Tennant,6* Amit Kapoor,4 Brad R. Rosenberg6,3 Charles M. Rice,7 Thomas J. Divers,6 Gerlinde R. Van de Walle,1,4 and Troels K.H. Scheel6,7*

BACKGROUND AND AIMs: Equine hepacivirus (EqHV) is phylogenetically the closest relative of HCV and shares genome organization, hepatotropism, transient or persistent infection outcome, and the ability to cause hepatitis. Thus, EqHV studies are important to understand equine liver disease and further as an outbred surrogate animal model for HCV pathogenesis and protective immune responses. Here, we aimed to characterize the course of EqHV infection and associated protective immune responses.

APPROACH AND RESULTS: Seven horses were experimentally inoculated with EqHV, monitored for 6 months, and rechallenged with the same and, subsequently, a heterologous EqHV. Clearance was the primary outcome (6 of 7) and was associated with subclinical hepatitis characterized by lymphocytic infiltrate and individual hepatocyte necrosis. Serocconversion was delayed and antibody titers waned slowly. Clearance of primary infection conferred nonsterilizing immunity, resulting in shortened duration of viremia after rechallenge. Peripheral blood mononuclear cell responses in horses were minimal, although EqHV-specific T cells were identified. Additionally, an interferon-stimulated gene signature was detected in the liver during EqHV infection, similar to acute HCV in humans. EqHV, as HCV, is stimulated by direct binding of the liver-specific microRNA (miR), miR-122. Interestingly, we found that EqHV infection sequesters enough miR-122 to functionally affect gene regulation in the liver. This RNA-based mechanism thus could have consequences for pathology.

CONCLUSIONS: EqHV infection in horses typically has an acute resolving course, and the protective immune response lasts for at least a year and broadly attenuates subsequent infections. This could have important implications to achieve the primary goal of an HCV vaccine; to prevent chronicity while accepting acute resolving infection after virus exposure. (Hepatology 2021;74:1148-1163).

HCV is an important human pathogen of the Flaviviridae family, chronically infecting ~70 million persons, who are at increased risk of...
severe liver disease. Therapeutics have been developed, whereas a vaccine and thorough understanding of pathology and immune responses are lagging. This is largely attributable to the lack of robust immunocompetent animal models, given that chimpanzees are no longer available for research. The enigmatic GB virus B (GBV-B), although related to HCV, never became widely used as a model. Many other related hepaciviruses were subsequently discovered, including those in bats, rodents, monkeys, horses, and cows (reviewed in an earlier work), and these can serve as potential surrogate models. Despite the large diversity of these viruses, equine hepacivirus (EqHV; initially named nonprimate hepacivirus, NPHV) remains the closest genetic relative of HCV and therefore is of particular interest.

EqHV closely resembles HCV, including genome organization, hepatotropism, dual infection outcomes (spontaneous clearance and persistence for >6 months), and, seemingly, the ability to cause fibrotic disease with chronic infection. HCV-RNA accumulation is stimulated by binding of the liver-specific microRNA (miR), miR-122, to the viral 5' untranslated region (5'UTR), and miR-122 similarly binds the EqHV 5'UTR. Infection kinetics are also similar between EqHV in horses and HCV in humans, including rapid onset of viremia and delayed seroconversion. EqHV infection in adult horses led to 43%-100% clearance within 6 months (n = 3-12), which is higher than the 15%-45% observed for HCV. It appears that foals are more prone to chronicity, given that 6 of 6 experimental infections persisted. Only one study characterized the immune response to EqHV infection and found possible evidence of EqHV-specific CD8 T-cell responses in 1 in 3 horses. Viral clearance resulted in nonsterilizing immunity to rechallenge inoculations in 2 horses. For HCV, transcriptomic analyses of peripheral blood mononuclear cells (PBMCs) and liver samples of infected humans and chimpanzees demonstrated strong interferon (IFN) responses associated with viral clearance, whereas T-cell exhaustion often is associated with chronicity. Understanding equine immune responses to EqHV could provide insights critical to understand hepaciviral pathogenesis and

offer immune correlates relevant for HCV vaccine development. Here, we aimed to characterize the course of experimental EqHV infection, with an emphasis on the nature of antiviral immunity and pathology associated with clearance and protection from reinfection, and characterize gene expression changes in the liver and periphery.

Materials and Methods

ANIMALS

All animal procedures were approved by the Cornell University Institutional Animal Care and Use Committee, and horses received humane care according to the Guide for the Care and Use of Laboratory Animals. Horses were median 4 years old (range, 2–8), 5 geldings and 3 mares. Breeds included Morgan Horse (2), Warmblood (2), Arabian (1), Thoroughbred (1), Thoroughbred-Quarter Horse cross (1), and Quarter Horse (1). Horses were confirmed EqHV and equine parvovirus-hepatitis (EqPV-H) serum RNA/DNA and antibody (non-structural protein [NS] 3 or NS1) negative, as described, and healthy by physical examination, complete blood counts, and serum biochemistry, including markers of liver function. Horses were again confirmed EqPV-H negative at the completion of the study.

INOCULATIONS AND SAMPLE COLLECTION

Horses were inoculated i.v. with 5 mL of 10⁷ genome equivalents (GE)/mL of acute-phase NZP1 strain serum. Physical examination was performed at each blood draw. Horses were rechallenged i.v. with the same NZP1 inoculum at 6 months, then with 1 mL of 5 × 10⁷ GE/mL of the divergent CU strain serum 1 month later. Two horses were followed for an additional year and rechallenged again with the CU strain. Serum was collected at week −1, days 0, 1, and 3, and weekly thereafter for 34 weeks. PBMCs were collected at weeks −1, 0, and 1 and then every other week for 26 weeks and prepared by Ficoll density gradient, as described, for flow cytometry. At each collection, additional aliquots of 3.5 × 10⁶ cells were lysed in TRIzol and stored at −80°C until RNA extraction for RNA sequencing (RNA-seq).

Ultrasound-guided transcutaneous liver biopsy was performed with 14-gauge 11.4 cm Tru-Cut biopsy needles (Medline Industries, Northfield, IL) under sedation with i.v. xylazine and local anesthesia with 2% lidocaine. Biopsies were fixed in 10% neutral buffered formalin for histopathology or stored in RNAlater at −80°C for RNA-seq.

One naïve horse (horse N) was administered CU inoculum to demonstrate infectivity of this inoculum. Serum was collected weekly until viral clearance.

SAMPLE ANALYSIS

Weekly serum biochemistry, EqHV RT-qPCR, and serology by a luciferase immunoprecipitation system (LIPS) was performed. Serum miR-122 quantification was performed preinfection and at peak hepatitis. Flow cytometric phenotyping of PBMCs was performed biweekly. RNA-seq on PBMCs and liver biopsies and histopathology on liver biopsies were performed preinoculation (PRE), during early acute infection (ACUTE), near seroconversion (SC), during falling viremia or hepatitis (FV, HEP), and at week 26 (POST; Fig. 1A and Supporting Fig. S1). Hepatitis, or liver injury, was determined by elevation above the reference interval of any of the following circulating liver markers: sorbitol dehydrogenase (SDH); glutamate dehydrogenase (GLDH); aspartate aminotransferase (AST); gamma-glutamyl transferase (GGT); bile acids; or direct bilirubin. Libraries for RNA-seq and scRNA-seq were prepared as described in Supporting Text S2.

STATISTICAL ANALYSIS

Descriptive statistics are provided as median and range. Mixed-effects analysis with horse as a random effect and Dunnett’s post hoc tests were performed on clinical parameters. Significance was set at \( P < 0.05 \). Differential expression for RNA-seq data
was analyzed in R Studio using Limma and Voom packages as described. Primary time points for the samples analyzed are shown in Fig. 1A and Supporting Fig. S1.

**Results**

To characterize the course of infection and immune responses to EqHV, 7 adult horses were inoculated with strain NZP1 virus, originating from a molecular clone. Primary time points for the samples analyzed are shown in Fig. 1A and Supporting Fig. S1.

**EqHV HAS A LOW CHRONICITY RATE IN HORSES**

After primary inoculation, all horses became viremic within 1-3 days. Peak viremia developed by a median of 1 week with titers of $10^7$-$10^8$ GE/mL of serum. Viremia became undetectable by 15.5 (5-19) weeks in 6 of 7 horses (86%; Fig. 1B), and liver viral load reflected viremia (Fig. 1C). Horse J had a markedly shorter duration of viremia, more similar to rechallenge infections (described below). Horse D had multiple reoccurring phases of detectable viremia (Fig. 1B), which could not be explained by natural reinfection (e.g., from cohousing). Sequence analysis further suggested either recrudescence or persistent infection for horse D (Supporting Fig. S3). Thus, primary infection predominantly led to an acute resolving outcome.

At the time of enrollment, horses R and J were naturally and experimentally infected with equine pegivirus (EPgV)-1 and -2 (previously Theiler’s disease–associated virus, TDAV), respectively. EPgVs, like human pegivirus (HPgV/GBV-C), are highly prevalent, clinically silent, and can persistently infect the bone marrow. Here, we observed a transient reduction in EPgV titers upon EqHV infection. Interestingly, horses J and R cleared their persistent EPgV infection concomitantly and within 6 weeks of EqHV clearance, respectively (Supporting Fig. S4). Hence, unrelated general immune activation might play a role in the typical sudden clearance of persistent pegivirus infection. Alternatively, given shared peptide sequences, a role for epitopes conserved between EqHV and EPgV cannot be excluded (Supporting Table S5).

**PRIOR EqHV INFECTION PROVIDES PARTIAL IMMUNE PROTECTION**

Twenty-six weeks after primary inoculation, all horses except horse D were rechallenged i.v.
the same NZP1 strain. Three horses (A, B, and P) experienced short-lived viremia for <2 weeks and titers 2-3 logs lower compared to primary infection. Horse J had borderline detectable viremia (Fig. 1D). Four to 6 weeks after homologous rechallenge, the 6 horses were rechallenged with highly divergent heterologous serum from a persistently infected horse (CU strain). Two horses (N and R) experienced reinfection with duration of <3 weeks and ~1 log lower viremia compared to primary infections (Fig. 1D). No horses became viremic from both rechallenge inoculations. One year later, horses N and P were rechallenged with the CU inoculum. Both horses became viremic with slightly longer viremia lasting ~3 weeks (Fig. 1D). In summary, clearance of primary infection resulted in broad nonsterilizing immunity that reduced viremia levels and duration, and this partial immune protection lasted at least a year.

**EqHV INFECTION CAUSES SUBCLINICAL HEPATITIS**

Hepatitis, as determined by elevated circulating liver markers, began a median of 4 (1-14) weeks after primary inoculation and lasted for a median of 8 (4-16) weeks. Hepatitis was mild and subclinical (Fig. 2A and Supporting Fig. S6A), consistent with mild liver injury. Given that enhanced miR-122 serum levels can be observed during other types of acute and chronic liver injury, we measured serum miR-122 levels and found a significant increase for all 7 horses during peak hepatitis (P < 0.001; Fig. 2A), as well as a significant association with serum AST (P = 0.0499; Supporting Fig. S6B). Measurement of miR-122 levels over time for 2 horses showed that miR-122 was 250%-1,250% of baseline whereas other markers remained near baseline (Supporting Fig. S6C). Thus, miR-122 serves as a marker of acute hepacivirus-induced liver damage in horses as well and appears more sensitive compared to other markers.

Subclinical hepatitis was not a significant feature during rechallenge inoculations. No horses developed hepatitis during NZP1 rechallenge, and 1 developed mild hepatitis during CU rechallenge (horse R; peak GLDH 438% of reference interval, all other liver markers within reference intervals).

**ANTI-NS3 SEROCONVERSION PRECEDES VIRAL CLEARANCE**

To understand humoral immune responses, we analyzed antibodies to the viral nonstructural protein, NS3, which is among the most conserved regions of the polyprotein. Although anti envelope protein responses would be of interest as a potential marker of neutralization potential, their measurement has proven less robust, either for technical reasons or because of lower immunogenicity. Horses seroconverted to NS3 at 7 (1-11) weeks after inoculation (Fig. 2B and Supporting Fig. S6A). Horse J showed markedly shorter time to seroconversion, suggestive of an anamnestic response. Timing of seroconversion did not correlate to the onset of hepatitis (Pearson's r^2 = 0.017; P = 0.78), whereas it always preceded viral clearance by 7.5 (4-12) weeks (Pearson's r^2 = 0.74; P = 0.027; Fig. 2B). Antibody titers slowly waned over time, but increased after productive rechallenge inoculations (Supporting Fig. S7).

**LITTLE EVIDENCE FOR SELECTION OF IMMUNE ESCAPE VARIANTS**

HCV continuously evolves to avoid adaptive immunity. Here, for the NZP1 inoculum and for most acute phase samples, only minimal variation from the consensus sequence was observed (Fig. 3A and Supporting Figs. S3 and S8A). Whereas low-frequency variants (0.1%-20%) accumulated over time, nonsynonymous changes to the consensus sequence were observed only for horse J during its short acute infection: A688V in E2 and I889V in NS2 (Fig. 3A). In homologous rechallenge samples analyzed from 2 horses (A and P), two complete changes in E2 (M409L, L502P) and two ~50% changes in NS5A-B (G2006S, E2682G) were observed for horse P (Fig. 3A), whereas none were observed for horse A (Supporting Fig. S8A). Evidence of immune pressure on residue 409 was observed already at day 65 of the primary infection in horse P (Fig. 3A). The nonsynonymous changes for horses J and P likely represented attempts to escape preexisting immunity.

The CU inoculum differed by 161 amino acids from the NZP1 strain (94.5% identity), and was highly diverse, consisting of three subpopulations.
Major non-synonymous variation was found in E1, E2, NS2, and NS5A (Fig. 3D), with particular variation in the E2 N-terminus, corresponding to the HCV hypervariable region 1 (HVR1), but also in downstream E2 regions (Fig. 3E and Supporting Fig. S8C). Interestingly, after rechallenge of horse R, subpopulation CU II dominated, whereas subpopulations CU II and CU III were selected in horse N and all subpopulations were present in horse P after the 1-year rechallenge. After CU inoculation of a naïve horse (horse O), subpopulation CU III was selected.

In summary, EqHV sequences were stable over time, and we observed little evidence of selection of escape variants to adaptive immunity, including for the presumed low-level persistently infected horse D.

**NO MAJOR CHANGES IN PBMC POPULATIONS DURING EqHV INFECTION**

To monitor cellular immune responses to EqHV infection, complete blood count and flow cytometric phenotyping of PBMCs were performed. Overall, no significant differences were observed in any PBMC...
population over the 26 weeks after primary inoculation (Fig. 4 and Supporting Fig. S9). Total T cells (Fig. 4A), and in particular CD4 T cells (Fig. 4B), comprised the largest PBMC subpopulations and showed little variation over time. Although some horses showed prominent expansion of smaller subpopulations at single time points (Fig. 4; B cells in horse J, monocytes in horse R, and Ki-67+ T cells in horse B), these findings were not consistent across animals and time points. Similar variation was observed in the horses after viral clearance (Supporting Fig. S9), suggesting natural or technical variability.

To reveal potential changes to cellular gene expression not affecting cell frequency, we performed poly(A)-specific RNA-seq on PBMCs at PRE, ACUTE, SC, FV, and POST time points. No
significant differentially expressed (DE) genes were detected at any time point among the 6 resolving horses. To address changes to minor cell-type populations, we further performed scRNA-seq on horse N at the PRE and ACUTE time points. The ACUTE time point was chosen as near peak viremia, when a strong IFN response might be expected. This analysis resolved equine PBMC subpopulations in great depth (21) (Fig. 5A,B). Nonetheless, no infection-mediated differences in cell-population proportions (Fig. 5C) and only minimal differences in gene expression (Fig. 5D) were observed, corroborating the bulk RNA-seq analysis.

ANALYSIS OF EqHV-SPECIFIC T CELLS

To detect EqHV-specific T cells, we stimulated PBMCs with three peptide pools spanning the complete NZP1 NS3 protein. A significant, but variable, increase in the frequency of EqHV-specific IFN-γ-producing T cells after infection or reinfection was observed in all 7 horses (Fig. 6). In 4 horses (B, D, N, and P), the first robust production of EqHV-specific T cells was detected around the time of seroconversion. In horse A, T cells appeared early during infection (4 weeks) and persisted through the study. Horse R only had minimal responses during the entire course of primary infection. Horse J in particular had evidence of preexisting anti-EqHV-specific T cells. Combined with its rapid clearance of infection (Fig. 1B), early seroconversion (Fig. 2B and Supporting Figs. S6A and S7), and rapid viral sequence changes (Fig. 3A), this would be consistent with previous EqHV exposure. An increased number of EqHV-specific T cells was observed after clearance (FV) for horses B, J, and P or after productive rechallenge in accordance with a recall T-cell response for horses A, N, and R. Interestingly, no T-cell expansion was observed after productive rechallenge of horses B, J, or P.
LIVER HISTOPATHOLOGY IS CHARACTERIZED BY NECROTIC HEPATOCYTES AND T-CELL INFILTRATES

HCV causes lymphocytic necroinflammation during acute infection in humans. Here, PRE liver histology was normal, except in horses B (fibrosis) and N (cholangitis; Supporting Fig. S10). These histological findings were distinctly different from findings during EqHV infection in the other horses. During viremia (ACUTE, SC) and HEP, lesions suggestive of viral infection were evident in all 7 horses, including increased numbers of sinusoidal T cells (Fig. 7A,B), portal lymphocytic infiltrates with some breaching of the limiting plate, and small nodules of lymphocytes, neutrophils, and dendritic cells in the parenchyma. Samples from 4 horses had individual necrotic hepatocytes with lymphocytic satellitosis and fewer neutrophils (Fig. 7C). Horse D had active hepatitis at the POST time point, associated with recrudescence of EqHV. There was significant lymphocyte infiltration across all time points in portal tracts ($P = 0.045$; Fig. 7D), but not sinusoids ($P = 0.095$; Fig. 7E). Fibrosis was not a significant feature (Supporting Fig. S10).

LIVER TRANSCRIPTIONAL RESPONSES REVEAL SIGNATURES OF INNATE IMMUNE RESPONSES

To assess intrahepatic transcriptome responses, total RNA-seq was performed on PRE, ACUTE, SC, FV, and POST infection liver biopsies from resolving horses. In a multiple comparison $F$-test for 5 resolving horses (horse B excluded for technical reasons), 46 host genes were significantly (false discovery rate [FDR], <0.1) up-regulated and one down-regulated at any time point compared to PRE (Fig. 8A). The strongest response was at the ACUTE and FV time points (Fig. 8B). Among the 47 DE genes (Fig. 8C and Supporting Fig. S11A), 14 were IFN-stimulated genes (ISGs) and others were consistent with an increase in leukocytes (interleukin-2 receptor subunit gamma [IL2RG], C-X-C motif chemokine receptor 4 [CXCR4], etc.).
CD68, glycoprotein NMB [GPNMB], and macrophage expressed 1 [MPEG1]). The week 5 (FV) and week 27 (POST/second FV) samples from horse D both represented time points of falling viremia and resembled the FV time point for other horses (Fig. 8C). Viral RNA was significant in our analysis and followed intrahepatic RT-qPCR data, with a 100-fold excess of (+) to (−) strand reads (Fig. 8C and Supporting Fig. S11A-C). Among rechallenge samples, horse R, taken during peak viremia and hepatitis and within a week of clearance, showed strong responses; horse P, taken within a week of clearance, showed intermediate responses; whereas horse A, taken 2 weeks after the last positive serum sample, showed no responses (Fig. 8C). An overlap of genes, in particular among ISGs, was found with acute-phase liver samples of HCV-infected chimpanzees or humans, liver transplant organs becoming HCV infected posttransplantation, and rodent hepacivirus (RHV)-infected rats (Fig. 8C). Genes up-regulated at the ACUTE and FV time points were significantly enriched for ISGs (Fig. 8D). Gene Ontology (GO) analysis across the 46 genes up-regulated at any time point showed enrichment for response to virus, exogenous RNA, and innate immunity (Fig. 8E). For the ACUTE time point, terms associated with immune response, antigen presentation and chemokine activity, were enriched, suggesting antigen presentation in the liver taking place already at this time. Down-regulated
genes at the ACUTE time point were enriched for GO terms associated with normal cell and liver function (Supporting Fig. S1). In summary, acute resolving EqHV infection was consistent with signatures of innate immunity and antigen presentation in the liver.
EqHV INFECTION FUNCTIONALLY SEQUESTERS miR-122 IN VIVO

In addition to the direct role of miR-122 in supporting HCV replication, in vitro studies show that HCV sequesters enough miR-122 to deplete the available cellular pool and cause functional derepression of mRNAs normally repressed by miR-122. (30) Here, we intriguingly found that cellular mRNAs normally repressed by miR-122, that is, harboring a (7- or 8-mer) miR-122 seed site in their 3' UTR, were significantly up-regulated at ACUTE and SC time points of EqHV infection, consistent with derepression (Fig. 8F). Up-regulation was less pronounced at FV, and no difference was observed at the POST time point. miRNA-specific derepression was not observed for other abundant miRNAs (Fig. 8F and Supporting Fig. S11E-I). These data represent a functional miRNA sequestration by an RNA virus observed in vivo, and emphasize the functional importance of this intriguing RNA-based mechanism of gene regulation. This might have particular relevance for HCV-induced liver cancer, in that miR-122 is a tumor suppressor. (31)

Discussion

EqHV infection of horses could serve as an animal model to understand fundamental aspects of intrahepatic immune responses that can protect against, or lead to clearance of, hepatoviral infection and thus could be of direct relevance for design of HCV vaccine candidates. Here, we observed a clinical course similar to previous reports, (7-9) with a low chronicity rate and subclinical hepatitis as the primary outcome. Importantly, the inoculum and study animals were negative for EqPV-H, a recently discovered hepatitis virus of horses. (32) Histopathological changes in horses were similar to acute HCV in humans, with lymphocytic infiltrate and some hepatocyte necrosis. A recent report of liver disease associated with chronic EqHV infection also showed similarities to chronic HCV infection in humans. (11) Thus, EqHV also appears to be of clinical importance in equine medicine and warrants further study.

The initial goal of an HCV vaccine is to prevent chronicity while accepting acute resolving infection. (33) Indeed, resolving infection was the primary outcome of EqHV infection in this and previous
studies,\textsuperscript{(6-9)} providing an opportunity to characterize the immune responses leading to viral clearance and protection from challenge infections, which is difficult to study for other species of hepatitis virus, where chronicity is the primary outcome. Clearance was associated with earlier seroconversion and elevated circulating liver markers. This included elevated serum miR-122, which we established as a marker of hepatitis during acute hepatitis virus infection. Given its high sequence conservation, miR-122 may be particularly attractive for studies in nonmodel organisms. Despite no major changes in PBMC populations, EqHV-specific T-cell responses were observed in all horses and expanded during rechallenge and therefore likely contributed to clearance. Therefore, further study of immune responses to EqHV could yield valuable information on protective immunity to hepatitis viruses. Importantly, primary infection with NZP1 provided broad protection against homologous and heterologous rechallenges.

Protective immunity waned over time, with longer duration of reinfection when rechallenged after 1 year. This correlated with observations for HCV in chimpanzees and GBV-B in tamarins.\textsuperscript{(34,35)} Declining antibody titers were also previously observed in horses.\textsuperscript{(7)} This might explain how horses J and O could be NS3 seronegative before inoculation, although progressing with a clinical course consistent with previous infection. Given that only NS3 antibodies were assessed, these horses could have developed responses to other viral proteins, as observed for HCV.\textsuperscript{(36)} Such recurrent infections throughout the life of a horse could explain the high seropositivity rates reported (30\%-40\%).\textsuperscript{(8,37)}

Although HCV rapidly evolves to escape immune pressure and establish persistence,\textsuperscript{(25)} we observed little evidence of immune evasion in primarily resolving EqHV infection. Nonsynonymous changes in horses J (primary infection) and P (rechallenge) might represent adaptive immunity-induced selection, which, however, did not lead to escape. Escape mutations were also not observed for horse D, which was persistently infected for at least 7 months. Our study therefore did not allow evaluation of viral escape in persistently infected horses. We did, however, find that EqHV sequence diversity was particularly high in the N-terminus of the E2 protein, suggesting the existence of an HVR1 similar to that of HCV.\textsuperscript{(26)} For HCV, HVR1 plays a role in viral immune evasion.\textsuperscript{(26)}

Compared to acute HCV infection, equine immune response to EqHV showed similarities in intrahepatic responses, but notable differences in peripheral responses. We observed no major changes in PBMC populations, phenotypes, or gene expression in acute resolving horses, whereas PBMCs from acutely HCV-infected patients showed a strong innate response with type I IFN and inflammatory gene signatures and a possible reduction in B cells.\textsuperscript{(16)} In contrast, equine liver transcriptomic responses were similar to hepatitis-virus-infected human, chimpanzee, and rat liver,\textsuperscript{(17-19,29)} with strong innate immune responses. Whereas we observed a transcriptome signature suggestive of dendritic cell or macrophage antigen presentation during early acute infection, the lymphocytic infiltrate observed on immunohistochemistry (IHC) during seroconversion and hepatitis was not strongly reflected in transcriptomic data. The study may be underpowered to clearly detect this, or the abundant RNA in hepatocytes may have overshadowed any leukocyte signal. Overall, the similar liver response between horses and humans for EqHV and HCV infections, respectively, suggests that horses are likely to be a useful outbred surrogate animal model for intrahepatic pathology and immune responses to HCV. An additional benefit of horses over rodent models is that longitudinal liver tissue from a single animal is readily accessible, allowing multi-time-point analyses, as exemplified here.

HCV sequestration of miR-122, at least \emph{in vitro}, can lead to indirect gene regulation through miRNA “sponging.”\textsuperscript{(30)} This is of particular interest, given that miR-122 is a tumor suppressor, and that miR-122 knockout mice spontaneously develop HCV-like liver disease.\textsuperscript{(31)} Here, we found miR-122-specific derepression of cellular mRNAs upon EqHV infection of the liver and strong correlation with viral load in the liver. Although a causative effect cannot be established, this is a demonstration of functional miRNA sequestration by an RNA virus \emph{in vivo}. These findings emphasize a putative functional importance of this RNA-based mechanism in the cause of liver pathology as a result of hepaciviral infection.

We noted that coinfecting pegiviruses in two cases were cleared concomitantly with the superinfecting EqHV. This was preceded by a transient reduction in EPgV titers upon EqHV infection, which was similar to observations with simian-pegivirus–infected macaques superinfected with simian immunodeficiency
These findings suggest that general innate immune activation incurred by other infections, such as EqHV, might explain the spontaneous clearance of pegivirus even years after infection.\(^{(39)}\) Indeed, concomitant clearance of HPgV and HCV infection was observed in patients after therapeutically administered IFN-\(\alpha\).\(^{(40)}\) It cannot be excluded, however, that the peptide sequences of up to nine amino-acid residues shared between EqHV and EPgVs are targets of adaptive immunity, as demonstrated for HCV and influenza virus.\(^{(22)}\) Whereas interference was observed between different strains of HCV, or HCV and HBV competing for the same liver cells,\(^{(41)}\) coinfection-mediated concomitant viral clearance in unrelated tissues should be explored further.

In summary, our findings suggest an equine immune response more competent in clearing infection compared to human immune responses to HCV. Thus, EqHV infection in horses could provide a useful model to understand drivers of hepacivirus clearance and, consequently, for development of HCV vaccines. We uncovered a primarily hepatic response driving viral clearance, and our findings reveal the specifics of, particularly innate, immune responses linked to resolving infection. The change and waning of these responses over time should be a focus for further understanding of hepaciviral immunity. Although RHV models similarly mirror HCV infection and will be highly useful,\(^{(4)}\) EqHV could be an important parallel system to understand hepaciviral pathology and immune responses, especially because of its closer genetic relatedness to HCV and suitability for within-animal longitudinal sampling. Additionally, EqHV is a significant equine pathogen, thereby improving our understanding of equine liver disease.
