Stochastic Load Balancing on Unrelated Machines

Anupam Gupta∗ Amit Kumar† Viswanath Nagarajan‡ Xiangkun Shen‡

Abstract

We consider the problem of makespan minimization on unrelated machines when job sizes are stochastic. The goal is to find a fixed assignment of jobs to machines, to minimize the expected value of the maximum load over all the machines. For the identical machines special case when the size of a job is the same across all machines, a constant-factor approximation algorithm has long been known. Our main result is the first constant-factor approximation algorithm for the general case of unrelated machines. This is achieved by (i) formulating a lower bound using an exponential-size linear program that is efficiently computable, and (ii) rounding this linear program while satisfying only a specific subset of the constraints that still suffice to bound the expected makespan. We also consider two generalizations. The first is the budgeted makespan minimization problem, where the goal is to minimize the expected makespan subject to scheduling a target number (or reward) of jobs. We extend our main result to obtain a constant-factor approximation algorithm for this problem. The second problem involves $q$-norm objectives, where we want to minimize the expected $q$-norm of the machine loads. Here we give an $O(q/\log q)$-approximation algorithm, which is a constant-factor approximation for any fixed $q$.

1 Introduction

We consider the problem of scheduling jobs on machines to minimize the maximum load (i.e., the problem of makespan minimization). This is a classic NP-hard problem, with Graham’s list scheduling algorithm for the identical machines being one of the earliest approximation algorithms known. If the job sizes are deterministic, the problem is fairly well-understood, with PTASes for the identical [6] and related machines cases [7], and a constant-factor approximation and APX-hardness [16, 25] for the unrelated machines case. Given we understand the basic problem well, it is natural to consider settings which are less stylized, and one step closer to modeling real-world scenarios: what can we do if there is uncertainty in the job sizes?

We take a stochastic optimization approach where the job sizes are random variables with known distributions. In particular, the size of each job $j$ on machine $i$ is given by a random variable $X_{ij}$. Throughout this paper we assume that the sizes of different jobs are independent of each other. Given just this information, an algorithm has to assign these jobs to machines, say resulting in jobs $J_i$ being assigned to each machine $i$. The expected makespan of this assignment is

$$E \left[ \max_{i=1}^{m} \sum_{j \in J_i} X_{ij} \right],$$

where $m$ denotes the number of machines. The goal for the algorithm is to minimize this expected makespan. Observe that the entire assignment of jobs to machines is done up-front without knowledge of the actual outcomes of the random variables, and hence there is no adaptivity in this problem.

Such stochastic load-balancing problems are common in real-world systems where the job sizes are indeed not known, but given the large amounts of data, one can generate reasonable estimates for the distribution. Moreover static (non-adaptive) assignments are preferable in many applications as they are easier to implement.

Inspired by work on scheduling and routing problems in several communities, Kleinberg, Rabani, and Tardos first posed the problem of approximating the expected makespan in 1997 [14]. They gave a constant-factor approximation for the identical machines case, i.e., for the case where for each job $j$, the sizes $X_{ij} = X_{i'j}$ for all $i, i' \in [m]$. A key concept in their result was the effective size of a random variable (due to Hui [8]) which is a suitably scaled logarithm of the moment generating function. This effective size (denoted $\beta_m$) depended crucially on the number $m$ of machines. Roughly speaking, the algorithm in [14] solved the deterministic makespan minimization problem by using the effective size $\beta_m(X_j)$ of each job $j$ as its deterministic size. The main part of their analysis involved proving that the resulting schedule also has small expected makespan when viewed as a solution to the stochastic problem. See Section 2 for a more detailed discussion.

Later, Goel and Indyk [4] gave better approximation ratios for special classes of job size distributions, again for identical machines. Despite these improvements and refined understanding of the identical machines case, the above stochastic load-balancing problem has remained open, even for the related machines setting. Recall that related machines refers to the case where each machine $i$ has a speed $s_i$, and the sizes for each job $j$ satisfy $X_{ij} s_i = X_{i'j} s_{i'}$ for all $i, i' \in [m]$.

1.1 Results and Techniques

Our main result is:

**Theorem 1.** There is an $O(1)$-approximation algorithm for the problem of finding an assignment to minimize the expected makespan on unrelated machines.

Our work naturally builds on the edifice of [14]. However, we need several new ideas to achieve this. As mentioned above, the prior result for identical machines used the notion of effective size, which depends on the number $m$ of machines available. When machines are not identical, consider just the “restricted assignment” setting where each job needs to choose from a specific subset of machines: here it is not even clear how to define the effective size of each job. Instead of working with a single deterministic value as the effective size of any random variable $X_{ij}$, we use all the $\beta_k(X_{ij})$ values for $k = 1, 2, \cdots m$.

Then we show that in an optimal solution, for every $k$-subset of machines, the total $\beta_k$ effective size of jobs assigned to those machines is at most some bound depending on $k$. Such a property for $k = m$ was also used in the algorithm for identical machines. We then formulate a linear program (LP) relaxation that enforces such a “volume” constraint for every subset of machines. Although our LP relaxation has an exponential number of constraints, it can be solved in polynomial time using the ellipsoid algorithm and a suitable separation oracle.

Finally, given an optimal solution to this LP, we show how to carefully choose the right parameter for effective size of each job and use it to build an approximately optimal schedule. Although our LP relaxation has an exponential number of constraints (and it seems difficult to preserve them all), we show that it suffices to satisfy a small subset of these constraints in the integral solution.
Roughly, our rounding algorithm uses the LP solution to identify the “correct” deterministic size for each job and then applies an existing algorithm for deterministic scheduling [25].

**Budgeted Makespan Minimization.** In this problem, each job \( j \) has a reward \( r_j \) (having no relationship to other parameters such as its size), and we are given a target reward value \( R \). The goal is to assign some subset \( S \subseteq [n] \) of jobs whose total reward \( \sum_{j \in S} r_j \) is at least \( R \), and to minimize the expected makespan of this assignment. Clearly, this generalizes the basic makespan minimization problem (by setting all rewards to one and the target \( R = n \)).

**Theorem 2.** There is an \( O(1) \)-approximation algorithm for the budgeted makespan minimization problem on unrelated machines.

To solve this, we extend the ideas for expected makespan scheduling to include an extra constraint about high reward. We again write a similar LP relaxation. Rounding this LP requires some additional ideas on top of those in Theorem 1. The new ingredient is that we need to round solutions to an assignment LP with two linear constraints. To do this without violating the budget, we utilize a “reduction” from the Generalized Assignment Problem to bipartite matching [25] as well as certain adjacency properties of the bipartite matching polytope [2].

**Minimizing \( \ell_q \) Norms.** Finally, we consider the problem of stochastic load balancing under \( \ell_q \) norms. Note that given some assignment, we can denote the “load” on machine \( i \) by \( L_i := \sum_{j \in J_i} X_{ij} \), and the “load vector” by \( L = (L_1, L_2, \ldots, L_m) \). The expected makespan minimization problem is to minimize \( \mathbb{E}[\|L\|_\infty] \). The \( q \)-norm minimization problem is the following: find an assignment of jobs to machines to minimize

\[
\mathbb{E}[\|L\|_q] = \mathbb{E}\left[ \left( \sum_{i=1}^{m} \left( \sum_{j \in J_i} X_{ij} \right)^q \right)^{1/q} \right].
\]

Our result for this setting is the following:

**Theorem 3.** There is an \( O\left( \frac{q}{\log q} \right) \)-approximation algorithm for the stochastic \( q \)-norm minimization problem on unrelated machines.

The main idea here is to reduce this problem to a suitable instance of deterministic \( q \)-norm minimization with additional side constraints. We then show that existing techniques for deterministic \( q \)-norm minimization [1] can be extended to obtain a constant-factor approximation for our generalization as well. We also need to use/prove some probabilistic inequalities to relate the deterministic sub-problem to the stochastic problem. We note that using general polynomial concentration inequalities [13, 24] only yields an approximation ratio that is exponential in \( q \). We obtain a much better \( O(q/\log q) \)-approximation factor by utilizing the specific form of the norm function. Specifically, we use the convexity of norms, a second-moment calculation and a concentration bound [11] for the \( q^{th} \) moment of sums of independent random variables.

We note that Theorem 3 implies a constant-factor approximation for any fixed \( q \geq 1 \). However, our techniques do not extend directly to provide an \( O(1) \)-approximation algorithms for all \( q \)-norms.

### 1.2 Other Related Work

Goel and Indyk [4] considered the stochastic load balancing problem on identical machines (same setting as [14]) but for specific job-size distributions. For Poisson distributions they showed that Graham’s algorithm achieves a 2-approximation, and for Exponential distributions they obtained a PTAS. Kleinberg et al. [14] also considered stochastic versions of knapsack and bin-packing: given
an overflow probability $p$, a feasible single-bin packing here corresponds to any subset of jobs such that their total size exceeds one with probability at most $p$. [4] gave better/simpler algorithms for these problems, under special distributions.

Recently, Deshpande and Li [17], and Li and Yuan [18] considered several combinatorial optimization problems including shortest paths, minimum spanning trees, where elements have weights (which are random variables), and one would like to find a solution (i.e. a subset of elements) whose expected utility is maximized. These results also apply to the stochastic versions of knapsack and bin-packing from [14] and yield bicriteria approximations. The main technique here is a clever discretization of probability distributions. However, to the best of our knowledge, such an approach is not applicable to stochastic load balancing.

Stochastic scheduling has been studied in many different contexts, by different fields (see, e.g., [22]). The work on approximation algorithms for these problems is more recent; see [20] for some early work and many references. In this paper we consider the (non-adaptive) fixed assignment model, where jobs have to be assigned to machines up-front, and then the randomness is revealed. Hence, there is no element of adaptivity in these problems. This makes them suitable for settings where the decisions cannot be instantaneously implemented (e.g., for virtual circuit routing, or assigning customers to physically well-separated warehouses). A number of papers [20, 19, 10, 5] have considered scheduling problems in the adaptive setting, where assignments are done online and the assignment for a job may depend on the state of the system at the time of its assignment. See Section 2 for a comparison of adaptive and non-adaptive settings in the load balancing problem.

Very recently (after the preliminary version of this paper appeared), Molinaro [21] obtained an $O(1)$-approximation algorithm for the stochastic $q$-norm problem for all $q \geq 1$, which improves over Theorem 3. In addition to the techniques in our paper, the main idea in [21] is to use a different notion of effective size, based on the L-function method [15]. We still present our algorithm/analysis for Theorem 3 as it is conceptually simpler and may provide better constant factors for small $q$.

## 2 Preliminaries

The stochastic load balancing problem (STOCMAKESPAN) involves assigning $n$ jobs to $m$ machines. For each job $j \in [n]$ and machine $i \in [m]$, we are given a random variable $X_{ij}$ which denotes the processing time (size) of job $j$ on machine $i$. We assume that the random variables $X_{ij}, X_{i'j'}$ are independent when $j \neq j'$ (the size of job $j$ on different machines may be correlated). We assume access to the distribution of these random variables via some (succinct) representation. A solution is a partition $\{J_i\}_{i=1}^m$ of the jobs among the machines, such that $J_i \subseteq [n]$ is the subset of jobs assigned to machine $i \in [m]$. The expected makespan of this solution is $\mathbb{E} \left[ \max_{i=1}^m \sum_{j \in J_i} X_{ij} \right]$. Our goal is to find a solution which minimizes the expected makespan.

The deterministic load balancing problem is known to be $NP$-hard even on identical machines. The stochastic version introduces considerable additional complications. For example, [14] showed that given Bernoulli random variables $\{X_j\}$, it is $\#P$-hard to compute the overflow probability, i.e. $\text{Pr}[\sum_j X_j > 1]$. We now show that it is $\#P$-hard even to compute the objective value of a given assignment in the identical machines setting.

**Theorem 4.** It is $\#P$-hard to compute the expected makespan of a given assignment for stochastic load balancing on identical machines.

**Proof:** We will reduce the overflow probability problem [14] to this problem. Formally, an instance of the overflow probability problem is: given Bernoulli trials $Y_1, \cdots, Y_n$, where each $Y_j$ has size $s_j$ with probability $q_j$, compute $\text{Pr} \left( \sum_{j=1}^n Y_j > 1 \right)$. 

4
For an instance of the overflow probability problem, we construct two instances of stochastic load balancing with Bernoulli jobs and \( m = 2 \) machines. For each \( Y_j \) of type \((q_j, s_j)\), we create random variable \( X_j \) of type \((q_j, \bar{s}_j)\) where \( \bar{s}_j = Bs_j \) and \( B \) is a scalar such that \( \bar{s}_j \in \mathbb{Z}, \forall j \). We also create two additional random variable: \( Z_B \) of type \((1, B)\) and \( Z_{B+1} \) of type \((1, B + 1)\). Then the first instance contains two machines and jobs \( X_1, \ldots, X_n \) and \( Z_B \). The second one contains two machines and jobs \( X_1, \ldots, X_n \) and \( Z_{B+1} \). We want to compute the expected makespan of the following assignment for both instances: assign jobs \( X_1, \ldots, X_n \) to machine 1 and the remaining job to machine 2. We use \( Obj_B \) and \( Obj_{B+1} \) to denote the expected makespans of the two instances. Then we have

\[
Obj_B = \mathbb{E} \left[ \max \left\{ B, \sum_{j=1}^{n} X_j \right\} \right] = B + \mathbb{E} \left[ \max \left\{ 0, \sum_{j=1}^{n} X_j - B \right\} \right] \\
= B + \sum_{t \geq B+1} \Pr \left( \sum_{j=1}^{n} X_j \geq t \right).
\]

Similarly,

\[
Obj_{B+1} = B + 1 + \sum_{t \geq B+2} \Pr \left( \sum_{j=1}^{n} X_j \geq t \right).
\]

It follows that \( \Pr \left( \sum_{j=1}^{n} Y_j > 1 \right) = \Pr \left( \sum_{j=1}^{n} X_j \geq B + 1 \right) = Obj_B - Obj_{B+1} + 1 \). Therefore, it is \#P-hard to compute the expected makespan of a given assignment.

**Scaling the optimal value.** Using a standard binary search approach, in order to obtain an \( O(1) \)-approximation algorithm for \textsc{StocMakespan} it suffices to solve the following problem. Given a bound \( M > 0 \), either find a solution with expected makespan \( O(M) \) or establish that the optimal makespan is \( \Omega(M) \). Moreover, by scaling down all random variables by factor \( M \), we may assume that \( M = 1 \).

We now provide some definitions and background results that will be used extensively in the rest of the paper.

### 2.1 Truncated and Exceptional Random Variables

It is convenient to divide each random variable \( X_{ij} \) into its *truncated* and *exceptional* parts, defined below:

- \( X'_{ij} := X_{ij} \cdot 1_{\{X_{ij} \leq 1\}} \) (called the *truncated* part), and
- \( X''_{ij} := X_{ij} \cdot 1_{\{X_{ij} > 1\}} \) (called the *exceptional* part).

The reason for doing this is that these two kinds of random variables (r.v.s) behave very differently with respect to the expected makespan. It turns out that expectation is a good notion of “deterministic” size for exceptional r.v.s, whereas one needs a more nuanced notion (called effective size) for truncated r.v.s: this is discussed in detail below.

We will use the following result (which follows from [14]) to handle exceptional r.v.s.

**Lemma 1** (Exceptional Items Lower Bound). Let \( X_1, X_2, \ldots, X_t \) be non-negative discrete random variables each taking value zero or at least \( L \). If \( \sum_j \mathbb{E}[X_j] \geq L \) then \( \mathbb{E}[\max_j X_j] \geq L/2 \).
Proof: The Bernoulli case of this lemma appears as [14, Lemma 3.3]. The extension to the general case is easy. For each \( X_j \), introduce independent Bernoulli random variables \( \{X_{jk}\} \) where each \( X_{jk} \) corresponds to a particular instantiation \( s_{jk} \) of \( X_j \), i.e. \( \Pr[X_{jk} = s_{jk}] = \Pr[X_j = s_{jk}] \). Note that \( \max_k X_{jk} \) is stochastically dominated by \( X_j \); so \( \mathbb{E}[\max_j X_j] \geq \mathbb{E}[\max_j X_{jk}] \). Moreover, \( \sum_{jk} \mathbb{E}[X_{jk}] = \sum_j \mathbb{E}[X_j] \geq L \). So the lemma follows from the Bernoulli case. \( \square \)

2.2 Effective Size and Its Properties

As is often the case for stochastic optimization problems, we want to find some deterministic quantity that is a good surrogate for each random variable, and then use this deterministic surrogate instead of the actual random variable. Here, we use the effective size, which is based on the logarithm of the (exponential) moment generating function [8,12,3].

Definition 1 (Effective Size). For any random variable \( X \) and integer \( k \geq 2 \), define

\[
\beta_k(X) := \frac{1}{\log k} \cdot \log \mathbb{E} \left[ e^{(\log k) \cdot X} \right].
\]

Also define \( \beta_1(X) := \mathbb{E}[X] \).

To get some intuition for this, consider independent r.v.s \( Y_1, \ldots, Y_n \). Then if \( \sum_i \beta_k(Y_i) \leq b \),

\[
\Pr[\sum_i Y_i \geq c] = \Pr[e^{\log k \sum_i Y_i} \geq e^{(\log k) c}] \leq \frac{\mathbb{E}[e^{\log k \sum_i Y_i}]}{e^{(\log k) c}} = \prod_i \mathbb{E}[e^{(\log k) Y_i}] e^{(\log k) c}
\]

Taking logarithms, we get

\[
\log \Pr[\sum_i Y_i \geq c] \leq \log k \cdot \left[ \sum_i \beta_k(Y_i) - c \right] \quad \Rightarrow \quad \Pr[\sum_i Y_i \geq c] \leq \frac{1}{k^{c-b}}.
\]

The above calculation, very reminiscent of the standard Chernoff bound argument, can be summarized by the following lemma (shown, e.g., in [3]).

Lemma 2 (Upper Bound). For independent random variables \( Y_1, \ldots, Y_n \), if \( \sum_i \beta_k(Y_i) \leq b \) then \( \Pr[\sum_i Y_i \geq c] \leq (1/k)^{c-b} \).

The usefulness of this definition comes from a partial converse, proved in [14]:

Lemma 3 (Lower Bound). Consider independent Bernoulli random variables \( Y_1, \ldots, Y_n \) where each \( Y_i \) has non-zero size \( s_i \) being an inverse power of 2 such that \( 1/(\log k) \leq s_i \leq 1 \). If \( \sum_i \beta_k(Y_i) \geq 7 \) then \( \Pr[\sum_i Y_i \geq 1] \geq 1/k \).

Outline of the algorithm for identical machines In using the effective size, it is important to set the parameter \( k \) carefully. For identical machines [14] used \( k = m \) the total number of machines. Using the facts discussed above, we can now outline their algorithm/analysis (assuming that all r.v.s are truncated). If the total effective size is at most (say) 20m then the jobs can be assigned to \( m \) machines in a way that the effective-size load on each machine is at most 21. By Lemma 2 and union bound, it follows that the probability of some machine exceeding load 23 is at most \( m \cdot (1/m)^2 = 1/m \). On the other hand, if the total effective size is more than 20m then even if the solution was to balance these evenly, each machine would have effective-size load at least 7. By Lemma 3 it follows that the load on each machine exceeds one with probability 1/m, and so with \( m \) machines this gives a certificate that the makespan is \( \Omega(1) \).
Challenges with unrelated machines For unrelated machines, this kind of argument breaks down even in the restricted-assignment setting where each job can go on only some subset of machines. This is because we don’t know what probability of success we want to aim for. For example, even if the machines had the same speed, but there were jobs that could go only on $\sqrt{m}$ of these machines, and others could go on the remaining $m - \sqrt{m}$ of them, we would want their effective sizes to be quite different. (See the example below.) And once we go to general unrelated machines, it is not clear if any combinatorial argument would suffice. Instead, we propose an LP-based lower bound that enforces one such constraint (involving effective sizes) for every subset of machines.

Bad Example for Simpler Effective Sizes For stochastic load balancing on identical machines [14] showed that any algorithm which maps each r.v. to a single real value and performs load balancing on these (deterministic) values incurs an $\Omega(\frac{\log m}{\log \log m})$ approximation ratio. This is precisely the reason they introduced the notion of truncated and exceptional r.v.s. For truncated r.v.s, their algorithm showed that it suffices to use $\beta_m(X_j)$ as the deterministic value and perform load balancing with respect to these. Exceptional r.v.s were handled separately (in a simpler manner). For unrelated machines, we now provide an example which shows that even when all r.v.s are truncated, any algorithm which maps each r.v. to a single real value must incur approximation ratio at least $\Omega(\frac{\log m}{\log \log m})$. This suggests that more work is needed to define the “right” effective sizes in the unrelated machine setting.

There are $m$ machines and $m + \sqrt{m}$ jobs. Each r.v. $X_j$ takes value 1 with probability $\frac{1}{\sqrt{m}}$ (and 0 otherwise). The first $\sqrt{m}$ jobs can only be assigned to machine 1. The remaining $m$ jobs can be assigned to any machine. Note that $OPT \approx 1 + 1/e$ which is obtained by assigning the first $\sqrt{m}$ jobs to machine 1, and each of the remaining $m$ jobs in a one-to-one manner. Given any fixed mapping of r.v.s to reals, note that all the $X_j$ get the same value (say $\theta$) as they are identically distributed. So the optimal value of the corresponding (deterministic) load balancing instance is $\sqrt{m} \cdot \theta$. Hence the solution which maps $\sqrt{m}$ jobs to each of the first $1 + \sqrt{m}$ machines is an optimal solution to the deterministic instance. However, the expected makespan of this assignment is $\Omega(\frac{\log m}{\log \log m})$.

We will use the following specific result in dealing with truncated r.v.s.

**Lemma 4** (Truncated Items Lower Bound). Let $X_1, X_2, \ldots, X_n$ be independent $[0, 1]$ r.v.s, and $\{J_i\}_{i=1}^n$ be any partition of $[n]$. If $\sum_{j=1}^n \beta_m(X_j) \geq 17m$ then $E\left[\max_{i=1}^n \sum_{j \in J_i} X_j\right] = \Omega(1)$.

**Proof:** This is a slight extension of [14] Lemma 3.4, with two main differences. Firstly, we want to consider arbitrary instead of just Bernoulli r.v.s. Secondly, we use a different definition of effective size than they do. We provide the details below for completeness.

At the loss of factor two in the makespan, we may assume (by rounding down) that the only values taken by the $X_j$ r.v.s are inverse powers of 2. For each r.v. $X_j$, applying [14] Lemma 3.10 yields independent Bernoulli random variables $\{Y_{jk}\}$ so that for each power-of-2 value $s$ we have

$$\Pr[X_j = s] = \Pr[s \leq \sum_k Y_{jk} < 2s].$$

Let $\overline{X_j} = \sum_k Y_{jk}$, so $X_j \leq \overline{X_j} < 2 \cdot X_j$ and $\beta_m(\overline{X_j}) = \sum_k \beta_m(Y_{jk})$. Note also that $\beta_m(\overline{X_j}) \geq \beta_m(X_j)$. Hence $\sum_{jk} \beta_m(Y_{jk}) \geq \sum_{j=1}^n \beta_m(X_j) \geq 17m$. Now, consider the assignment of the $Y_{jk}$ r.v.s corresponding to $\{J_i\}_{i=1}^m$, i.e. for each $i \in [m]$ and $j \in J_i$, all the $\{Y_{jk}\}$ r.v.s are assigned to part $i$. Then applying [14] Lemma 3.4 which works for Bernoulli r.v.s, we obtain
\[
\mathbb{E} \left[ \max_{i=1}^{m} \sum_{j \in J_i} \sum_{k} Y_{jk} \right] = \Omega(1). \quad \text{Observe that the above lemma used a different notion of effective size: } \beta'_{1/m}(X) := \min \{ s, sqm^{s} \} \text{ for any Bernoulli r.v. } X \text{ taking value } s \text{ with probability } q. \]

However, as shown in \cite[Prop 2.5]{14}, \( \beta_{m}(X) \leq \beta'_{1/m}(X) \) which implies the version that we use here.

Finally, using \( X_{j} > \frac{1}{2}X_{j} \) we obtain

\[
\mathbb{E} \left[ \max_{i=1}^{m} \sum_{j \in J_i} X_{j} \right] \geq \frac{1}{2} \mathbb{E} \left[ \max_{i=1}^{m} \sum_{j \in J_i} X_{j} \right] = \frac{1}{2} \mathbb{E} \left[ \max_{i=1}^{m} \sum_{j \in J_i} \sum_{k} Y_{jk} \right] = \Omega(1),
\]

which completes the proof. \qed

2.3 Non-Adaptive and Adaptive Solutions

We note that our model involves computing an assignment that is fixed \textit{a priori}, before observing any random instantiations. Such solutions are commonly called non-adaptive. A different class of solutions (called adaptive) involves assigning jobs to machines sequentially, observing the random instantiation of each assigned job. Designing approximation algorithms for the adaptive and non-adaptive models are mutually incomparable. For makespan minimization on identical machines, Graham’s list scheduling already gives a trivial 2-approximation algorithm in the adaptive case (in fact, it is 2-approximate on an per-instance basis), whereas the non-adaptive case is quite non-trivial and the Kleinberg et al. \cite{14} result was the first constant-factor approximation.

We now provide an instance with identical machines where there is an \( \Omega(\frac{\log m}{\log \log m}) \) gap between the best non-adaptive assignment (the setting of this paper) and the best adaptive assignment. The instance consists of \( m \) machines and \( n = m^2 \) jobs each of which is identically distributed taking size 1 with probability \( \frac{1}{m} \) (and 0 otherwise). Recall that Graham’s algorithm considers jobs in any order and places each job on the least loaded machine. It follows that the expected makespan of this adaptive policy is at most \( 1 + \frac{1}{m} \cdot \mathbb{E}[X_{j}] = 2 \). On the other hand, the best static assignment has expected makespan \( \Omega(\frac{\log m}{\log \log m}) \), which is obtained by assigning \( m \) jobs to each machine.

2.4 Useful Probabilistic Inequalities

\textbf{Theorem 5 (Jensen’s Inequality).} Let \( X_{1}, X_{2}, \ldots, X_{t} \) be random variables and \( f(x_{1}, \cdots, x_{t}) \) any convex function. Then

\[
\mathbb{E}[f(X_{1}, \cdots, X_{t})] \geq f(\mathbb{E}[X_{1}], \cdots, \mathbb{E}[X_{t}]).
\]

\textbf{Theorem 6 (Rosenthal Inequality).} \cite{23,11,15} Let \( X_{1}, X_{2}, \ldots, X_{t} \) be independent non-negative random variables. Let \( q \geq 1 \) and \( K = \Theta(q/\log q) \). Then it is the case that

\[
\mathbb{E} \left[ \left( \sum_{j} X_{j} \right)^{q} \right] \leq K^{q} \cdot \max \left\{ \left( \sum_{j} \mathbb{E}[X_{j}] \right)^{q}, \sum_{j} \mathbb{E}[X_{j}^{q}] \right\}.
\]

3 MakeSpan Minimization

The main result of this section is:

\textbf{Theorem 1.} There is an \( O(1) \)-approximation algorithm for the problem of finding an assignment to minimize the expected makespan on unrelated machines.
Using a binary search scheme and scaling, it suffices to find one of the following:

(i) **upper bound:** a solution with expected makespan at most $O(1)$, or

(ii) **lower bound:** a certificate that the optimal expected makespan is more than one.

Hence, we assume that the optimal solution for the instance has unit expected makespan, and try to find a solution with expected makespan $b = O(1)$; if we fail we output a lower bound certificate.

At a high level, the ideas we use are the following: first, in §3.1 we show a more involved lower bound based on the effective sizes of jobs assigned to every subset of machines. This is captured using an exponentially-sized LP which is solvable in polynomial time. Then, to show that this lower bound is a good one, we give a new rounding algorithm for this LP in §3.2 to get an expected makespan within a constant factor of the lower bound.

### 3.1 A New Lower Bound

Our starting point is a more general lower bound on the makespan. The (contrapositive of the) following lemma says that if the effective sizes are large then the expected makespan must be large too. This is much the same spirit as Lemma 3, but for the general setting of unrelated machines.

**Lemma 5** (New Valid Inequalities). Consider any feasible solution that assigns jobs $J_i$ to each machine $i \in [m]$. If the expected makespan $\mathbb{E} \left[ \max_{i=1}^{m} \sum_{j \in J_i} X_{ij} \right] \leq 1$, then

$$
\sum_{i=1}^{m} \sum_{j \in J_i} \mathbb{E}[X''_{ij}] \leq 2, \quad \text{and} \quad (3)
$$

$$
\sum_{i \in K} \sum_{j \in J_i} \beta_k(X'_{ij}) \leq O(1) \cdot k, \quad \text{for all } K \subseteq [m], \text{ where } k = |K|. \quad (4)
$$

**Proof:** The first inequality (3) focuses on the exceptional parts, and loosely follows from the intuition that if the sum of biases of a set of independent coin flips is large (exceeds 2 in this case) then you expect one of them to come up heads. Formally, the proof follows from Lemma 1 applied to $\{X''_{ij} : j \in J_i, i \in [m]\}$.

For the second inequality (4), consider any subset $K \subseteq [m]$ of the machines. Then the total effective size of the jobs assigned to these machines must be small, where now the effective size $\beta_k$ can be measured with parameter $k = |K|$. Formally applying Lemma 4 only to the $k$ machines in $K$ and the truncated random variables $\{X'_{ij} : i \in K, j \in J_i\}$ corresponding to jobs assigned to these machines, we obtain the desired inequality. \(\square\)

Given these valid inequalities, our algorithm now seeks an assignment satisfying (3)–(4). If we fail, the lemma assures us that the expected makespan must be large. On the other hand, if we succeed, such a “good” assignment by itself is not sufficient. The challenge is to show the converse of Lemma 5 i.e., that any assignment satisfying (3)–(4) gives us an expected makespan of $O(1)$.

Indeed, towards this goal, we first write an LP relaxation with an exponential number of constraints, corresponding to (4). We can solve this LP using the ellipsoid method. Then, instead of rounding the fractional solution to satisfy all constraints (which seems very hard), we show how to satisfy only a carefully chosen subset of the constraints (4) so that the expected makespan can still be bounded. Let us first give the LP relaxation.

In the ILP formulation of the above lower bound, we have binary variables $y_{ij}$ to denote the assignment of job $j$ to machine $i$, and fractional variables $z_i(k)$ denote the total load on machine $i$...
in terms of the deterministic effective sizes $\beta_k$. Lemma 3 shows that the following feasibility LP is a valid relaxation:

$$\sum_{i=1}^{m} y_{ij} = 1, \forall j \in [n],$$

$$z_i(k) - \sum_{j=1}^{n} \beta_k(X'_{ij}) \cdot y_{ij} = 0, \forall i \in [m], \forall k = 1, 2, \ldots m,$$

$$\sum_{i=1}^{m} \sum_{j=1}^{n} \mathbb{E}[X''_{ij}] \cdot y_{ij} \leq 2,$$

$$\sum_{i \in K} z_i(k) \leq b \cdot k, \forall K \subseteq [m] \text{ with } |K| = k, \forall k = 1, 2, \ldots m,$$

$$y_{ij}, z_i(k) \geq 0, \forall i, j, k.$$

In the above LP, $b = O(1)$ denotes the constant multiplying $k$ in the right-hand-side of (4).

Although this LP has an exponential number of constraints (because of (8)), we can give an efficient separation oracle. Indeed, consider a candidate solution $(y_{ij}, z_i(k))$, and some integer $k$; suppose we want to verify (8) for sets $K$ with $|K| = k$. We just need to look at the $k$ machines with the highest $z_i(k)$ values and check that the sum of $z_i(k)$ for these machines is at most $bk$. So, using the Ellipsoid method we can assume that we have an optimal solution $(y, z)$ for this LP in polynomial time. We can summarize this in the following proposition:

**Proposition 1** (Lower Bound via LP). The linear program (5)–(9) can be solved in polynomial time. Moreover, if it is infeasible, then the optimal expected makespan is more than 1.

### 3.2 The Rounding

**Intuition.** In order to get some intuition about the rounding algorithm, let us first consider the case when the assignment variables $y_{ij}$ are either 0 or 1, i.e., the LP solution assigns each job integrally to a machine. In order to bound the expected makespan of this solution, let $Z_j$ denote the variable $X_{ij}$, where $j$ is assigned to $i$ by this solution. First consider the exceptional parts $Z''_{ij}$ of the random variables. Constraint (7) implies that $\sum_{j} \mathbb{E}[Z''_{ij}]$ is at most 2. Even if the solution assigns all of these jobs to the same machine, the contribution of these jobs to the expected makespan is at most $\sum_{j} \mathbb{E}[Z''_{ij}]$, and hence at most 2. Thus, we need only worry about the truncated $Z'_j$ variables.

Now for a machine $i$ and integer $k \in [m]$, let $z_i(k)$ denote the sum of the effective sizes $\beta_k(Z'_j)$ for the truncated r.v.s assigned to $i$. We can use Lemma 2 to infer that if $z_i(m) = \sum_{j} \beta_m(Z_j) \leq b$, then the probability that these jobs have total size at most $b + 2$ is at least $1 - 1/m^2$. Therefore, if $z_i(m) \leq b$ for all machines $i \in [m]$, then by a trivial union bound the probability that makespan is more than $b + 2$ is at most $1/m$. Unfortunately, we are not done. All we know from constraint (8) is that the average value of $z_i(m)$ is at most $b$ (the average being taken over the $m$ machines). However, there is a clean solution. It follows that there is at least one machine $i$ for which $z_i(m)$ is at most $b$, and so the expected load on such machines stays $O(1)$ with high probability. Now we can ignore such machines, and look at the residual problem. We are left with $k < m$ machines. We recurse on this sub-problem (and use the constraint (8) for the remaining set of machines). The overall probability that the load exceeds $O(1)$ on any machine can then be bounded by applying a union bound.

Next, we address the fact that $y_{ij}$ may be not be integral. It seems very difficult to round a fractional solution while respecting all the (exponentially many) constraints in (8). Instead, we
observe that the expected makespan analysis (outlined above) only utilizes a linear number of constraints in \( k \), although this subset is not known \textit{a priori}. Moreover, for each machine \( i \), the above analysis only uses \( z_i(k) \) for a \textit{single} value of \( k \) (say \( k_i \)). Therefore, it suffices to find an integral assignment that bounds the load of each machine \( i \) in terms of effective sizes \( \beta_{k_i} \). It turns out that this problem is precisely an instance of the Generalized Assignment Problem (GAP), for which we utilize the algorithm from \cite{25}.

The Rounding Procedure. We now describe the iterative procedure formally. Assume we have an LP solution \( \{y_{ij}\}_{i \in [m], j \in [n]}, \{z_i(k)\}_{i, k \in [m]} \).

1. Initialize \( \ell \leftarrow m, L \leftarrow [m], c_{ij} \leftarrow E[X''_{ij}] \).
2. While (\( \ell > 0 \)) do:
   (a) Set \( L' \leftarrow \{i \in L : z_i(\ell) \leq b\} \). Machines in \( L' \) are said to be in \textit{class} \( \ell \).
   (b) Set \( p_{ij} \leftarrow \beta_{\ell}(X'_{ij}) \) for all \( i \in L' \) and \( j \in [n] \).
   (c) Set \( L \leftarrow L \setminus L' \) and \( \ell = |L| \).
3. Define a deterministic instance \( I \) of the GAP as follows: the set of jobs and machines remains unchanged. For each job \( j \) and machine \( i \), define \( p_{ij} \) and \( c_{ij} \) as above. The makespan bound is \( b \). Use the algorithm of Shmoys and Tardos \cite{25} to find an assignment of jobs to machines. Output this solution.

Recall that in an instance \( I \) of GAP, we are given a set of \( m \) machines and \( n \) jobs. For each job \( j \) and machine \( i \), we are given two quantities: \( p_{ij} \) is the processing time of \( j \) on machine \( i \), and \( c_{ij} \) is the cost of assigning \( j \) to \( i \). We are also given a makespan bound \( b \). Our goal is to assign jobs to machines to minimize the total cost of assignment, subject to the total processing time of jobs assigned to each machine being at most \( b \). If the natural LP relaxation for this problem has optimal value \( C^* \) then the algorithm in \cite{25} finds in polynomial-time an assignment with cost at most \( C^* \) and makespan is at most \( B + \max_{i,j} p_{ij} \).

3.3 The Analysis
We begin with some simple observations:

Observation 1. The above rounding procedure terminates in at most \( m \) iterations. Furthermore, for any \( 1 \leq \ell \leq m \), there are at most \( \ell \) machines of class at most \( \ell \).

Proof: The first statement follows from the fact that \( L' \neq \emptyset \) in each iteration. To see this, consider any iteration involving a set \( L \) of \( \ell \) machines. The LP constraint \( \leq b \cdot \ell \), which means there is some \( i \in L \) with \( z_i(\ell) \leq b \), i.e., \( L' \neq \emptyset \). The second statement follows from the rounding procedure: the machine classes only decrease over the run of the algorithm, and the class assigned to any unclassified machine equals the current number of unclassified machines.

Observation 2. The solution \( y \) is a feasible fractional solution to the natural LP relaxation for the GAP instance \( I \). This solution has makespan at most \( b \) and fractional cost at most \( 2 \). The rounding algorithm of Shmoys and Tardos \cite{25} yields an assignment with makespan at most \( b + 1 \) and cost at most \( 2 \) for the instance \( I \).
Proof: Recall that the natural LP relaxation is the following:

\[
\begin{align*}
\min & \quad \sum_{ij} c_{ij} y_{ij} \\
\text{s.t.} & \quad \sum_j p_{ij} y_{ij} \leq b, \quad \forall i, \\
& \quad \sum_i y_{ij} = 1, \quad \forall j, \\
& \quad y_{ij} = 0, \quad \forall j \text{ s.t. } p_{ij} > 1, \\
& \quad y \geq 0.
\end{align*}
\] (10)

Firstly, note that by (5), \(y\) is a valid fractional assignment that assigns each job to one machine, which satisfies (11).

Next we show (10), i.e., that \(\max_{i=1}^m \sum_{j=1}^n p_{ij} \cdot y_{ij} \leq b\). This follows from the definition of the deterministic processing times \(p_{ij}\). Indeed, consider any machine \(i \in [m]\). Let \(\ell\) be the class of machine \(i\), and \(L\) be the subset of machines in the iteration when \(i\) is assigned class \(\ell\). This means that \(p_{ij} = \beta_\ell(X'_{ij})\) for all \(j \in [n]\). Also, because machine \(i \in L\), we have \(z_i(\ell) = \sum_{j=1}^n \beta_\ell(X'_{ij}) \cdot y_{ij} \leq b\). So we have \(\sum_{j=1}^n p_{ij} \cdot y_{ij} \leq b\) for each machine \(i \in [m]\).

Finally, since the random variable \(X'_{ij}\) is at most 1, we get that for any parameter \(k \geq 1\), \(\beta_k(X'_{ij}) \leq 1\); this implies that \(p_{\text{max}} := \max_{i,j} p_{ij} \leq 1\) and hence the constraints (12) are vacuously true. Finally, by (10), the objective is \(\sum_{i=1}^m \sum_{j=1}^n c_{ij} \cdot y_{ij} = \sum_{i=1}^m \sum_{j=1}^n E[X''_{ij}] \cdot y_{ij} \leq 2\). Therefore the rounding algorithm [25] yields an assignment of makespan at most \(b + p_{\text{max}} \leq b + 1\), and of cost at most 2.

In other words, if \(J_i\) be the set of jobs assigned to machine \(i\) by our algorithm, Observation 2 shows that this assignment has the following properties (let \(\ell_i\) denote the class of machine \(i\)):

\[
\sum_{i=1}^m \sum_{j \in J_i} E[X''_{ij}] \leq 2, \quad \text{and} \quad \sum_{j \in J_i} \beta_{\ell_i}(X'_{ij}) \leq b + 1, \quad \forall i \in [m].
\] (13) (14)

Note that we ideally wanted to give an assignment that satisfied (3)–(4), but instead of giving a bound for all sets of machines, we give just the bound on the \(\beta_{\ell_i}\) values of the jobs for each machine \(i\). The next lemma shows this is enough.

Lemma 6 (Bounding the Makespan). The expected makespan of the assignment \(\{J_i\}_{i \in [m]}\) is at most \(4b + 10\).

Proof: Let \(I^h\) denote the index set of machines of class 3 or higher. Observation 1 shows that there are at most 3 machines which are not in \(I^h\). For a machine \(i\), let \(T_i = \sum_{j \in J_i} X'_{ij}\) denote the total load due to truncated sizes of jobs assigned to it. Clearly, the makespan is bounded by

\[
\max_{i \in I^h} T_i + \sum_{i \notin I^h} T_i + \sum_{i=1}^m \sum_{j \in J_i} X''_{ij}.
\]

The expectation of third term is at most two, using (13). We now bound the expectation of the second term above. A direct application of Jensen’s inequality (Theorem 5) for concave functions shows that \(\beta_k(X) \geq E[X]\) for any random variable \(X\) and any \(k \geq 1\). Then applying inequality (14) shows that \(E[T_i] \leq b + 1\) for any machine \(i\). Therefore, the expected makespan of our solution is at most

\[
E \left[ \max_{i \in I^h} T_i \right] + 3(b + 1) + 2.
\] (15)

12
It remains to bound the first term above.

**Observation 3.** For any machine $i$, $\Pr\left[\sum_{j \in J_i} X'_{ij} > b + 1 + \alpha\right] \leq \ell_i^{-\alpha}$ for all $\alpha \geq 0$.

**Proof:** Inequality (14) for machine $i$ shows that $\sum_{j \in J_i} \beta_{\ell_i}(X'_{ij}) \leq b + 1$. But recalling the definition of the effective size (Definition 1), the result follows from Lemma 2. □

Now we can bound the probability of any machine in $I^h$ having a high makespan.

**Lemma 7.** For any $\alpha > 2$,

$$\Pr\left[\max_{i \in I^h} T_i > b + 1 + \alpha\right] \leq \frac{2^{2-\alpha}}{(\alpha - 2)}.$$

**Proof:** Using a union bound, we get

$$\Pr\left[\max_{i \in I^h} T_i > b + 1 + \alpha\right] \leq \sum_{\ell=3}^m \sum_{i : \ell_i = \ell} \Pr[T_i > b + 1 + \alpha]$$

$$\leq \sum_{\ell=3}^m \ell^{-\alpha} \cdot (\# \text{ of class } \ell \text{ machines})$$

$$\leq \sum_{\ell=3}^m \ell^{-\alpha+1} \leq \int_{x=2}^{\infty} x^{-\alpha+1} dx = \frac{2^{-\alpha+2}}{\alpha - 2}.$$

The first inequality uses a trivial union bound, the second uses Observation 3 above, and the third inequality is by Observation 1. □

Using the above lemma, we get

$$E[\max_{i \in I^h} T_i] = (b + 4) + \int_{\alpha=3}^{\infty} \Pr[\max_{i \in I^h} T_i > b + 1 + \alpha] d\alpha \leq (b + 4) + \int_{\alpha=3}^{\infty} 2^{2-\alpha} d\alpha \leq b + 5.$$

Inequality (15) now shows that the expected makespan is at most $(b + 5) + 3(b + 1) + 2$. □

This completes the proof of Theorem 1.

### 4 Budgeted Makespan Minimization

We now consider a generalization of the STOCMAKESPAN problem, called BUDGETSTOCMAKESPAN, where each job $j$ also has reward $r_j \geq 0$. We are required to schedule some subset of jobs whose total reward is at least some target value $R$. The objective, again, is to minimize the expected makespan. If the target $R = \sum_{j \in [n]} r_j$ then we recover the STOCMAKESPAN problem. We show:

**Theorem 2.** There is an $O(1)$-approximation algorithm for the budgeted makespan minimization problem on unrelated machines.

Naturally, our algorithm/analysis will build on the ideas developed in §3 but we will need some new ideas to handle the fact that only a subset of jobs need to be scheduled. As in the case of STOCMAKESPAN problem, we can formulate a suitable LP relaxation. A similar rounding procedure reduces the stochastic problem to a deterministic problem, which we call BUDGETED GAP. An instance of BUDGETED GAP is similar to that of GAP, besides the additional requirement that jobs have rewards and we are required to assign jobs of total reward at least some target $R$. Rounding the natural LP relaxation for BUDGETED GAP turns out to be non-trivial. Indeed,
using ideas from [25], we reduce this rounding problem to rounding a fractional matching solution with additional constraints, and solve the latter using polyhedral properties of bipartite matching polyhedra.

As before, using a binary-search scheme (and by scaling down the sizes), we can assume that we need to either (i) find a solution of expected makespan $O(1)$, or (ii) prove that the optimal value is more than 1. We use a natural LP relaxation which has variables $y_{ij}$ for each job $j$ and machine $i$. The LP includes the constraints (6)-(9) for the base problem, and in addition it has the following two constraints:

$$\sum_{i=1}^{m} y_{ij} \leq 1, \quad \forall j = 1, \cdots, n, \quad (16)$$

$$\sum_{j=1}^{n} r_j \cdot \sum_{i=1}^{m} y_{ij} \geq R. \quad (17)$$

The first constraint (16) replaces constraint (5) and says that not all jobs need to be assigned. The second constraint (17) ensures that the assigned jobs have total reward at least the target $R$.

For technical reasons that will be clear later, we also perform a preprocessing step: for $i, j$ pairs where $\mathbb{E}[X_{ij}'] > 2$, we force the associated $y_{ij}$ variable to zero. Note that by Lemma 5, this variable fixing is valid for any integral assignment that has expected makespan at most one (in fact, we have $\sum_{i} \sum_{j} \mathbb{E}[X_{ij}'] \cdot y_{ij} \leq 2$ for such an assignment). As in §3.1 this LP can be solved in polynomial time via the ellipsoid method. If the LP is infeasible we get a proof (using Lemma 5) that the optimal expected makespan is more than one. Hence we may assume the LP is feasible, and proceed to round the solution along the lines of §3.2.

Recall that the rounding algorithm in §3.2 reduces the fractional LP solution to an instance of the generalized assignment problem (GAP). Here, we will use a further generalization of GAP, which we call BUDGETED GAP. An instance of this problem is similar to an instance of GAP. We are given $m$ machines and $n$ jobs, and for each job $j$ and machine $i$, we are given the processing time $p_{ij}$ and the associated assignment cost $c_{ij}$. Now each job $j$ has a reward $r_j$, and there are two “target” parameters: the reward target $R$ and the makespan target $B$. We let $p_{\max}$ and $c_{\max}$ denote the maximum values of processing time and cost respectively. A solution must assign a subset of jobs to machines such that the total reward of assigned jobs is at least $R$. Moreover, as in the case of GAP, the goal is to minimize the total assignment cost subject to the condition that the makespan is at most $B$. Our main technical theorem of this section shows how to round an LP relaxation of this BUDGETED GAP problem.

**Theorem 7.** There is a polynomial-time rounding algorithm for BUDGETED GAP that given any fractional solution to the natural LP relaxation of cost $C^*$, produces an integer solution having total cost at most $C^* + c_{\max}$ and makespan at most $B + 2p_{\max}$.

Before we prove this theorem, let us use it to solve the BUDGETSTOCMAKESPAN, and prove Theorem 2. Proceeding as in §3.2 we perform Steps 1-2 from the rounding procedure. This rounding gives us values $p_{ij}$ and $c_{ij}$ for each job/machine pair. Now, instead of reducing to an instance of GAP, we reduce to an instance $T'$ of BUDGETED GAP. The instance $T'$ has the same set of jobs and machines as in the original BUDGETSTOCMAKESPAN instance $T$. For each job $j$ and machine $i$, the processing time and the assignment cost are given by $p_{ij}$ and $c_{ij}$ respectively. Furthermore, the reward $r_j$ for job $j$, and the reward target $R$ are same as those in $T$. The makespan bound $b = O(1)$ (as in §3). It is easy to check that the fractional solution $y_{ij}$ is a feasible fractional solution to the natural LP relaxation for $T'$ (given below), and the assignment cost of this fractional
solution is at most 2. Applying Theorem 7 yields an assignment \( \{J_i\}_{i=1}^m \), which has the following properties:

- The makespan is at most \( b + 2 = O(1) \); i.e., \( \sum_{j \in J_i} p_{ij} \leq b + 2p_{\text{max}} \leq b + 2 \) for each machine \( i \). Here we used the fact that \( p_{\text{max}} \leq 1 \).
- The cost of the solution, \( \sum_{i=1}^m \sum_{j \in J_i} c_{ij} \), is at most 4. This uses the fact that the LP cost \( C^* = \sum c_{ij} \cdot y_{ij} \leq 2 \) and \( c_{\text{max}} \leq 2 \) by the preprocessing on the \( E[X'_{ij}] \) values.
- The total reward for the assigned jobs, \( \sum_{j \in \cup J_i} r_j \), is at least \( R \).

Now arguing exactly as in [3,2] the first two properties imply that the expected makespan is \( O(1) \). The third property implies the total reward of assigned jobs is at least \( R \), and completes the proof of Theorem 2.

### 4.1 Proof of Theorem 7

**Proof:** [Proof of Theorem 7] Let \( I \) be an instance of BUDGETED GAP as described above. The natural LP relaxation for this problem is as follows:

\[
\begin{align*}
\min & \quad \sum_{ij} c_{ij} y_{ij} \\
\text{s.t.} & \quad \sum_j p_{ij} y_{ij} \leq B, \quad \forall i, \quad (18) \\
& \quad \sum_i y_{ij} \leq 1, \quad \forall j, \quad (19) \\
& \quad \sum_{i,j} y_{ij} r_j \geq R, \quad \forall j \text{ s.t. } p_{ij} > b, \quad (20) \\
& \quad y_{ij} = 0, \quad \forall j \text{ s.t. } p_{ij} \leq b, \quad (21) \\
& \quad y \geq 0.
\end{align*}
\]

Let \( \{y_{ij}\} \) denote an optimal fractional solution to this LP. For each machine \( i \), let \( t_i := \lceil \sum_j y_{ij} \rceil \) be the (rounded) fractional assignment to machine \( i \). Using the algorithm in Theorem 2.1 of [25], we obtain a bipartite graph \( G = (V_1 \cup V_2, E) \) and a fractional matching \( y' \) in \( G \), where:

- \( V_1 = [n] \) is the set of jobs and \( V_2 \) (indexed by \( i' = 1, \ldots, m' \)) consists of \( t_i \) copies for each machine \( i \in [m] \). The cost \( c_{i'j} = c_{ij} \) for any job \( j \in [n] \) and any machine-copy \( i' \) of machine \( i \in [m] \).
- for each job \( j \in [n] \) we have \( \sum_{i=1}^{m'} y'_{ij} = \sum_{i=1}^{m} y_{ij} \leq 1 \) for all \( j \in [n] \).
- the reward \( \sum_{j=1}^{n} r_j \sum_{i=1}^{m'} y'_{ij} \geq R \) and the cost \( \sum_{i=1}^{m'} \sum_{j=1}^{n} c_{i'j} y'_{ij} = C^* \) are same as for \( y \).
- the jobs of \( V_1 \) incident to copies of any machine \( i \in [m] \) can be divided into (possibly overlapping) groups \( H_{i,1}, \ldots, H_{i,t_i} \) where

\[
\sum_{j \in H_{i,g}} y'_{ij} = 1 \text{ for all } 1 \leq g \leq t_i - 1 \quad \text{and} \quad \sum_{j \in H_{i,t_i}} y'_{ij} \leq 1,
\]

and for any two consecutive groups \( H_{i,g} \) and \( H_{i,g+1} \) we have \( p_{ij} \geq p_{ij'} \) for all \( j \in H_{i,g} \) and \( j' \in H_{i,g+1} \). Informally, this is achieved by sorting the jobs in non-increasing order of \( p_{ij} \), and assigning the \( k^{th} \) unit of \( \sum_j y_{ij} \) to the \( k^{th} \) machine-copy for each \( 1 \leq k \leq t_i \).
A crucial property of this construction shown in [25] is that any assignment that places at most one job on each machine-copy has makespan at most \( B + p_{\text{max}} \) in the original instance \( I \) (where for every machine \( i \), we assign to it all the jobs which are assigned to a copy of \( i \) in this integral assignment). We will use the following simple extension of this property: if the assignment places two jobs on one machine-copy and at most one job on all other machine-copies, then it has makespan at most \( B + 2p_{\text{max}} \) in the instance \( I \).

Observe that the solution \( y' \) is a feasible solution to the following LP with variables \( \{z_{ij}\}_{(i,j) \in E} \).

\[
\begin{align*}
\min \quad & \sum_{ij} c_{ij} z_{ij} \\
\text{s.t.} \quad & \sum\limits_{i \in [m'] : (ij) \in E} z_{ij} \leq 1, \quad \forall j \in [n], \quad (22) \\
& \sum\limits_{j \in [n] : (ij) \in E} z_{ij} \leq 1, \quad \forall i \in [m'], \quad (23) \\
& \sum\limits_{(ij) \in E} r_j \cdot z_{ij} \geq R, \quad (24) \\
& z \geq 0. \quad (26)
\end{align*}
\]

So the optimal value of this auxiliary LP is at most \( C^* \). We note that its integrality gap is unbounded even when \( c_{\text{max}} \) is small; see the example below. So this differs from [25] for the usual GAP where the corresponding LP (without [25]) is actually integral. However, we show below how to obtain a good integral solution that violates the matching constraint for just a single machine-copy in \( V_2 \).

Indeed, let \( z \) be an optimal solution to this LP; so \( c^T z \leq C^* \). Note that the feasible region of this LP is just the bipartite-matching polytope on \( G \) intersected with one extra linear constraint [25] that corresponds to the total reward being at least \( R \). So \( z \) must be a convex combination of two adjacent extreme points of the bipartite-matching polytope. Using the integrality and adjacency properties (see [2]) of the bipartite-matching polytope, it follows that \( z = \lambda_1 \cdot 1_{M_1} + \lambda_2 \cdot 1_{M_2} \) where:

- \( \lambda_1 + \lambda_2 = 1 \) and \( \lambda_1, \lambda_2 \geq 0 \).
- \( M_1 \) and \( M_2 \) are integral matchings in \( G \).
- The symmetric difference \( M_1 \oplus M_2 \) is a single cycle or path.

For any matching \( M \) let \( c(M) \) and \( r(M) \) denote its total cost and reward respectively. Without loss of generality, we assume that \( r(M_1) \geq r(M_2) \). If \( c(M_1) \leq c(M_2) \) then \( M_1 \) is itself a solution with reward at least \( R \) and cost at most \( C^* \). So we assume \( c(M_1) > c(M_2) \) below.

If \( M_1 \oplus M_2 \) is a cycle then we output \( M_2 \) as the solution. Note that the cycle must be an even cycle: so the set of jobs assigned by \( M_1 \) and \( M_2 \) is identical. As the reward function is only dependent on the assigned jobs (and not the machines used in the assignment) it follows that \( r(M_2) = r(M_1) \geq R \). So \( M_2 \) is indeed a feasible solution and has cost \( c(M_2) \leq c^T z \leq C^* \).

Now consider the case that \( M_1 \oplus M_2 \) is a path. If the set of jobs assigned by \( M_1 \) and \( M_2 \) are the same then \( M_2 \) is an optimal integral solution (as above). The only remaining case is that \( M_1 \) assigns one additional job (say \( j^* \) to \( i^* \)) over the jobs in \( M_2 \). Then we return the solution \( M_2 \cup \{ (j^*, i^*) \} \). Note that this is not a feasible matching. But the only infeasibility is at machine-copy \( i^* \) which may have two jobs assigned; all other machine-copies have at most one job. The reward of this solution is \( r(M_1) \geq R \). Moreover, its cost is at most \( c(M_2) + c_{i^*j^*} \leq C^* + c_{\text{max}} \).

Now using this (near-feasible) assignment gives us the desired cost and makespan bounds, and completes the proof of Theorem [7].

**Integrality Gap for Budgeted Matching LP.** Here we show that the LP [22]–[26] used in the algorithm for budgeted GAP has an unbounded integrality gap, even if we assume that \( c_{\text{max}} \ll OPT \). The instance consists of \( n \) jobs and \( m = n - 1 \) machines. For each machine \( i \in [m] \),
there are two incident edges in $E$: one to job $i$ (with cost 1) and the other to job $i+1$ (with cost $n$). So $E$ is the disjoint union of two machine-perfect matchings $M_1$ (of total cost $m$) and $M_2$ (of total cost $mn$). The rewards are

$$r_j = \begin{cases} 
1 & \text{if } j = 1 \\
4 & \text{if } 2 \leq j \leq n-1 \\
2 & \text{if } j = n 
\end{cases}.$$

and the target $R = 4(n-2) + 1 + \epsilon$ where $\epsilon \to 0$. Note that the only (minimal) integral solution involves assigning the jobs $\{2, 3, \cdots, n\}$ which has total reward $4(n-2) + 2$. This solution has cost $OPT = mn$ and corresponds to matching $M_2$. On the other hand, consider the fractional solution $z = \epsilon 1_{M_2} + (1-\epsilon) 1_{M_1}$. This is clearly feasible for the matching constraints, and its reward is $\epsilon(4(n-2) + 2) + (1-\epsilon)(4(n-2) + 1) = R$. So $z$ is a feasible fractional solution. The cost of this fractional solution is at most $m + \epsilon(mn) \ll OPT$.

5 $\ell_q$-norm Objectives

In this section, we prove Theorem 3. Given an assignment $\{J_i\}_{i=1}^m$, the load $L_i$ on machine $i$ is the r.v. $L_i := \sum_{j \in J_i} X_{ij}$. Our goal is to find an assignment to minimize the expected $q$-norm of the load vector $L := (L_1, L_2, \ldots, L_m)$. Recall that the makespan is $\|L\|_{\infty}$ which is approximated within constant factors by $\|L\|_{\log m}$. So the $q$-norm problem is a generalization of STOCMAKESPAN. Our main result here is:

**Theorem 3.** There is an $O(\frac{q}{\log q})$-approximation algorithm for the stochastic $q$-norm minimization problem on unrelated machines.

We begin by assuming that we know the optimal value $M$ of the $q$-norm. Our approach parallels that for the case of minimizing the expected makespan, with some changes. In particular, the main steps are: (i) find valid inequalities satisfied by any assignment for which $E[\|L\|_q] \leq M$, (ii) reduce the problem to a deterministic assignment problem for which any feasible solution satisfies the valid inequalities above, (iii) solve the deterministic problem by writing a convex programming relaxation, and give a rounding procedure for a fractional solution to this convex program, and (iv) prove that the resulting assignment of jobs to machines has small $q$-norm of the load vector.

5.1 Useful Bounds

We start with stating some valid inequalities satisfied by any assignment $\{J_i\}_{i=1}^m$. For each $j \in [n]$ define $Y_j = X_{ij}$ where $j \in J_i$. By definition of $M$, we know that

$$E\left[\left(\sum_{i=1}^m \left(\sum_{j \in J_i} Y_j\right)^r\right)^{1/q}\right] \leq M. \quad (27)$$

As in Section 3 we split each random variable $Y_j$ into two parts: truncated $Y'_j = Y_j \cdot I_{Y_j \leq M}$ and exceptional $Y''_j = Y_j \cdot I_{Y_j > M}$. The claim below is analogous to (3), and states that the total expected size of the exceptional parts cannot be too large.

**Claim 1.** For any schedule satisfying (27), we have $\sum_{j=1}^n E[Y''_j] \leq 2M$. 

17
Proof: Suppose for a contradiction that \( \sum_{j=1}^{n} E[Y''_j] > 2M \). Lemma 1 implies \( E[\max_{j=1}^{n} Y''_j] > M \). Now using the monotonicity of norms and the fact that \( Y_{j''} \leq Y_j \), we have

\[
\max_{j=1}^{n} Y''_j \leq \|(Y_{1''}, \ldots, Y_{n''})\|_q \leq \left( \sum_{i=1}^{m} \left( \sum_{j \in J_i} Y_j \right)^q \right)^{1/q},
\]

which contradicts (27). \( \square \)

Our next two bounds deal with the truncated r.v.s \( Y'_j \). The first one states that if we replace \( Y'_j \) by its expectation \( E[Y'_j] \), the \( q \)-norm of this load vector of expectations cannot exceed \( M \). The second bound states that the expected \( q \)-th moment of the vector \( (Y'_j)^n_{j=1} \) is bounded by a constant times \( M^q \).

Claim 2. For any schedule satisfying (27) we have

\[
\sum_{i=1}^{m} \left( \sum_{j \in J_i} E[Y'_j] \right)^q \leq M^q.
\]

Proof: Since the function

\[
f(Y'_1, \ldots Y'_n) := \left( \sum_{i=1}^{m} \left( \sum_{j \in J_i} Y'_j \right)^q \right)^{1/q}
\]

is a norm and hence convex, Jensen’s inequality (Theorem 5) implies \( E[f(Y'_1, \ldots Y'_n)] \geq f(E[Y'_1], \ldots E[Y'_n]) \). Raising both sides to the \( q \)-th power and using (27), the claim follows.

Claim 3. Let \( \alpha = 2^{q+1} + 8 \). For any schedule satisfying (27) we have

\[
\sum_{j=1}^{n} E[(Y'_j)^q] \leq \alpha \cdot M^q.
\]

Proof: Define \( Z := \sum_{j=1}^{n} (Y'_j)^q \) as the quantity of interest. Observe that it is the sum of independent \([0, M^q] \) bounded random variables. Since \( q \geq 1 \) and the r.v.s are non-negative, \( Z \leq \sum_{i=1}^{m} \left( \sum_{j \in J_i} Y'_j \right)^q \). Thus (27) implies \( E[Z^{1/q}] \leq M \). However, now Jensen’s inequality cannot help upper-bound \( E[Z] \).

Instead we use a second-moment calculation. To reduce notation let \( Z_j := (Y'_j)^q \), so \( Z = \sum_{j=1}^{n} Z_j \). The variance of \( Z \) is \( \text{var}(Z) = E[Z^2] - E[Z]^2 \leq \sum_{j=1}^{n} E[Z_j^2] \leq M^q \cdot E[Z] \) as each \( Z_j \) is \([0, M^q] \) bounded. By Chebyshev’s inequality,

\[
\Pr \left[ Z < \frac{E[Z]}{2} - 4M^q \right] \leq \frac{\text{var}(Z)}{(E[Z]/2 + 4M^q)^2} \leq \frac{\text{var}(Z)}{(E[Z]/2) \cdot 4M^q} \leq \frac{2M^q \cdot E[Z]}{E[Z] \cdot 4M^q} \leq \frac{1}{2}
\]

This implies

\[
E[Z^{1/q}] \geq \frac{1}{2} \left( \frac{E[Z]}{2} - 4M^q \right)^{1/q}
\]

Using the bound \( E[Z^{1/q}] \leq M \) from above, we now obtain \( E[Z] \leq 2 \cdot ((2M)^q + 4M^q) \) as desired. \( \square \)

In the next sections, we show that the three bounds above are enough to get a meaningful lower bound on the optimal \( q \)-norm of load.
5.2 Reduction to a Deterministic Scheduling Problem

We now formulate a surrogate deterministic scheduling problem, which we call \( q \)-DetSched. An instance of this problem has \( n \) jobs and \( m \) machines. For each job \( j \) and machine \( i \), there is a processing time \( p_{ij} \) and two costs \( c_{ij} \) and \( d_{ij} \). There are also bounds \( C \) and \( D \) on the two cost functions respectively. The goal is to find an assignment of jobs to machines that minimizes the \( q \)-norm of the machine loads subject to the constraint that the total \( c \)-cost and \( d \)-cost of the assignments are at most \( C \) and \( D \) respectively. We now show how to convert an instance \( I_{\text{stoc}} \) of the (stochastic) expected \( q \)-norm minimization problem to an instance \( I_{\text{det}} \) of the (deterministic) \( q \)-DetSched problem.

Suppose \( I_{\text{stoc}} \) has \( m \) machines and \( n \) jobs, with random variables \( X_{ij} \) for each machine \( i \) and job \( j \). As before, let \( X'_{ij} = X_{ij} \cdot I_{X_{ij} \leq M} \) and \( X''_{ij} = X_{ij} \cdot I_{X_{ij} > M} \) denote the truncated and exceptional parts of each random variable \( X_{ij} \) respectively. Then instance \( I_{\text{det}} \) has the same set of jobs and machines as those in \( I \). Furthermore, define

- the processing time \( p_{ij} = \mathbb{E}[X'_{ij}] \),
- the \( c \)-cost \( c_{ij} = \mathbb{E}[X''_{ij}] \) with bound \( C = 2M \), and
- the \( d \)-cost \( d_{ij} = \mathbb{E}[(X'_{ij})^q] \) with bound \( D = \alpha \cdot M^q \).

**Observation 4.** If there is any schedule of expected \( q \)-norm at most \( M \) in the instance \( I_{\text{stoc}} \), then optimal value of the instance \( I_{\text{det}} \) is at most \( M \).

**Proof:** This follows directly from Claims 1, 2 and 3.

5.3 Approximation Algorithm for \( q \)-DetSched

Our approximation algorithm for the \( q \)-DetSched problem is closely based on the algorithm for unrelated machine scheduling to minimize \( \ell_q \)-norms [1]. We show:

**Theorem 8.** There is a polynomial-time algorithm that given any instance \( I_{\text{det}} \) of \( q \)-DetSched, finds a schedule with (i) \( q \)-norm of processing times at most \( 2^{1+2/q} \cdot \text{OPT}(I_{\text{det}}) \), (ii) \( c \)-cost at most \( 3C \), and (iii) \( d \)-cost at most \( 3D \).

**Proof:** We only provide a sketch as many of these ideas parallel those from [1]. Start with a convex programming “relaxation” with variables \( x_{ij} \) (for assigning job \( j \) to machine \( i \)).

\[
\begin{align*}
\min & \quad \sum_{i=1}^{m} \ell_i^q + \sum_{ij} p_{ij}^q \cdot x_{ij} \\
\text{s.t.} & \quad \ell_i = \sum_{j} p_{ij} \cdot x_{ij}, \quad \forall i, \\
& \quad \sum_{i} x_{ij} = 1, \quad \forall j, \\
& \quad \sum_{ij} c_{ij} \cdot x_{ij} \leq C, \\
& \quad \sum_{ij} d_{ij} \cdot x_{ij} \leq D.
\end{align*}
\]

This convex program can be solved to arbitrary accuracy and its optimal value is \( V \leq 2 \cdot \text{OPT}(I_{\text{det}})^q \). Let \((x, \ell)\) denote the optimal fractional solution below.
We now further reduce this $q$-norm problem to GAP. The GAP instance $I_{gap}$ has the same set of jobs and machines as those in $I_{det}$. For a job $j$ and machine $i$, the processing time remains $p_{ij}$. However, the cost of assigning $j$ to $i$ is now $\gamma_{ij} := \frac{c_{ij}}{q} + \frac{d_{ij}}{q} + \frac{p_{ij}^q}{q}$. Furthermore, we impose a bound of $\ell_i$ on the total processing time of jobs assigned to each machine $i$ (i.e., the makespan on $i$ is constrained to be at most $\ell_i$). Note that the solution $x$ to the convex program is also a feasible fractional solution to the natural LP-relaxation for $I$ set of jobs and machines as those in $I_{det}$.

5.4 Interpreting the Rounded Solution

Starting from an instance $I_{stoc}$ of expected $q$-norm minimization problem, we first constructed an instance $I_{det}$ of $q$-DetSched. Let $J = (J_1, \ldots, J_m)$ denote the solution found by applying Theorem 8 to the instance $I_{det}$. If the $q$-norm of processing times of this assignment (as a solution for $I_{det}$) is more than $2^{1+2/q}M$ then using Observation 4 and Theorem 8, we obtain a certificate that the optimal value of $I_{det}$ is more than $M$. So we assume that $J$ has objective at most $2^{1+2/q}M$ (as a solution to $I_{det}$). We use exactly this assignment as a solution for the stochastic problem as well. It remains to bound the expected $q$-norm of this assignment.

By the reduction from $I_{stoc}$ to $I_{det}$, and the statement of Theorem 8 we know that

$$\sum_{i=1}^{m} \sum_{j \in J_i} \mathbb{E}[X_{ij}^q] = \sum_{i=1}^{m} \sum_{j \in J_i} c_{ij} \leq 6M$$

$$\sum_{i=1}^{m} \left( \sum_{j \in J_i} \mathbb{E}[X_{ij}^q] \right)^q = \sum_{i=1}^{m} (\sum_{j \in J_i} p_{ij})^q \leq 2^{q+2} \cdot M^q$$

$$\sum_{i=1}^{m} \sum_{j \in J_i} \mathbb{E}[(X_{ij}')^q] = \sum_{i=1}^{m} \sum_{j \in J_i} d_{ij} \leq 3\alpha M^q$$

We now derive properties of this assignment as a solution for $I_{stoc}$.

Claim 4. The expected $q$-norm of exceptional jobs $\mathbb{E}[(\sum_{i=1}^{m} (\sum_{j \in J_i} X_{ij}^q)^{1/q})^{1/q}] \leq 6M$.

Proof: This follows from (28), since the $\ell_q$-norm of a vector is at most its $\ell_1$-norm. $\square$

Claim 5. The expected $q$-norm of truncated jobs $\mathbb{E}[(\sum_{i=1}^{m} (\sum_{j \in J_i} X_{ij}')^{q})^{1/q}] \leq O(\frac{\alpha M^q}{\log q})M$.

Proof: Define random variables $Q_i := (\sum_{j \in J_i} X_{ij}')^q$, so that the $q$-norm of the loads is $Q := (\sum_{i=1}^{m} Q_i)^{1/q} = (\sum_{i=1}^{m} (\sum_{j \in J_i} X_{ij}')^q)^{1/q}$. $\square$
Since \( f(Q_1, \cdots, Q_m) = (\sum_{i=1}^m Q_i)^{1/q} \) is a concave function for \( q \geq 1 \), using Jensen’s inequality (Theorem 5) again,

\[
E[Q] \leq \left( \sum_{i=1}^m E[Q_i] \right)^{1/q}.
\]  

(31)

We can bound each \( E[Q_i] \) separately using Rosenthal’s inequality (Theorem 6):

\[
E[Q_i] = E\left[ (\sum_{j \in J_i} X'_{ij})^q \right] \leq K^q \cdot \left( (\sum_{j \in J_i} E[X'_{ij}]^q \right) + \sum_{j \in J_i} E[(X'_{ij})^q]
\]

where \( K = O(q/\log q) \). Summing this over all \( i = 1, \ldots, m \) and using (29) and (30), we get

\[
\sum_{i=1}^m E[Q_i] \leq K^q \cdot (2^{q+2} + 3\alpha) M^q
\]

(32)

Recall from Claim 3 that \( \alpha = 2^{q+1} + 8 \). Now plugging this into (31) we obtain \( E[Q] \leq O(K) \cdot M \).

□

Finally, using Claims 4 and 5 and the triangle inequality, the expected \( q \)-norm of solution \( J \) is \( O(\frac{q}{\log q}) \cdot M \), which completes the proof of Theorem 3.

**Explicit approximation ratio**  Here we show approximation ratios explicitly. By equations (31) and (32), we have the expected \( q \)-norm of truncated jobs is

\[
E[Q] \leq (K^q \cdot (2^{q+2} + 3\alpha) M^q)^{1/q} = (K^q \cdot (2^{q+2} + 3(2^{q+1} + 8)) M^q)^{1/q} = (10 + 3 \cdot 2^{3-q})^{1/q} 2K M.
\]

And the expected \( q \)-norm of exceptional jobs is at most \( 6M \) by Claim 4. By the triangle inequality, the expected \( q \)-norm of solution \( J \) is at most \( (6 + (10 + 3 \cdot 2^{3-q})^{1/q} 2K M)(1 + \epsilon) \), for any \( \epsilon > 0 \), where \( K \) is the parameter in Theorem 6.

The following known result provides a bound of the parameter \( K^q \) in Theorem 6.

**Theorem 9**  Let \( Z \) denote a random variable with Poisson distribution with parameter 1, i.e., \( \Pr[Z = k] = e^{-1}/k! \) for integer \( k \geq 0 \). Then Theorem 6 holds with parameter \( K = (\mathbb{E}Z^q)^{1/q} \).

**Example**  For \( \ell_2 \)-norm, \( K^2 \leq \mathbb{E}Z^2 = 2 \Rightarrow K = \sqrt{2} \). The overall approximation ratio is \( (6 + (10 + 3 \cdot 2^q)^{1/2} \sqrt{2})(1 + \epsilon) = (6 + 8\sqrt{2})(1 + \epsilon) = 17.31(1 + \epsilon) \). For \( \ell_3 \)-norm, \( K^3 = 5 \Rightarrow K = \frac{3}{\sqrt[3]{5}} \) and the approximation ratio is \( (6 + (10 + 3)^{1/3} \sqrt[3]{5})(1 + \epsilon) = 14.04(1 + \epsilon) \).
