbital-free kinetic energy (OFKE) functionals, has at least two motivations. One is simply the beguiling notion of direct realization of the content of the Hohenberg-Kohn theorem\cite{Hohenberg-Kohn, Kohn-Sham}. The other is practical, namely the possibility of eliminating the computational bottleneck of solving the Kohn-Sham (KS) eigenvalue equations, thereby dramatically broadening the applicability of Born-Oppenheimer molecular dynamics run with DFT electronic energies. The practical aspect is the main focus of the present work.

In OF-DFT, the total electronic energy of an $N_e$ electron system is a functional of the electron density $n(r)$

$$E^{\text{OF-DFT}}[n] = T_s[n] + E_{Ne}[n] + E_H[n]$$

$$+ E_{xc}[n] + E_{NN},$$

where $T_s[n]$ is the KS (non-interacting) kinetic energy functional given explicitly as a density functional, $E_{Ne}[n]$ is the nuclear-electron interaction energy, $E_H[n]$ is the Hartree energy (classical electron-electron repulsion), $E_{xc}[n]$ is the exchange-correlation (XC) energy functional, and $E_{NN}$ is the inter-nuclear repulsion energy. Minimization of the functional Eq. (1) gives a single Euler equation to be solved,

$$\frac{\delta T_s[n]}{\delta n(r)} + v_{KS}([n]; r) = \mu.$$

Here $v_{KS}$ is the Kohn-Sham potential, $\delta(E_{Ne} + E_H + E_{xc})/\delta n$ and $\mu$ is the chemical potential. The ordinary KS equation has the same potential but requires solution for $N_e$ or $N_e/2$ orbitals (in the all-electron, spin-polarized and non-spin-polarized cases respectively). Solution of the ordinary KS problem scales computationally as $\approx N_e^3$ in general, whereas solution of Eq. (2) should scale approximately linearly.

Practical implementation of OF-DFT requires approximation of both $T_s[n]$ and $E_{xc}[n]$. Simply because of their relative magnitudes, the quality of an OF-DFT calculation is dominated by the quality of the approximate $T_s$. There are two distinct classes of approximation in the literature, one-point functionals,

$$T_s[n] = \int t_s([n]; r)d^3r$$

and two-point functionals

$$T_s[n] = \int f_{1,s}([n]; r)\chi(r, r')f_{2,s}([n]; r')d^3rd^3r'.$$

Here $f_{1,s}$ and $f_{2,s}$ are weighting functionals and $\chi(r, r')$ is a type of response function. For reasons of computational efficiency as well as conceptual simplicity (two-point functionals take the development out of the framework of an effective Kohn-Sham equation (see Eq. (8) below) unless an optimized effective potential is used, itself an extra complication), we (and our collaborators) have focused exclusively on one-point functionals and do so here as well.

An interesting feature of the literature on developing approximate OFKE functionals, including our contributions with collaborators, is that there are more tests of approximate functionals using inputs from other sources (e.g. conventional KS calculations, Hartree-Fock calculations, etc.) than tests by solving the Euler equation, Eq. (2). A side effect is that comparatively little is known about the difficulty of solving that equation with approximations other than of the Thomas-Fermi kind (see below) and about the relative effectiveness of various solution techniques.

To frame that issue and the calculations reported here, it is useful to decompose the non-interacting KE functional into the von Weizsäcker contribution plus a non-negative remainder, the Pauli term\cite{Pauli, Pauli2},

$$T_s[n] = T_W[n] + T_\theta[n], \quad T_\theta[n] \geq 0.$$
The von Weizsäcker functional (in Hartree atomic units) is

\[ T_W[n] = \frac{1}{8} \int \frac{\left| \nabla n(r) \right|^2}{n(r)} d^3r \equiv \int t_W([n]; r) d^3r . \tag{6} \]

It is exact for one electron and for a two-electron singlet. From

\[ \frac{\delta T_W[n]}{\delta n(r)} = \frac{1}{\sqrt{n(r)}} \left( -\frac{1}{2} \nabla^2 \right) \sqrt{n(r)} , \tag{7} \]

the Euler equation Eq. (11) takes a Schrödinger-like form\textsuperscript{23–25}

\[ \left\{ -\frac{1}{2} \nabla^2 + v_\theta([n]; r) + v_{KS}([n]; r) \right\} \sqrt{n(r)} = \mu \sqrt{n(r)} . \tag{8} \]

Observe that, unlike familiar quantum mechanical eigenvalue problems, the “orbital” in Eq. (8) is normalized to \( N_e \), not unity. Here \( v_\theta \) is the Pauli potential,

\[ v_\theta([n]; r) = \frac{\delta v_\theta[n]}{\delta n(r)} \geq 0 . \tag{9} \]

Non-negativity of \( v_\theta \) and \( v_\theta \) has proved to be an important pair of constraints for OFKE functional development\textsuperscript{26,27}.

Eq. (8) resembles the ordinary KS equation, a fact that has led to contradictory statements about solution techniques. On the one hand, Ref.\textsuperscript{24} declares that Eq. (8) “…can be solved iteratively to self-consistency by any Kohn-Sham computer program: just select the lowest eigenvalue. The solution is very simple and quick, for there is only one ‘orbital’ ….”. Ref.\textsuperscript{26} makes precisely the contrary claim, at least in the context of the widely used Gaussian-type orbital (GTO) basis sets. Those authors expanded \( \sqrt{n} \) in a GTO basis with coefficients \( c_i \), with respect to which they minimized \( L := E^{\text{OF-DFT}}[n] - \mu N_e \). They state that “Due to the highly nonquadratic nature of the kinetic energy, the optimization of \( L \) is a nontrivial problem. The iterative self-consistent procedure used in Kohn-Sham calculations does not work, and we require more robust minimization techniques. Moreover, …first derivative methods such as conjugate gradient minimization and quasi-Newton search perform poorly, requiring many hundreds of iterations to achieve convergence.” A related discussion and references to the few earlier papers on the issue is at p. 135 of Ref.\textsuperscript{14} This is one of the issues addressed in the present study.

\section{II. APPROXIMATE KINETIC ENERGY FUNCTIONALS}

To set the stage for another technical issue, we consider types of approximate one-point OFKE functionals next. For work on minimization involving two-point functionals, see Refs.\textsuperscript{31–34} and references therein.

\section{A. Thomas-Fermi Type}

Diverse approximate OFKE functionals can be written in the generic form

\[ T_s[n] = T_W[n] + \lambda T_{TF}[n] + T_\Delta[n] \]

\[ 0 \leq \lambda \leq 1 . \tag{10} \]

The simplest local approximation for the KE is the Thomas-Fermi (TF)\textsuperscript{33,34} functional

\[ T_{TF}[n] \equiv \int t_{TF}([n]; r) d^3r = c_0 \int n^{5/3} r d^3r \]

\[ c_0 = \frac{3}{16}(3\pi^2)^{2/3} \tag{11} \]

along with the local Dirac exchange functional. Early reports of special self-consistent OF-DFT calculations mentioned above were for this model\textsuperscript{36,37}.

As an aside, there is an extensive literature of efforts to determine an optimal value of \( \alpha \) in Eq. (12). Since the Pauli term decomposition, Eq. (5), provides both an exact lower bound on \( T_s \) and leads to the density Schrödinger equation, Eq. (8), that decomposition, and its elaboration Eq. (10), seems preferable to using \( T_{TF,W,\alpha} \) and attempting to optimize \( \alpha \). But because \( T_{TF,W,\alpha} \) is prevalent in the literature, we consider the numerical issues associated with it as well.

\section{B. Generalized Gradient Approximation KE Functionals}

Generalized gradient approximations (GGA) are best known in DFT as improvements on the local approximation for \( E_{xc} \). For either \( E_{xc} \) or \( T_s \), a GGA is a truncation of the corresponding gradient expansion which is altered to meet relevant constraints and suppress unphysical behaviors. For the KE functional, a GGA can be written as

\[ T_s^{GGA}[n] = \int t_{TF}([n]; r) F_i(s(r)) d^3r , \tag{13} \]

where \( F_i \) is the kinetic energy enhancement factor. It is a function of the dimensionless reduced density gradient,

\[ s \equiv \frac{\left| \nabla n \right|}{(2k_F)n} \equiv \frac{1}{2(3\pi^2)^{1/3}} \frac{\left| \nabla n \right|}{n^{2/3}} . \tag{14} \]
Because $t_W = \frac{5}{3} s^2 t_{TF}$, the GGA Pauli term in Eq. (4) is

$$T^{GGA}_\theta[n] = \int t_{TF}(|n|; r) F_\theta(s(r)) d^3 r$$

$$F_\theta(s) = F_1(s) - \frac{5}{3} s^2.$$  \hspace{1cm} (15)

Ref. \ref{10} showed that the KS KE of a molecular system is dominated by the behavior of $F_\theta$ over a relatively small range of $s$. For much of that range, Figure \ref{1} displays the Pauli enhancement factors for the functionals $T_{TFvW,\alpha}$, with $\alpha = 1, 1/9$ Eq. (12), the Tran-Wesolowski GGA \cite{TFvW} (PBE-TW), and the mcGGA functional (PBE2) of Ref. \ref{38}. The latter two use the same enhancement factor form as the Perdew, Burke, and Ernzerhof (PBE) GGA X functional, $F_s(s) = 1 + c s^2/(1 + a s^2)$. In PBE-TW $F_1 \propto F_{s,PBE}$ with parameters fitted to reproduce the kinetic energy of a small training set, an assumption called conjointness. PBE2 is a “modified conjoint” GGA (mcGGA) functional because the parameters in it were constrained to satisfy Pauli-term non-negativity; see Ref. \ref{10} for details.

Observe in Fig. \ref{1} that the PBE-TW and $T_{TFvW,\alpha=1/9}$ Pauli enhancement factors are almost identical, especially for small $s$. There, both have negative slope (with respect to $s^2$) which causes violation of $v_\theta$ non-negativity, \ref{10} recall Eq. (9). The common property of the $T_{TFvW,\alpha=1}$ and PBE2 approximations is satisfaction of that non-negativity constraint. The low slope of the PBE2 enhancement factor at small values of $s^2$, $F_{pBE2}^{T}(s) \approx 1 + 0.364 s^2$, makes the enhancement factors for $T_{TFvW,\alpha=1}$ and $T_{PBE2}$ close for $s < 1$. This comparison suggests that the results obtained with the PBE-TW KE functional should be close to those from $T_{TFvW,\alpha=1/9}$ and, similarly, the results from PBE2 should be close to those from $T_{TFvW,\alpha=1}$.

A technical problem common to these GGAs is that both $v_\theta,PBE\_TW$ and $v_\theta,PBE2$ are singular at nuclear sites, the former negative, the latter positive. Numerical solution of the Euler equation Eq. (2) must address this problem, an issue to which we return below.

### III. All-Electron Solutions of the OF-DFT Euler Equation

As in ordinary KS calculations, solution of Eq. (5) can be either all-electron or via pseudo-potentials. In this section, we consider all-electron solutions, by both GTO-basis and numerical grid techniques and address pseudo-potentials in the subsequent section.

#### A. Atoms

To test the notion that any standard KS code can be used straightforwardly\cite{SOAtom}, we modified the GTO-basis code SOAtom to handle $T_\phi$ and $v_\theta$ as in Eqs. (5), (8), and (9). SOAtom, a part of the GTOFF suite\cite{soatom}, solves the KS equation in a Hermite Gaussian basis with analytical evaluation of all the matrix elements except for those involving XC. Those are done on a radial grid. We also modified the Laaksonen all-numerical diatomic molecular code\cite{Laaksonen} correspondingly. It is based on a prolate spheroidal grid.

Insofar as numerical stability is concerned, the results are quite clear. Even for $T_{TFvW,\alpha=1}$ with simple Slater exchange (\textit{i.e.} TFvWD), the typical iterative SCF procedure is only marginally stable. The problem is worse in the GTO basis than in the grid-based calculation, at least in the specific sense that a simple SCF stabilization scheme converge in a few iterations. Ordinary KS calculations on the same atoms with the same simple stabilization scheme converge in a few iterations.

The lithium and carbon atoms are examples. For Li in a 9s GTO basis in the SOAtom code, the pure TF form (Eq. (12) with $\alpha = 0$), the $T_{\phi} = T_{TF}$ form (Eq. (10) with $\lambda = 1, T_\alpha = 0$), and the $T_{\phi} = \lambda T_{TF}$ form (Eq. (10) with $\lambda = 0$) can be brought to numerical convergence but the mcGGA form $T_\phi = T_{mcGGA} - T_{vW}$ cannot. For the successes, more iterations by one to two orders of magnitude are required than for conventional KS and the numerical convergence is poor. One can get to fractional total energy errors of $10^{-4} \rightarrow 10^{-2}$ for lighter to heavier atoms respectively, but not much better. The contrast with conventional KS atomic calculations is stark: in them convergence to $10^{-6}$ is trivial to achieve.

Table \ref{tab:results} illustrates this point with comparison of nu-
merical grid and GTO-basis results for $T_s = T_{vW}$ and $T_{vW} + T_{TF}$ with simple Slater exchange (Dirac exchange) on H, Li, and Ne. (The GTO calculations are with 9s basis sets for H and Li, 13s for Ne.) The two total energies for Li differ at the 1 mHartree scale. Notice that the numerical-grid results match rather well with the values from Ref. 26, which were calculated with a direct minimization scheme, not a modified KS code. Ironically, a misbehavior of simple Slater exchange, namely that it satisfies the virial theorem in the form $E_{\text{tot}} = -T_s$ (which the exact $E_{\text{xc}}$ does not), in this case highlights the convergence problem, especially in the GTO calculation.

Results for the carbon atom in the GTO basis, not shown in the Table, are worse. The $T_{TFvW,\alpha=1/5}$ calculation with a 13s basis cannot be brought to SCF convergence, even with tricks such as starting with full $T_W$ and no $T_{TF}$ contribution, then slowly scaling down the former while scaling up the latter. The corresponding standard KS calculation converges trivially.

For the numerical-grid calculations, SCF convergence is very slow compared to standard KS calculations, but reasonable results can be obtained. Table II shows total energies for the first row atoms obtained from numerical-grid self-consistent OF-DFT calculations with various OFKE approximations, again with Slater exchange. For TFvWD and $T_{TFvW,\alpha=1/5}/g$, comparison with the direct minimization of Ref. 26 (the first six columns of data) confirms that our calculations succeeded.

Note that the total energies from the TF+vW and mcGGA(PBE2) kinetic energy functionals are overestimated (as a consequence of overestimation of the KS KE). In contrast, all of the functionals with scaled von Weizsäcker contributions underestimate the KS KE, so that the resulting total energies are below the reference KS values. Such behavior is characteristic of a failure of $N$-representability in the KE functional. Observe also that TF+1/9vW and GGA(PBE-TW) total energies are close to each other, though the functional forms differ.

Table III shows the effects of using the full LDA $E_{\text{xc}}$, in this case the VWN parameterization. Unsurprisingly but reassuringly, inclusion of the C functional shifts the total energies downward without altering the trends.

These atomic results lead us to nuanced agreement with the claim of Ref. 26 and disagreement with the claim of Ref. 27. The OF-DFT Euler equation is not, in general, solvable by simple modification of a standard GTO KS code (the norm for molecular calculations). Even a good all-numerical KS code is challenged to achieve so-satisfactory solutions for several light molecules.

### B. Diatomic Molecules

Numerical-grid solution of Eq. (11) for diatomic molecules, if possible, would yield two kinds of insight: numerical method behavior and the comparative behavior of $n(r)$ and $v_\theta(r)$ for different OFKE approximations. Though the difficulties of using a modified KS code are just as evident in this case, we have been able to achieve solutions for several light molecules.

Numerical requirements include extremely tight convergence tolerances on the eigenvalue $\mu$ and normalization ($10^{-3}$ more stringent than normal KS calculations), much larger maximum distance cutoff (80 to 100 a.u. vs. normal KS 30 to 40 a.u.), and about a factor of five more points in both of the prolate spheroidal coordinates (roughly $1100 \times 1300$ points vs. the typical $200 \times 300$). Even so, the total energy convergence is mediocre for GGA and mcGGA functionals, about 0.01 Hartree at best. Convergence is better for the $T_{TFvW,\alpha}$ functionals, between 0.1 and 1 mHartree. This need for extreme measures to achieve limited-quality outcomes is an additional confirmation of the unsuitability of unmodified conventional KS schemes for solutions of the OF-DFT Euler equation.

The solutions nevertheless provide real comparative insight regarding different OFKE approximations. Figure 2 compares the all-electron KS density ($E_{\text{xc},\text{LDA}},\ VWN$) around the Si site in SiO with the densities from $T_{GGA,PBE-TW}$ (the Tran-Wesolowski GGA), $T_{mcGGA,PBE2}$ (the PBE2 mcGGA), and $T_{TFvW,\alpha=1/5}$. These approximate functionals form pairs, $T_{GGA,PBE-TW}$ pairs with $T_{TFvW,\alpha=1/5}$, while $T_{TFvW,\alpha=1}$ pairs with $T_{mcGGA,PBE2}$. This pairing conforms to the expectations formed in considering the small-s behavior of the respective enhancement factors. The pairing also is interpretable directly from the near-nucleus repulsion or attraction behavior of the various approximations. $T_{GGA,PBE-TW}$ generates a $v_\theta$ with a spurious negative singularity near the nuclei, while $T_{TFvW,\alpha=1}$ drastically lowers the von Weizsäcker lower bound to $T_s$. Both lead to excess near-nucleus density. In contrast, $v_\theta,mcGGA,PBE2$ has spurious positive nuclear site singularities. Near the nuclei, however, $v_\theta,mcGGA,PBE2$ and $v_\theta,TFvW,\alpha=1$ match quite well, as shown in Fig. 3.

The result, shown in Fig. 2, is that these two functionals give rather close to the same density. Observe that the behavior of $v_\theta$ in the vicinity of the nucleus for each of these approximate functionals differs dramatically from that of $v_\theta$ obtained by inversion of the standard KS scheme. It is that improper behavior which we believe causes the problems with convergence of standard KS codes used with approximate OFKE functionals. The positive near-nuclei singularities appear, in particular, to pose numerical problems.

Details of the density near the Si site are provided

in Fig. 4. For purposes of display, the densities are weighted by a quasi-radial factor with origin at the Si site, $4\pi(\vert z \vert - R/2)^2$. The proper KS shell structure is missing, as is usual with single-point OFKE functionals. The more repulsive nature of the pair $T_{\text{mcGGA,PBE2}}$ and $T_{\text{TFvW,}\alpha=1}$ compared to $T_{\text{GGA,PBE-TW}}$ also is evident. It is interesting that in the region $-2.5 < z < 2.0$ $T_{\text{mcGGA,PBE2}}$ does give a weak mimicry of the outermost shell structure in $T_s$, unlike the other models. We are uncertain as to how reliable or useful this feature is.

Fig. 5 compares the behavior of $E_{\text{OF} - \text{DFT}}[n]$ as a function of SiO bond length with standard KS results. One sees immediately that the GGA and mcGGA forms introduce numerical difficulties because of their dependence on the reduced density gradient $s$, Eq. (14). Clearly there is a grid interval-size problem which could be obviated by going to even denser grids but at obvious computational cost. The known failure of $T_{\text{GGA,PBE-TW}}$ to give binding$^2$ is evident. $E_{\text{TFvW,}\alpha=1/9}$ apparently does not bind either, in keeping with the too-weakened lower bound just discussed. Full TFvWD and $E_{\text{mcGGA,PBE2}}$ are fairly close, with the mcGGA being the best of the lot with respect to equilibrium bond length.

C. Simple Analysis of the Difficulty

The barrier to use of a standard KS code to solve Eq. (8) can be traced to the near-nucleus repulsion of $v_\theta$. As displayed in Fig. 3 the exact $v_\theta$ is strongly repulsive in a fairly small region around the nuclear site. Ref. 11. Fig. 2 shows that the exact $v_\theta$ can have rather sharp structure within a radius of about 1 bohr of a nuclear site.

$^a$Spin-restricted LDA calculation.

FIG. 2: All-electron self-consistent Kohn-Sham and OF-DFT electron densities plotted along the SiO molecule internuclear axis in the vicinity of the Si site. Si at (0,0,-1.05) Å, O out of the picture at (0,0,+1.05) Å. See text.

FIG. 3: Pauli potentials $v_\theta$ around the Si site in SiO from self-consistent all-electron Kohn-Sham and OF-DFT calculations with the PBE2 mcGGA, TW GGA, and $T_{\text{TF+VW}}$, $\alpha=1/9,1$ OFKE functionals.

FIG. 4: All-electron self-consistent Kohn-Sham and OF-DFT electron densities near the Si site along the SiO molecular axis. These are scaled by the factor $4\pi(\text{R}/2)^2$, with $R = 2.10$ Å, the internuclear distance. This puts the origin of the scaling at the Si site (0,0,-1.05) Å. The O is out of the picture at (0,0,+1.05) Å.

In contrast, some simple approximations which are properly positive definite, including our mcGGA, actually are singular at the nuclei; again see Fig. 3. Such strong repulsion overwhelms the attractive $v_{xc}$. That figure also shows that some approximations deliver Pauli potentials with negative nuclear-site singularities. We consider that case below. First, however, the simplest example will suffice to illustrate the problem with properly positive $v_\theta$. Pick $T_\theta = T_{\text{TF}}$, Eq. (11), and $E_{xc}$ to be simplest Slater exchange:

$$E_{xc} = c_x \int n^{4/3} r^3 dr$$

$$c_x = -\frac{3}{4} \left( \frac{3}{\pi} \right)^{1/3}$$

(16)
Then in Eq. \([9]\), the potentials become

\[
v_{\theta} = \frac{1}{2} \left( \frac{3\pi^2}{n} \right)^{2/3} n^{2/3}(r)
\]

\[
v_{KS} = v_{H} + v_{Ne} + v_{xc}
\]

\[
v_{xc} = -\left( \frac{3}{\pi} \right)^{1/3} n^{1/3}(r)
\]

(17)

A hydrogen-like density,

\[
n_{H}(r) := \frac{N_e^4}{\pi} \exp(-2N_e r) ,
\]

obeys the Kato cusp condition near the nucleus\cite{26,27,30}, hence is useful for testing. At the nucleus, this density yields the ratio of potentials

\[
\frac{v_{xc}(0) + v_{\theta}(0)}{|v_{xc}(0)|} = -1 + 3.318004 N_e^{4/3} .
\]

(19)

For \(N_e = 6\), this ratio is already 35.2. By \(N_e = 10\) it is 70.5. Additional simple calculations with the potential which appears in Eq. \([9]\) without the positive Hartree contribution, that is \(v_{Ne}(r) + v_{\theta}(r) + v_{xc}(r)\), illustrate the point. At small \(r\) with \(N_e = 6\), that potential becomes positive for \(r > 0.028\) Bohr. For \(N_e = 10\) it is positive for \(r > 0.011\) Bohr. These little exercises illustrate why the use of an ordinary K-S code becomes so difficult. Such peculiar behavior is quite different from what is encountered in the ordinary KS problem.

From the perspective of numerical stability, the case of a \(v_{\theta}\) which has a spurious negative singularity near each nuclear site, \textit{e.g.} PBE-TW, is at least as bad if not worse. As a site is approached, such potentials first are increasingly repulsive, then plunge abruptly into the negative singularity; see Fig. [3].

IV. PSEUDO-POTENTIAL SOLUTIONS OF THE OF-DFT EULER EQUATION

Having demonstrated the difficulties with solving the OF-DFT Euler-Lagrange problem with a modified KS eigenvalue code, we turn to the use of direct Euler-Lagrange minimization. The specific objective is to exploit the numerical methodology in the \textsc{profess} code\cite{31,32}. Written originally for use with two-point functionals, \textsc{profess} performs OF-DFT calculations by minimization of the Euler-Lagrange equation as a functional of \(n(r)\) under periodic boundary conditions. It uses a numerical 3D mesh and FFTs. As published, the code includes the TF, \(vW\), and \(TFvW\) functionals as well as the Wang-Teter (WT)\cite{45}, and Wang-Govind-Carter (WGC)\cite{46} OFKE functionals. The PZ and PBE \(E_{xc}\) functionals are implemented in \textsc{profess}. For this study, we added the Tran-Wesolowski GGA\cite{38} and our PBE2 mcGGA\cite{47} OFKE functionals.

As is the case with standard KS calculations done in a plane-wave basis, \textsc{profess} relies upon pseudo-potential (PP) techniques to screen the nuclear-electron potential cuff and exclude chemically inactive core states. Though OF-DFT has no problem with core states and the density (and its square root) is a comparatively unstructured, smooth function, regularization of the nuclear-electron interaction singularity still is a requisite for an efficient implementation.

High-quality pseudo-potentials developed for conventional KS calculations generally are non-local, in the specific sense that they contain projection operators which provide different potentials for different orbital angular momenta. That explicit orbital dependence makes non-local pseudo-potentials (NLPP) inapplicable in OF-DFT calculations. Instead, local pseudo-potentials (LPP), \textit{i.e.}, of the form of a simple multiplicative operator which is the same for all orbitals, must be developed. \textsc{profess} requires a LPP in real or reciprocal space as input. Observe that this limitation to local form is an additional approximation, over and beyond the PP itself, which has accuracy limitation implications for both conventional, orbital-based KS or OF-DFT implementations.

In addition to their simplicity, there is a formal advantage of LPPs which is at least of peripheral interest here. Calculations with local PPs are within the framework of the standard KS scheme, which assumes a local effective potential. The NLPP case obviously does not meet that assumption. Although the Hohenberg-Kohn theorem has been extended to the case of a non-local external potential\cite{47}, the exchange-correlation energy in
that case becomes a functional of the one-particle reduced density matrix instead of a functional of the one-particle reduced density matrix alone. Many methods have been proposed to develop LPPs. Among them we mention (i) empirical (or model) LPPs as, for example in Refs. 48–52, (ii) local potentials obtained from non-local ones, for example, by use of just one \( l \)-channel from an NLPP as a LPP (for example, Ref. 53), (iii) LPPs constrained to reproduce atomic properties, eigenvalues, or pseudo-density, etc., which follow from a (presumably superior) NLPP (for example, Ref. 54), and finally (iv) local LPPs derived to reproduce some bulk property values, either experimental or those predicted by NLPP calculations.

A. Local Pseudo-potentials for OF-DFT Calculations

1. Development

Some time ago, an iterative procedure was developed\(^{57,58}\) to solve the inverse problem of determining the KS effective potential \( v_{KS}(r) \) from a given density \( n(r) \). Subsequently, \( v_{KS}(r) \) was introduced and tested an improvement. In the case of Li, however, both versions share a problem. For a single valence orbital (singly or doubly occupied) the solution of the inverse problem is trivial and known. The local pseudo-potential is equal to the \( s \)-channel of the NLPP, \( v_{local}(r) = v_{l=0}(r) \). Hence the LPP contains no information about the \( l \) > 0 channels of the NLPP. Those channels are critical in crystalline binding.

Therefore, to include information about all \( l \) channels of the reference NLPP, we consider a sort of normalized linear combination of \( l \) components of that NLPP,

\[
v_{max}(r) = \sum_{l=0}^{l_{max}} c_l v_l(r) / \sum_{l=0}^{l_{max}} c_l\]

where the parameters \( \{c_l\} \) are to be adjusted to fit selected equilibrium bulk material properties calculated with the reference KS method. This particular method of LPP generation amounts to a mixture of methods (ii) and (iv) described at the outset of this Section.

In the present case, we simply took the bcc Li lattice constant as predicted by a standard KS calculation with PBE\(^{49}\), \( E_{xc} \), and the plane wave (PW) basis set (see Table I), namely \( a = 3.44 \text{ Å} \). Components of the Troullier-Martins norm-conserving NLPP were used in Eq. (20). For generation of the NLPP with PBE XC, we took the core radius to be 2.45 a.u. We designate this LPP as \( v_{GGA,spd1} \). To generate the LDA local LPP, \( v_{LDA,spd1} \) for the Perdew-Zunger\(^{63}\) LDA XC functional, components of the LDA NLPP and the same set of the channel-mixing parameters were used in Eq. (20).

An alternative LPP form which we also studied is a modification of the potential proposed by Heine and Abarenkov\(^{49,51}\). In real space, the Heine-Abarenkov model potential is

\[
v_{mod}(r) = \begin{cases} -A, & r < r_c \\ -Z/r, & r \geq r_c \end{cases}
\]

where \( A \) is a constant, \( r_c \) is the core radius, and \( Z \) is the core charge. The model potential in reciprocal space is given by

\[
v_{mod}(q) = -\frac{4\pi}{\Omega} (\cos(qr_c) + (A/q)\sin(qr_c)),
\]

where \( \Omega \) is the unit cell volume. In Ref. 51, this potential was multiplied by a smoothed step function \( f(q) = \exp[-q/q_c]^9 \) to reduce spurious oscillations in \( v_{mod}(q) \) and to ensure rapid decay of \( v_{mod}(q) \) at large wave-vectors. Those oscillations are caused by the discontinuity of the real-space potential at the core radius. Here, the parameter \( q_c \) was chosen as suggested in Ref. 51, namely, to equal the second zero position of \( v_{mod}(q) \).

To obtain counterparts of the local potentials \( v_{GGA,spd1} \) and \( v_{LDA,spd1} \), Eq. (21) of the simple modified Heine-Abarenkov model form, the two parameters, \( A \) and \( r_c \), were determined by minimization of \( \int dr |v_{GGA,mod1}(r) - v_{mod1}(r)|^2 \). This yields \( A = 0.45499 \) Hartree, \( r_c = 2.2261 \) Bohr, \( q_c = 2.86 \) Bohr\(^{-1} \) for \( v_{GGA,mod1} \), and \( A = 0.45376 \) Hartree, \( r_c = 1.8818 \) Bohr, \( q_c = 2.94 \) Bohr\(^{-1} \) for \( v_{LDA,mod1} \). The local potentials \( v_{GGA,spd1} \) and \( v_{LDA,spd1} \) in reciprocal space are multiplied by the same smoothed step function \( f(q) \) with \( q_c \) values equal to 2.95 and 3.25 Bohr\(^{-1} \) respectively.

Figure 6 shows the \( v_{GGA,spd1} \) LPP in real space in comparison with the NLPP \( l \) channels, along with the two pseudo-densities which result. Figure 7 shows the \( v_{GGA,spd1} \) and \( v_{GGA,mod1} \) LPPs in reciprocal space.

2. KS Tests of Local Pseudo-potentials

Kohn-Sham calculations with the LPPs were performed using the ABINIT PW code\(^{64}\) with PZ and PBE exchange-correlation functionals. We also used SIESTA with the same exchange-correlation functionals and a 2s\(^2\)2p\(^2\) numerical atomic orbital basis set (8 NAO per atom). Table IV shows the equilibrium lattice constants and bulk moduli for the various LPPs. Those results are compared to the Kohn-Sham calculations performed with the non-local projector augmented wave (PAW) scheme.
Reciprocal space local pseudo-potentials for Li: \( v_{\text{GGA,spd1}} \) and \( v_{\text{GGA,mod1}} \).

Real space pseudo-potentials for Li: \( v_{\text{GGA,spd1}} \) and \( v_{\text{GGA,mod1}} \).

The lattice constant and bulk modulus reported in Table IV were obtained by fitting the calculated total energies per cell to the stabilized jellium model equation of state (SJEOS). All the local PPs reproduce the PAW results rather closely for both lattice constant and bulk modulus. The bulk moduli calculated using NAO orbitals and norm conserving TM pseudo-potentials are slightly larger than the PAW plane wave results.

As a check against an all-electron localized-orbital calculation, we did high-quality GTO-basis KS calculations (10s6p3d basis) with the GTOFF code\(^{65}\). For \( E_{\text{xc,LDA}} \) and \( E_{\text{xc,PBE}} \), we obtained optimized bcc Li lattice parameters of 3.360 and 3.435 Å, respectively, essentially the same as from the SIESTA NAO and plane wave PAW calculations.

### Table IV: Kohn-Sham lattice constant (Å) and bulk modulus (GPa) for bcc Li calculated using VASP PW PAW schemes, ABINIT PW PAW and local pseudo-potentials, SIESTA non-local Troullier-Martins and local pseudo-potentials. Orbital-free calculations used \( T_{\text{mcGGA,PBE}}, T_{\text{TF+1/vW}}, T_{\text{OF-DFT}} \), and local pseudo-potentials \( v_{\text{LDA,spd1}}, v_{\text{GGA,spd1}}, v_{\text{LDA,mod1}}, v_{\text{GGA,mod1}} \).

| Method                  | LDA | GGA |
|-------------------------|-----|-----|
|                         | \( a \) | \( B \) | \( a \) | \( B \) |
| Kohn-Sham               |     |     |     |     |
| PW (VASP) PAW           | 3.37 | 15.0 | 3.45 | 13.7 |
| PW (ABINIT) PAW         | 3.37 | 15.1 | 3.44 | 13.9 |
| NAO (SIESTA) TM         | 3.37 | 15.6 | 3.44 | 14.3 |

| PW (ABINIT) spd1\(^a\) | 3.37 | 14.8 | 3.44 | 13.8 |
| NAO (SIESTA) mod1\(^b\) | 3.38 | 14.9 | 3.44 | 13.9 |
| Kohn-Sham               |     |     |     |     |
| PW (ABINIT) mod1\(^b\) | 3.37 | 14.8 | 3.44 | 13.9 |
| NAO (SIESTA) mod1\(^b\) | 3.38 | 14.9 | 3.44 | 13.9 |
| OF-DFT                  |     |     |     |     |
| mcGGA                   | 3.37 | 16.2 | 3.43 | 15.4 |
| TF+1/vW                 | 3.37 | 16.0 | 3.43 | 15.2 |
| GGA                     | 3.37 | 11.8 | 3.46 | 11.8 |
| TF+1/9vW                | 3.37 | 11.4 | 3.46 | 11.4 |

\(^a\)Real space potential defined by Eq. (20) (see text for details).

\(^b\)Real space potential defined by Eq. (21) (see text for details).

\(^c\)Reciprocal space potential defined by Fourier-Bessel transform of local potential Eq. (20) and multiplied by \( f(q) \) function (see text for details).

\(^d\)Reciprocal space potential defined by Eq. (22) multiplied by \( f(q) \) function (see text for details).

### B. Pseudo-potential OF-DFT Tests

#### 1. OF-DFT Comparison for bcc Li

For the OF-DFT bcc Li studies, we used a 128-atom supercell in PROFESS with the \( v_{\text{spd1}}, v_{\text{mod1}} \) LPPs just described and both \( E_{\text{xc,LDA}} \) and \( E_{\text{xc,GGA}} \). We did the PROFESS calculations for the \( T_{\text{TF}}, T_{\text{TF+1/vW}}, T_{\text{OF-DFT}} \), and \( T_{\text{mcGGA,PBE}} \) functionals. The computed \( E_{\text{tot}}/\text{atom} \) values are plotted as a function of bcc lattice constant in Fig. 8.

One sees that, as might be expected, the pure TF+XC model fails to bind. The pairing of other functionals,
local PAW PBE pseudo-potentials (Vasp) E bcc Li. OF-DFT results for FIG. 8: Energy per atom vs. lattice constant for bulk calculations with 128-atom supercell, vT Martin PPs with PBE exchange-correlation, 2s (8 NAO per atom) (Siesta) which we have discussed already, reappears. TFvW,α = 1 pairs with TmcGGA,PBE2, and TTFvW,α = 1/9 pairs with TGGA,PBE−TW. The former pair gives a better description of both the lattice constant and bulk modulus than the latter pair. The computed equilibrium lattice constants and bulk moduli are shown in Table IV.

The equilibrium lattice constants predicted by the OF-DFT calculations with vspd1 LPPs agree well with the KS PAW results. When the vmod1 model pseudo-potential is used, the lattice constant from the OF-DFT calculations with TGGA,PBE−TW and TTFvW,α = 1/9 is an over-estimate of about 1 % for both LDA and GGA XC functionals. This pair of OFKE functionals also predicts low bulk modulus values, again for both LDA and GGA XC cases. The mcGGA and TF+vW KE functionals do very well for the lattice parameter and slightly overestimate the bulk modulus value.

2. OF-DFT Comparison for fcc Al

The utility of existing LPPs for OFDFT calculations obviously is a pertinent issue. To explore that, we considered bulk Al. The model LPP in the form of Eq. 22 with parameters from Goodwin, Needs, and Heine21 was used in OF-DFT calculations. As before, this was done with the five OF-KE functionals, but here only in combination with the PBE GGA XC functional. Fig. 9 shows PROFESS results for a 4-atom fcc cell compared with conventional KS results obtained with VASP in the same cell with a $5 \times 5 \times 5$ k-mesh calculation. The GGA and mcGGA KE functionals introduce numerical instability at expanded geometry. Aside from that, one again observes the same pairing of KE functionals as before. The TGGA,PBE−TW and TTFvW,α = 1/9 functionals do not produce detectable minima. The TmcGGA,PBE2 and TTFvW,α = 1 pair predict equilibrium lattice constants ($a = 4.05$ and $4.06$ Å correspondingly), very close to the KS results ($a = 4.05$ and $4.09$ Å for PAW VASP and NAO DZP SIESTA calculations respectively). However, the shape of the two OF-DFT energy curves differs perceptibly from the KS results. In particular, the OF-DFT functionals predict a softer solid.

V. SUMMARY DISCUSSION

Several clear results emerge from this study. First, use of standard KS codes to solve the OF-DFT Euler equation as a modified KS eigenvalue problem is problematic at best. At least for the all-electron case, it seems implausible as a productive route to routine OF-DFT calculations. One could speculate that a better-behaved one-point approximate OFKE functional than mcGGA might not be such a challenge to standard KS algorithms. The repulsive nature of even the exact $v_9$ (recall Fig. 2) makes that outcome seem rather doubtful.

Second, even if a particular approximate one-point OFKE functional has singular behavior, it is possible that such a functional can deliver physically realistic results. Those results can be obtained with a sufficiently refined direct Euler-Lagrange solution of the effective KS equation, Eq. 2. Thus, we are able to extract useful, self-consistent solutions for the recently developed simple mcGGA OFKE functional as well as the Tran-
Wesolowski GGA. These solutions enable understanding of the consequence of the singular behavior of their respective Pauli potentials. The Tran-Wesolowski GGA has attractive singularities which cause strong over-estimates of the self-consistent density near the nuclear sites. In contrast, the properly positive mcGGA OFKE Pauli potential has positive singularities near the nuclei and the density is underestimated there.

Third, we have presented a procedure for developing a local pseudo-potential for OFDFT calculations by doing a multi-channel weighting of a corresponding non-local pseudo-potential. The weighting is determined by KS calculations with the LPP such that the equilibrium non-LPP lattice parameter is reproduced. We showed that this yields a very good LPP. A remaining challenge for the OFDFT agenda is to construct a good LPP from an existing non-LPP without appeal to any bulk or aggregate system KS calculations.

Fourth, once a suitable local pseudo-potential procedure is defined, the progress made on computational solution of the minimization problem for two-point OFKE approximations can be appropriated directly for use with one-point OFKE approximations. Even so, we do observe numerical instabilities in the case of the mcGGA and GGA OFKE functionals.
