Emerging roles of protein disulfide isomerase in cancer

Eunyoug Lee & Do Hee Lee*
Department of Bio and Environmental Technology, Seoul Women’s University, Seoul 01797, Korea

The protein disulfide isomerase (PDI) family is a group of multifunctional endoplasmic reticulum (ER) enzymes that mediate the formation of disulfide bonds, catalyze the cysteine-based redox reactions and assist the quality control of client proteins. Recent structural and functional studies have demonstrated that PDI members not only play an essential role in the proteostasis in the ER but also exert diverse effects in numerous human disorders including cancer and neurodegenerative diseases. Increasing evidence suggests that PDI is actively involved in the proliferation, survival, and metastasis of several types of cancer cells. Although the molecular mechanism by which PDI contributes to tumorigenesis and metastasis remains to be understood, PDI is now emerging as a new therapeutic target for cancer treatment. In fact, several attempts have been made to develop PDI inhibitors as anti-cancer drugs. In this review, we discuss the properties and diverse functions of human PDI proteins and focus on recent findings regarding their roles in the state of diseases including cancer and neurodegeneration. [BMB Reports 2017; 50(8): 401-410]

INTRODUCTION

Formation of disulfide bond (S-S bond) between cysteine residues is a crucial and rate-limiting step for the correct folding of nascent polypeptide chains in the ER (1). Nearly one-third of all eukaryotic proteins, including the majority of secretory proteins (∼80%), contain at least one S-S bond (2). During oxidative folding in the ER, S-S bonds are formed by oxidation of thiol groups of cysteines and then rearranged (isomerized) until the correct conformation is achieved (3). Although the formation of S-S bonds also occurs in the intermembrane space (IMS) of mitochondria, this post-translational modification takes place primarily in the ER and is critical for the maturation and stabilization of a majority of secretory and membrane proteins (4). The PDI family is a group of ER enzymes responsible for the formation, breakage, and rearrangement of protein disulfide bond. PDI, the first ER protein discovered as a folding catalyst, is a highly abundant ER protein constituting approximately 0.8% of a total protein (5). Inside cells, S-S bond is formed by thiol-disulfide exchange reactions in which electrons are initially transferred from the reduced substrates to oxidized PDI. Reduced PDI is then regenerated (oxidized) by the FAD-linked sulfhydryl oxidase Ero1, which generates H₂O₂ by transferring electrons directly onto oxygen (4, 6). The chemical aspects of thiol-disulfide exchange reactions and the enzymatic properties of PDI and its partners in oxidative protein folding are well-explained in several review articles (6-8). In this review, we will focus on the domain organizations and diverse functions of human PDI proteins as well as their relevance to disease states, especially cancer and neurodegenerative diseases.

THE PDI GENE FAMILY

The PDI family is a part of the thioredoxin (TRX) superfamiliy which also includes TRXs, peroxiredoxins, and glutaredoxins. Most of the enzymes catalyzing the formation of S-S bonds belong to the TRX superfamily (9). According to the HUGO gene nomenclature committee (HGNC) database, the human PDI gene family is comprised of 21 members (http://www.genenames.org/cgi-bin/genefamilies/set/692), which vary in length, domain arrangement and substrate specificity but share a common structural feature - the TRX-like domain (Table 1, Fig. 1). PDIA1 (usually referred as PDI) is the archetype PDI protein and originally identified as the β-subunit of prolyl-4-hydroxylase (P4H) that catalyzes the formation of 4-hydroxyproline in collagen (10). PDIA1 is a central mediator of the oxidative folding in the ER and catalyzes the oxidation, reduction, and isomerization of S-S bonds in the substrates. In addition, PDIA1 and other PDI proteins function as molecular chaperones, which are usually thiol-independent (11). PDIA1 has a multi-domain structure consisting of catalytic domains (i.e., TRX-like domains) and the C-terminal ER-retention sequence. Other PDI proteins also show a similar modular composition of TRX-like domains followed by the C-terminal ER-retention sequence (Fig. 1). All human PDI proteins contain at least one TRX-like domain, which can be divided into two types (a and b) depending on the presence of catalytic motif. The consensus sequence for those catalytic motives is CXXC...
Table 1. Members of the human PDI gene family

| Gene name | Protein size | Other aliases | TRX-like domain(s) | Catalytic-site sequence | ER retention sequence |
|-----------|--------------|---------------|-------------------|-------------------------|-----------------------|
| PDIA1     | 508aa        | PDI, P4HB, PHD8 | a-b-b'-a'         | CGHC, CGHC              | KDEL                  |
| PDIA2     | 525aa        | PDIp, PDA2     | a-b-b'-a'         | CGHC, CTHC              | KEEL                  |
| PDIA3     | 503aa        | ERp57, ERp60, GRP57, GRP58, P58 | a-b-b'-a'         | CGHC, CGHC              | QEDL                  |
| PDIA4     | 645aa        | ERp70, ERp72  | a'-a-b-b'-a'      | CGHC, CGHC, CGHC        | KEEL                  |

Table 1. Members of the human PDI gene family

and the most conserved motif is CGHC (12, 13). Catalytically active a-type domains (a and a’ domains) contain cysteines in the active sites that are thiol-reactive (7). Interestingly, a-type domains found in several PDI proteins (e.g., AGR2, AGR3, and ERp44) are lacking one cysteine in the active site motif (which is usually replaced with serine) and PDILT has no cysteine at the N-terminal a-type domain (13, 14). Despite their structural similarity to TRX, catalytically inactive b-type domains (b and b’ domains) do not contain cysteines and thus cannot mediate S-S bond formation. Instead, the b-type domains are involved in the protein recruitment, which is important for chaperone activity (13).

Although PDI members invariably contain the TRX-like domain, which is likely resulted from the duplications of a single TRX-like domain in the ancestral protein, they differ considerably in size, domain composition outside of the TRX-like domain and enzymatic properties. Phylogenetic analysis actually revealed the existence of subfamilies within the PDI family. Among the PDI members, AGR and TMX subfamilies are unique because they have only a-type domain (Fig. 1). Contribution of PDI proteins carrying non-canonical catalytic motifs in their a-type domains (e.g., AGR2, AGR3, PDILT, and ERp44) to thiol-reactive oxidative folding in vivo is unclear although they are capable of forming the mixed S-S bonds with client proteins (13, 15). More interestingly, ERp27 and ERp29 carry b-type domains only (16, 17). Presumably, these atypical PDI members function primarily as molecular chaperones rather than as oxidoreductases for a specific set of substrates. It reiterates that the grouping of human PDI proteins is primarily based on sequence and structural similarity rather than the enzymatic properties. Detailed information on the human PDI gene family can be found in a recent review article and references therein (1).

The CASQ subfamily is somewhat enigmatic because of its unusual domain organization and specialized functions. CASQ1 and CASQ2, the main calcium-binding proteins of the sarcoplasmic reticulum and the regulator of calcium release in muscle (18), have only b-type domains. Surprisingly, CASQ1 and CASQ2 are the only PDI proteins without ER-retention sequence (Fig. 1); instead, there are C-terminal Asp/Glu-rich (acidic) Ca\(^{2+}\) binding regions involved in Ca\(^{2+}\) flux via regulation of the Ca\(^{2+}\) channel and direct interaction with Ca\(^{2+}\) (19). Functions of CASQ proteins in non-muscle tissues are unknown and they could be functionally irrelevant to other PDI proteins despite the presence of b-type domains.

The AGR subfamily (AGR2, AGR3 and TXNDC12) was identified as novel members of PDI in 2005 (20). In contrast to CASQ proteins, AGR proteins contain single a-type domain plus an ER-retention sequence but no b-type domain. AGR proteins are thus the smallest PDI (> 200 amino acids vs. 400-650 amino acids for typical PDI proteins) (1). Although AGR2 protein contains a non-canonical catalytic motif lacking the C-terminal cysteine (CPHS), it is still capable of forming a mixed disulfide bond with mucin and the mutation of the
Fig. 1. Domain organization of human PDI proteins. Arrangement of TRX-like domains and ER-retention sequence in 21 members of the human PDI gene family are shown here. The catalytically active α-type domains (α and α') are depicted as black boxes with the active site motif sequences shown inside and the catalytically inactive β-type domains (β and β') are depicted as gray boxes. ER-retention sequences are depicted as white boxes with the motif sequences shown inside. The N-terminal signal sequences and other functional domains present in certain PDI proteins are not shown.

conserved cysteine (C81S) abolishes their association (15). Functional analyses of each cysteine in the consensus CXXC motif demonstrated that the N-terminal cysteine is important for the formation of a transient S-S bond with the substrate whereas the C-terminal cysteine is involved in the substrate release (21). An explanation is that the PDI members carrying the non-canonical catalytic motif (e.g., AGR2, AGR3, and ERP44) may have different (and possibly very limited) substrate specificities.

AGR2 and AGR3 were first identified as human orthologs of X. laevis secreted protein XAG-2 which expressed during the development of the mucus-secreting cement gland. Studies have revealed that AGR2 is highly expressed in estrogen receptor α (ERα)-positive malignant breast cancer cells as well as many other adenocarcinomas including colorectal, ovarian, pancreatic and prostate cancers (22). AGR3, originally discovered from a screening of membrane-associated proteins as breast cancer membrane protein 11 (BCMP11), is similarly over-expressed in ERα-positive breast cancer cells (23). The expression of AGR2 and AGR3 genes, both located at 7p21.1, is not always correlated. In fact, the uncoupled expression in prostate and ovarian cancer is also reported (24). Accumulating evidence indicates that AGR2 could function as an oncoprotein that can stimulate the proliferation and promote the metastasis of cancer cells. Clinical studies have focused on the exploitation of this PDI protein as a potential tumor biomarker and prognostic factor. The involvement of PDI proteins, especially AGR proteins, in oncogenesis will be discussed again (see below).

**BIOLOGICAL FUNCTIONS OF PDI PROTEINS**

The catalytic properties and structural features of PDI proteins and the regulation of redox balance by PDI members have been extensively studied and details can be found in a number of review articles (5, 8, 13, 14). In addition to their principal roles as catalysts for the formation and rearrangement of S-S bonds, PDI proteins are also functioning as chaperones (25). Molecular chaperones assist protein folding/refolding by inhibiting the non-productive folding and aggregation of partially folded intermediates or damaged polypeptides through their ability to recognize and interact with proteins in non-native conformation. As explained above, PDI (PDIA1) is the β-subunit of P4H and the chaperone activity rather than the enzyme activity of PDI is necessary for the assembly of P4H molecules (8, 10). Intriguingly, PDI helps the refolding of misfolded proteins without S-S bonds and PDI with no isomerase activity also increases the refolding of substrates (e.g., proinsulin) to a certain extent, suggesting that the catalytic activity and chaperone function of PDI can be dissociated (26). PDI also acts as a molecular chaperone for ERα, altering its conformation and affecting the ERα-ERE interaction. PDI mutant lacking isomerase activity was as effective as normal PDI in enhancing ERα-ERE interaction, indicating that the chaperone activity is independent of catalytic activity of the PDI protein (27). In vascular smooth muscle cells, PDI interacts with NAD(P)H oxidase, the source of reactive oxygen species, and acts as a redox-sensitive regulatory factor by modulating the RhoGTPase activation (28, 29). These results demonstrate that the chaperone activities of PDI are crucial for many client proteins.

While a wealth of information on the functions of archetypal PDI (PDIA1) - as a general catalyst of native S-S bond formation and as a molecular chaperone assisting protein folding - is available, less is known about the functions of other PDI members despite their similarities in sequence and
domain organization. Analysis of mixed disulfide bonds formed by major PDI proteins (e.g., PDIA1, ERp57, and ERp72) revealed distinct substrate specificities and showed that each PDI member is specialized for different sets of substrates (30). There are several members (e.g., PDIp, PDIR, P5, PDILT, ERp44, and Erdj5) also possessing chaperone activities (31). PDIR (PDIp), originally identified as a pancreas-specific PDI protein, plays a similar role as PDIA1 but is less effective in oxidation/reduction (1). Moreover, the substrate specificity (i.e., the binding motif) of PDIR is different from that of PDIA1 (32). PDIp also functions as a chaperone of denatured substrates, which is independent of its enzymatic activity (33). ERp57 (PDIA3), a glycoprotein-specific PDI protein, plays a central role in the peptide loading onto major histocompatibility complex (MHC) class I molecules. In fact, ERp57 is a component of the peptide-loading complex (PLC) which includes TAP1, TAP2, tapasin and calreticulin (34). The redox activity of ERp57 is not required for the peptide loading and the stability of MHC class I molecules is also unaffected by the mutation of the catalytic motif of ERp57 (35). ERp57 is also a major player in the quality control of newly synthesized glycoproteins in conjunction with another ER chaperones calnexin (CNX) and calreticulin (CRT). ERp57 is protecting the substrates from ER-associated degradation (ERAD) at the early stage of chaperone-mediated sorting and, at the later stage, promoting the maturation of substrates that eventually exit to the cell surface via Golgi apparatus (36).

ERp57 is up-regulated in the neurons of prion-related disorders (PrDs) and physically interacts with the cellular prion protein (PrP) (37). Subsequent studies demonstrated that ERp57 controls the maturation and total levels of PrP suggesting that this PDI protein is a cellular factor regulating the biosynthesis and folding of PrP (38). In contrast, PDIA1 promotes the ERAD of misfolded proteins by recognizing and targeting them for degradation (39). The degradation of dislocated MHC class I heavy chain molecules induced by the human cytomegalovirus US2 also requires the substrate binding activity of PDIA1 (40). These results establish that PDI proteins, especially PDIA1 and ERp57, are important for the quality control and proper degradation of proteins in the ER (termed as ‘proteostasis’).

Physiological roles of other PDI family members carrying catalytic α-type domains are poorly understood and data on their functions on ER proteostasis is limited. ERp72 (PDIA4) is one of the largest PDI members (645 aa) and contains five TRX-like domains (Table 1). ERp72 is a component of the multiprotein chaperone complex that includes ER Hsp70 (BiP), Grp94, PDI and ERp29 (41). ERp72 is shown to associate with thyroglobulin and the cell surface NAD(P)H oxidase Nox-1 (13). PDIR (PDIA5) is structurally unique because a N-terminal non-catalytic b-type domain precedes three catalytic α-type domains (Fig. 1). Functions of PDIR are largely unknown, although its expression pattern indicates a role in the folding of glycoproteins. Interestingly, the b-type domain of PDIR has a binding surface for ERp72 and CRT suggesting a functional relationship with these ER proteins (42). In contrast, P5 (PDIA6) cooperates with BiP and acts as a key reductase for the ERAD of misfolded proteins (e.g., proinsulin carrying a mutation). Although P5 shows narrow substrate specificity, it associates preferentially with the proteins requiring BiP function (30, 43, 44). PDILT (PDIA7) is an interesting member of the PDI family because it is expressed specifically in testis and contains unusual catalytic site motifs (SKQS and SKKC) (45). A recent study demonstrated that PDILT, together with the testis-specific CRT-like protein calsperin, is involved in the S-S bond formation and maturation of a membrane-bound metalloprotease ADAM3, which is required for sperm migration (46). ERp44 (PDIA10), a PDI protein in secretory cells, plays a regulatory role in the assembly of IgM and adiponectin in the early secretory pathway (47, 48).

ERp44 is a special member of PDI family since its activity is regulated by pH change which occurs when it shuttles between the ER and cis-Golgi compartment. This pH change enables this PDI to act as a post-ER quality control factor for the assembly of secretory proteins (49, 50). ERp46 (PDIA16, EnrDo-PDI) was originally reported as a PDI protein preferentially expressed in endothelial cells and functions as a survival factor against hypoxic stress (51). Interestingly, ERp46 contains multiple α-type domains linked by unusually long loops but no b-type domain (Fig. 1). This arrangement is not observed in any other PDI proteins and may account for the functional difference between ERp46 and archetype PDI (52). Erdj5 (PDIA19, DNAJC10) is the largest member of the PDI family (793 aa) and also belongs to the DnaJ (Hsp40) heat shock protein family. Erdj5 possesses a N-terminal J-domain that mediates the interaction with BiP. It also associates with EDEM (ER degradation-enhancing α-mannosidase-like protein) and reduces S-S bonds in the client proteins. Erdj5 is a reductase component of the ERAD supramolecular complex that facilitates the accelerated degradation of misfolded proteins (53). A recent study revealed that Erdj5 acts as an ER reductase not only for the proteins to be dislocated to the cytosol for degradation (ERAD substrates) but also for the proteins (e.g., LDL receptor) undergoing productive folding (54). TMX proteins (PDIA11-14) carrying a single α-type domain are the only PDI proteins with a transmembrane domain. Although their enzymatic activities and the expression levels in a variety of tissues have been reported, little is known about their physiological functions (1).
client proteins, PDI proteins play a key role in the maintenance and regulation of proteostasis. Disturbance of proteostasis can lead to the activation of ER stress response known as ‘unfolded protein response (UPR)’. At earlier stages, UPR alleviates the ER stress by up-regulating the chaperones for protein folding and by inducing ERAD and autophagy to eliminate misfolded proteins (55). UPR and ER stress are increasingly implicated in many disease states and accumulating evidence indicates that PDI proteins, as a vital component of UPR, play important roles in the pathophysiology of many disorders. However, recent studies suggest that the impacts of PDI proteins on diseases are much more complex and the unconventional roles of PDI in pathophysiology have also been reported.

PDI and Neurodegenerative Diseases
Neurodegenerative disorders, such as Alzheimer’s diseases (AD), Parkinson’s disease (PD), Huntington’s diseases (HD), amyotrophic lateral sclerosis (ALS) and prion-related disorders, are classified as protein misfolding disorders (PMD) because a hallmark of these diseases is the accumulation of misfolded proteins within affected tissues (56). Special attention has been given to the importance of UPR in PMD and roles of the regulatory factors, including PDI, have been investigated (57). PDI proteins are up-regulated in many PMD and associate with disease proteins in that they are often recruited to the insoluble aggregates (58). PDI proteins are usually cytoprotective and even prevent the aggregation of misfolded proteins (59). However, the opposite effects are also reported and the PDI inhibitor could provide protection against toxic effects (e.g., apoptotic cell death) (60). Interestingly, a number of studies reported S-nitrosylation of PDI in the brain tissues derived from AD and PD. This post-translational modification of PDI, triggered by reactive nitrogen species (RNS), inactivates the catalytic activity of PDI and perturbs proteostasis, which eventually leads to neuronal cell death (61). More information on the roles of each PDI protein in neurodegenerative diseases can be found in a recent review article and references therein (62).

PDI and Cancer
The need to both correct the folding defects and also eliminate the aggregated proteins may explain easily why PDI proteins play important roles in PMD. In contrast, the functions of PDI proteins in oncogenesis and cancer progression are much more complex. There is ample evidence supporting that PDI proteins are strongly associated with a variety of cancer. Although they are among the most abundant cellular proteins, PDI proteins are frequently up-regulated in cancers. Analysis of microarray data sets revealed that PDI (PDIA1) is significantly and universally over-expressed in a wide variety of cancer types including brain, lymphoma, kidney, ovarian, prostate and lung cancers (21). Similar results were also obtained from the analysis of cytosolic and cell surface proteomes derived from various cancers (63, 64). Moreover, over-expressed PDI is frequently correlated with metastasis and invasiveness (65, 66). Other PDI members are also up-regulated in various types of cancer, including metastatic cancer. Analyses of transcriptomes and proteomes revealed that ERp57, ERp72, and P5 are all highly expressed in breast, thyroid, rectal, gastric and liver cancers (67-69). Over-expressed ERp57 and P5 even confer the resistance to cisplatin-induced death of lung cancer cells (70). Accordingly, efforts have been made to use PDI proteins as a prognostic factor for clinical use (71).

PDI proteins are often concomitantly up-regulated with other UPR proteins (e.g., BiP and Grp94), which stresses the importance of UPR in controlling the cell survival (72). Given these findings, the oncogenic effects of PDI proteins are apparently mediated by their role in the UPR signaling pathway. A recent finding showed that PDIR (PDIA5) can activate ATF6α, a membrane-anchored transcription factor that modulates UPR signaling. PDIA5 mediates the rearrangement of S-S bonds in ATF6α and as a consequence promotes the packaging of ATF6α into COPII vesicles (73). Observations that PDI inhibitor(s) can enhance apoptosis in cancer cells or sensitize them to anti-cancer agents suggest a pro-survival role of PDI via regulation of apoptosis (74). Previously we reported that cytosolic PDI is cleaved by caspase-3 and -7 during apoptosis and over-expressed PDI can suppress apoptotic cell death (75). Knockdown of PDI contrarily reduces the growth of ovarian cancer cells (76). On the other hand, the pro-apoptotic effects of PDI were also reported. An organometallic anti-cancer agent causes cytotoxicity by induction of ER stress and up-regulation of several key UPR components including PDI. Similarly, sodium butyrate induces apoptosis in colorectal cancer cells via the up-regulation of UPR proteins (PDI included). Such effects are presumably caused by prolonged activation of UPR via the action of pro-apoptotic transcription factors, especially CHOP (77, 78).

While PDI plays a central role in UPR signaling and the control of cancer cell survival, PDI also facilitates the activation of metalloproteases at the cell surface (e.g., ADAM17) that modulate cell signaling by catalyzing the shedding of membrane-associated proteins (79). The activation of ADAM17 is regulated by redox change and such an effect must be important for the growth factor signaling in cancer cells. It is intriguing that PDI proteins, normally confined to the ER, are also localized at the cell surface and catalyze the thiol-disulfide exchange in extracellular proteins. The presence of PDI proteins at the cell surface and its functional implications have been debated for a while. As mentioned above, surface PDI proteins interacting with client proteins (e.g., metalloproteases, selectins and integrins) catalyze the formation/isomerization of S-S bonds in the clients (80). These effects are particularly interesting because PDI proteins also promote cancer invasion and metastasis. Thiol-disulfide exchange catalyzed by extracellular PDI may activate
proteolytic enzymes (e.g., MMPs) or membrane proteins
mediating cell adhesion/migration (e.g., integrins), both of
which are well-known adhesion/migration factors (21).

In addition to their roles in UPR signaling, control of
apoptosis and the catalysis of external thiol-disulfide exchange,
PDI proteins also contribute to cancer via different pathways.
PDI interacts with a wide variety of proteins (a partial list of
PDI interactome can be found in reference #11). The
chaperone activity of PDI, which is usually thiol-independent,
is crucial for many client proteins, some of which are located
at the cell surface, for proper folding and/or quality control.
Moreover, different PDI proteins have non-redundant functions
and the involvement of each member is mechanistically
distinct. TXNDC5 (endo-PDI), for example, is required for
angiogenesis that involves over-expressed cathepsin B and
MMP-9, which in turn specifically activate the Ras/Raf/MEK/
ERK pathway (81). Erp29 is even more surprising because it
has no catalytic a-type domain; this PDI member is
nevertheless involved in diverse aspects of cancer - progression,
metastasis and apoptosis. Erp29 also functions in UPR
signaling pathway and, more importantly, regulates the
epithelial-mesenchymal transition (EMT) which is critical for
cancer invasion and metastasis. In mesenchymal-like breast
cancer cells, over-expressed Erp29 increases E-cadherin by
inactivation of ERK signaling, which promotes transition into
epithelial properties (82). Erp29 also inhibits apoptosis in
breast cancer cells through the up-regulation of Hsp27 which
is caused by down-regulation of elf2a (83).

Among human PDI proteins, AGR proteins are probably the
most closely related to oncogenesis and several lines of
investigations have established their importance in the tumor
growth and metastasis of cancer. AGR proteins (mostly AGR2
and AGR3) are now considered as oncogenic and pro-
metastatic factors for most of the adenocarcinomas. Clinical
attempts have been made to use AGR2 as a cancer marker for
circulating tumor cells and metastatic cells in lymph nodes
(23). AGR2 is the most-studied member of AGR subfamily
and the elevated expression of AGR2 is frequently used as a
prognostic factor for patient outcome. In contrast, the roles of
AGR3 in tumor biology are relatively unknown despite high
sequence identity (~70%) with AGR2 (84). For simplicity, we
hereafter discuss mostly AGR2. Expression of AGR2 can be
induced by various stimuli including sex hormones, hypoxia,
and ER stress. Estrogen treatment increases AGR2 expression
in breast cancer cells (ER can directly bind to AGR2) and
androgen is also capable of inducing AGR2 in prostate cancer
cells (AGR2 has AR-binding sites in the promoter region) (23,
84, 85).

Mechanistically AGR2 demonstrates several distinct character-
istics. AGR2, plays a role in the regulation of UPR signaling
and control of apoptosis (similar to archetype PDI), which also
requires its dimerization (86, 87). However, the exact roles of
AGR2 in the thiol exchange reactions in the ER are not clearly
understood. Until now, mucin is the only known substrate
requiring AGR2 as a thiol-disulfide exchanger for its
processing (15). A recent report showed that AGR2 also
promotes the presentation of EGF receptor at the plasma
membrane by forming mixed S-S bonds indicating that other
physiological substrates requiring AGR2 function may exist
(88). Functional redundancy of AGR2 with other PDIs in
protein folding and UPR signaling also need to be addressed.
Similar to other PDI proteins, AGR2 can be localized
extracellularly and secreted (89). A recent study claimed that
extracellular AGR2, functionally independent of ER luminal
AGR2, is critical for the tumorigenesis (90). Yeast two-hybrid
assays show that several membrane proteins can interact with
AGR2 (therefore proposed as AGR2 receptors); however, their
actual association inside cells remains to be determined and
the biological consequence of such associations should also
be examined (89). In addition, AGR2 interacts with a number of
proteins with diverse functions, raising a possibility that it
can also act as a molecular chaperone (89). In the future
studies, it should be investigated whether AGR2 also functions
as a molecular chaperone and influences the folding or
assembly of the interacting proteins. Finally, the requirement
of AGR2 in proteostasis or ERAD pathways also needs to be
further studied.

CONCLUSIONS

In this review, we briefly explain the domain architecture of
members of the human PDI gene family and discuss their
biological functions with special attention to the involvement
in human diseases, e.g., neurodegenerative diseases and
cancer. Although PDI proteins serve primarily as ER enzymes
catalyzing the formation/isomerization of disulfide bonds and

Fig. 2. Sub-cellular localizations and functions of PDI proteins
related to cancer. PDI proteins located at the cell surface are
involved in the cell adhesion/migration via activation of metallo-
proteases and integrins. In the ER, PDI proteins are required for
UPR which determines the survival/death of cells via ATF6a
activation or ERAD/autophagy induction. Although the localization
of PDI in the cytosol and/or nucleus are not clearly understood,
PDI proteins control apoptosis via caspase activation and Hsp27
induction. PDI proteins also play a role in the regulation of the
epithelial-mesenchymal transition (EMT). See text for more details.
thus assisting the proper folding of proteins, they also have additional functions as molecular chaperones as well as regulatory factors for protein homeostasis in the ER. Multiple functions mediated by PDI proteins probably allow them to actively participate in diverse cellular processes including UPR signaling and apoptosis, which are critical for survival or death of cells. Increased expression of PDI observed in many types of cancer also indicates that cancer cells, which synthesize more proteins than normal cells to sustain rapid growth, may need higher ER capacity for proper protein folding. This phenomenon may render cancer cells more vulnerable to PDI inhibition than the normal cells, which makes PDI proteins a potential drug target for the treatment of cancers. Subcellular localization of PDI proteins and the proposed function(s) related to oncogenesis and metastasis are summarized in Fig. 2. However, the exact functions of PDIs at different localizations, their roles in cellular signaling pathways other than UPR and, functional difference (or redundancy) between the many PDI proteins need to be extensively studied before we can fully utilize these interesting proteins as an important target for intervention.
