Development of acoustic and optoacoustic on-chip technologies calls for new solutions to guiding, storing and interfacing acoustic and optical waves in integrated silicon-on-insulator (SOI) systems. One of the biggest challenges in this field is to suppress the radiative dissipation of the propagating acoustic waves, while co-localizing the optical and acoustic fields in the same region of an integrated waveguide. Here we address this problem by introducing Anti-Resonant Reflecting Acoustic Waveguides (ARRAWs) — mechanical analogues of the Anti-Resonant Reflecting Optical Waveguides (ARROWS). We discuss the principles of anti-resonant guidance and establish guidelines for designing efficient ARRAWs. Finally, we demonstrate examples of the simplest silicon/silica ARRAW platforms that can simultaneously serve as near-IR optical waveguides, and support strong backward Brillouin scattering.

I. INTRODUCTION

Almost all conventional optical step-index waveguides are unsuitable for confining and supporting the low-loss propagation of acoustic waves. This is because the high refractive index materials making up the core of optical waveguides tend to support acoustic waves propagating at larger velocities than in the low-refractive index cladding layers. Consequently, acoustic waves do not experience total internal reflection (TIR) at the core-cladding interface, and dissipate by free propagation into the cladding. Conversely, acoustic waveguides relying on a reversed design — with the acoustically fast material making up the core, and the fast material the cladding — usually do not guide optical waves, due to a general association between refractive index and material density. Therefore, if we are to pursue systems implementing efficient interaction between propagating optical and acoustic waves, and particularly Brillouin scattering, we need to look beyond the simple physics of TIR.

A number of designs have been put forward to address this challenge. In some, the waveguides are suspended in air by either sparsely positioned or specifically engineered supporting structures. In others, both light and sound are guided along line defects of photonic crystals. Finally, a combination of the desired material properties — high refractive index and low stiffness — has been identified in chalcogenides, allowing researchers to revisit step-index architectures for optoacoustic waveguides.

In this work, we suggest a simple, novel class of waveguides capable of supporting the simultaneous propagation of co-localized optical and acoustic waves, based on the concept of Anti-Resonant Reflection Optical Waveguides (ARROWS). ARROWS were originally studied to enable low-loss optical guidance in the earliest integrated optical waveguides. At that time, integrated photonic devices relied on a small contrast of refractive index inducing TIR between the doped silica medium making up the core, and the pure silica of the cladding. In ARROWS however, this design was inverted, allowing light to be guided in a low-refractive-index (fast) core, surrounded by a high-refractive-index (slow) cladding. This is achieved by engineering the cladding to behave like a Fabry-Perot layer operating at the anti-resonance condition. Variations of ARROWS are now widely used in liquid core waveguides developed for biomolecular detection.

As we show here, the acoustic analogue of such waveguides — Anti-Resonant Reflecting Acoustic Waveguides (ARRAWs), are capable of guiding acoustic waves through an acoustically fast core due to anti-resonances in the acoustically slow cladding. For example, in the particular designs of silicon/silica/silicon planar and cylindrical waveguides depicted in Fig. 1, the acoustic field of ARRAW modes would be predominantly localized to the silicon core.

Furthermore, such ARRAWs can simultaneously support the conventional TIR guidance of light in the high-refractive index core, and consequently amplify local optoacoustic interactions between the co-localized optical and acoustic waves, including Brillouin scattering. Out of the two interaction mechanisms previously identified as contributing to Brillouin effects: photoelasticity and radiation pressure, the former relies on the acoustic field locally modifying the refractive index of the bulk of the medium, forming a moving grating for the optical fields. This effect necessarily relies on the spatial overlap between the optical and acoustic field, and the built-up amplitude of the induced acoustic field, quantified by the mechanical quality factor of the acoustic mode $Q_m$. Here we will analyze in detail how ARRAWs can be optimized to support high-$Q_m$ acoustic, as well as optical modes, co-localized in the core of the waveguide, giving rise to

\[Q_m\]These two authors contributed equally.
strong backwards Brillouin scattering.

The paper is structured as follows: In the two following sections we discuss ARRAW behavior in planar and cylindrical waveguides. Since sound can propagate in a solid medium in the form of both transverse waves (referred to throughout as $S$ waves) and longitudinal waves ($P$ waves), characterized by different velocities, we expect that ARRAW waveguides will exhibit a richer structure of modes than their optical counterparts. For each structure we highlight special, optics-like cases in which shear waves become decoupled from the longitudinal components, and the system is an analogue of an anti-resonant optical waveguide. Finally, we demonstrate how cylindrical ARRAW waveguides can be used to support simultaneous and co-localized optical and acoustic modes in the core of the waveguide, and discuss how such structures thus support efficient backward Brillouin scattering.

![Schematics of (a) planar and (b) cylindrical waveguides.](image)

**FIG. 1.** Schematics of (a) planar and (b) cylindrical waveguides. In both systems the acoustically fast core is made of the same material as the outermost cladding, and supports both longitudinal ($P$) and shear ($S$) waves with velocities larger than the respective velocities in the slow inner claddings. The propagation along the waveguide ($\hat{z}$ axis) is characterized by the wavenumber $\beta$ which is constant throughout the structure, and the transverse wavenumbers $k_{\parallel,j}^{(1)}$ in medium $'j'$.

### II. ARRAW CONDITION IN PLANAR STRUCTURES

In this section, we consider the simplest geometry of a planar waveguide, shown schematically in Fig. 1(a). The central section of the waveguide — the core (marked as '3') — is made up of the same material as the semi-infinite outermost cladding layers ('1' and '5'), and supports $S$ waves with velocity $v_s^{(1)}$, larger than the respective velocity $v_s^{(2)}$ in the inner cladding layers '2' and '4' ($v_s^{(1)} > v_s^{(2)}$). Similar ordering is established for the velocities of $P$ waves in the core and cladding ($v_p^{(1)} > v_p^{(2)}$).

While a more realistic design of the waveguide would include a finite outermost cladding layer surrounded by air, we focus on the semi-infinite model to stress that the acoustic guidance is induced solely by the anti-resonance in the cladding layer, rather than reflection by the solid-air interface. We also neglect viscosity throughout this work, and assume that all the considered materials are isotropic. These approximations allow us to develop tractable analytical models for the physics of ARRAW. Here we demonstrate the ARRAW behavior in the particular platform consisting of a silicon waveguide core and outer cladding, and a silica inner cladding. This choice is motivated by the advancement of the fabrication protocols for these materials, and the significant interest in implementing platforms for Brillouin interaction in silicon.

The waveguiding modes of these structures are found by solving the elastic equation of motion in each layer $j$,

$$\rho^{(j)} \frac{d^2 u^{(j)}}{dt^2} = \nabla \cdot T^{(j)},$$

relating the density $\rho^{(j)}$, displacement field $u^{(j)}$, and stress tensor $T^{(j)}$. Stress is related to strain $S^{(j)} = \nabla \cdot u^{(j)}$ — the symmetrized gradient of the displacement field — via Hooke’s law and the rank 4 stiffness tensor $c^{(j)}$, by the dyadic product $T^{(j)} = c^{(j)} : S^{(j)}$. In isotropic media, this relationship can be expressed through the Lamé parameters $\lambda^{(j)}$ and $\mu^{(j)}$ as $T_{kl}^{(j)} = 2\mu^{(j)} c_{kl}^{(j)} + \lambda^{(j)} \delta_{kl} S_{nm}^{(j)}$. To obtain the solution, we use the ansatz

$$u^{(j)}(r_\perp, z, t) = U^{(j)}(r_\perp) e^{i(\beta z - \Omega t)} + \text{c.c.},$$

where c.c. denotes the complex conjugate, $\Omega$ and $\beta$ are the angular frequency and the longitudinal wavenumber of the mode, respectively, and $r_\perp$ is the transverse coordinate. The fields in neighboring layers are related via the elastic boundary conditions, which require the continuity of the normal components of the adjacent stress tensors, and all the components of the adjacent displacement fields.

The waveguide modes are found by requiring that the amplitudes of incoming fields in the outer-most layers ('1' and '5' in the planar structure — see Fig. 1(a)) vanish. For a planar structure, these modes are found in the basis of shear and longitudinal plane waves in each of the layers, with the transverse wavevectors in medium 'i' denoted by $k_{s}^{(j)}$ and $k_{p}^{(j)}$, respectively. Details of the calculations are given in Appendix A.
A. Out-of-plane polarization (pure shear)

We first consider the case of pure shear waves, with solely out-of-plane displacement fields \(u_x^{(j)} = u_z^{(j)} = 0\). These are uncoupled from longitudinal modes throughout the structure (see the derivations in Appendix A or Ref. [2]). The guidance condition (vanishing amplitude of incoming waves in the outermost layer) yields a rather complex transcendental equation relating \(\Omega, \beta\) and \(k_{s/p}^{(j)}\) (not shown here). However, it can be simplified by considering separately the modes which are symmetric and anti-symmetric with respect to the \(\hat{y}\)-\(\hat{z}\) symmetry plane of the structure at \(x = 0\). The resulting transcendental equations for the symmetric and anti-symmetric modes can be expressed as

\[
(-1 + e^{ick_s^{(1)}r_s}) - e^{2idk_s^{(2)}r_s}(-r_s + e^{ick_s^{(1)}}) = 0, \\
(1 + e^{ick_s^{(1)}r_s}) - e^{2idk_s^{(2)}r_s}(r_s + e^{ick_s^{(1)}}) = 0,
\]

respectively, where as marked in Fig. 1, \(c\) and \(d\) are the thicknesses of the core and cladding layers, and

\[
r_s = \frac{k_s^{(1)}\mu^{(1)} - k_s^{(2)}\mu^{(2)}}{k_s^{(1)}\mu^{(1)} + k_s^{(2)}\mu^{(2)}},
\]

is the acoustic reflection coefficient for a pure S wave propagating in medium ‘1’, reflecting off the interface with medium ‘2’.

1. Optics-like anti-resonance condition

We note that Eqs. (3) and (4) also describe the symmetric and antisymmetric s-polarized optical waveguiding modes, if we replace \(r_s\) with the optical reflection coefficient for non-magnetic materials \(r_{\text{opt}} = (k^{(1)} - k^{(2)})/(k^{(1)} + k^{(2)})\). This is thanks to the purely transverse nature of these modes, and the close mapping between acoustic and optical boundary conditions (with the continuity of tangential components of the electric field, and of normal components of the magnetic field, mirroring the continuity of acoustic displacement and normal stress components, respectively).

Furthermore, to further explore the analogy to optics for ARRAWs, we can simplify the conditions given in Eqs. (3) and (4) by eliminating the dependence on the thickness of the core layer \((c)\) from the transcendental equations. To this end, we choose the core radius \(c\) to correspond to the lowest order symmetric modes supported by the core,\(^{14}\)

\[
k_s^{(1)}c = (2n + 1)\pi,
\]

for \(n = 0, 1, 2, \ldots\), and arrive at the simplified symmetric ARRAW condition from Eq. (5)

\[
e^{2ik_s^{(2)}d} = r_s.
\]

Similarly, the lowest order antisymmetric modes (Eq. 4) are found for a core width satisfying

\[
k_s^{(2)}c = 2n\pi,
\]

which simplifies Eq. (4) to the ARRAW condition given in Eq. (7), identical to the symmetric ARRAW modes.

To simplify this condition even further, we can consider waves propagating in the core at a glancing incidence to the cladding interface, where the reflection coefficient \(r_s \approx -1\). We then retrieve from Eq. (7) the approximate relation:

\[
k_s^{(2)}d = (2m + 1)\frac{\pi}{2},
\]

for \(m = 0, 1, 2, \ldots\), which can be used to identify anti-resonant behavior in the dispersion of acoustic waveguides. This condition is analogous to that found for ARROWs, which reads \(k_s^{(2)}d = (2m + 1)\frac{\pi}{2}\).

2. Exact dispersion relation

The complete, exact dispersion relation of the symmetric, pure shear modes of the planar waveguide with arbitrary core radius \(c\) is found by solving Eq. (5) numerically, and includes families of both conventionally guided and leaky modes. To differentiate between the two, and to establish a parallel between acoustic and optical frameworks, we arbitrarily choose the largest shear velocity of the system \(v_s^{(1)}\) as a reference, and define an acoustic effective mode index

\[
n_{\text{eff}} = \frac{\text{Re}(\beta)}{k_s^{(1)}},
\]

where \(k_s^{(1)} = \Omega/v_s^{(1)}\). Conventionally guided modes, characterized by a real longitudinal wavenumber \(\beta\), and the acoustic field propagating predominantly in the slow cladding layer thus correspond to \(1 < n_{\text{eff}} < v_s^{(1)}/v_s^{(2)}\). Conversely, leaky modes found for \(n_{\text{eff}} < 1\) have complex longitudinal wavenumber.

These features are demonstrated in Fig. 2, where we analyze the symmetric, pure shear modes of a Si(core)/SiO\(_2\)(inner cladding)/Si(outer cladding) planar waveguide. For this setup, the ratio of shear velocities \(v_s^{(1)}/v_s^{(2)} \approx 1.42\). The core width is set to \(c = 1\) \(\mu\m\), and we vary the cladding width \(d\) from approximately 0 to \(d = 0.5\) \(\mu\m\) — a range of sizes which, for acoustic modes propagating at frequency \(\Omega/2\pi = 15\) \(\text{GHz}\), spans \(k_s^{(2)}d \approx 0\) to \(4\pi\). In Fig. 2(a) we plot the effective mode index \(n_{\text{eff}}\), and in (b) the normalized attenuation length \(\text{Im}(\beta)/k_s^{(1)}\).

In Fig. 2(a) we clearly identify the families of modes conventionally guiding the acoustic waves in the inner cladding layer, characterized by \(1 < n_{\text{eff}} < v_s^{(1)}/v_s^{(2)}\). These modes exhibit purely real transverse wavenumbers...
in the cladding ($k_s^{(2)}$), and purely imaginary transverse wavenumbers in the core ($k_s^{(1)}$). This indicates oscillatory behavior of the fields in the cladding, along the transverse direction $x$, and exponential localization of the fields to the interfaces in the core. We clearly identify these features in the two upper panels of Fig. 2(c), which show the displacement field profile of two modes depicted as A and B in Fig. 2(a,b), differentiated by the number of nodes of the displacement field in the cladding (with $k_s^{(2)}d \approx 3\pi/2$ in A and $5\pi/2$ in B).

Modes below the shear core sound line ($n_{\text{eff}} < 1$) are characterized by complex wavenumbers $\beta$, and $k_s^{(j)}$'s, meaning that the field in the core does not simply exponentially decay with $x$ away from the core/cladding interface, but exhibits oscillations governed by $\text{Re}(k_s^{(1)})$. Simultaneously, in a manner consistent with optical leaky modes, the imaginary part of $k_s^{(1)}$ becomes negative, and the outgoing fields increase exponentially with $x$ outside the structure. Just below the $n_{\text{eff}} = 1$ line, the glancing modes form flat-dispersion sections where acoustic waves are confined predominantly to the core (see panels C and E in Fig. 2(c); modes C, D and E were selected to match the local minima of normalized loss $\text{Im}(\beta)/k_s^{(1)}$). This behavior is described approximately by the horizontal gray dotted lines depicting resonances of the core ($n = 0$ in Eq. (6)), which cross with the colored dashed lines indicating the cladding anti-resonance ($m = 0, 1, 2$ in Eq. (9)) near the minimum of the loss function. This agreement breaks down for mode D, which lies far below the $n_{\text{eff}} = 1$ line, and does not meet the glancing incidence criterion. We also identify a prominent anti-crossing behavior near the crossings between the resonances of the core (horizontal dotted gray lines) and resonances of the cladding ($k_s^{(2)}d = m\pi$, anti-crossings marked with hollow circles). At these points the cladding transmission reaches a local maximum, suppressing the formation of a waveguiding mode.

This simple analysis allows us to identify the ARRAW modes as the leaky acoustic modes localized to the fast medium, and found at the local minima of loss, right below the sound line corresponding to the velocity of waves.
in the fastest medium (core) — here illustrated as modes C and E. As we show below, this definition naturally extends to polarizations and media supporting the propagation of $P$ waves.

B. In-plane polarization

In-plane polarization of the waveguiding modes ($u_y^{(i)} = 0$) necessarily couples the in-plane shear ($S$) and longitudinal ($P$) waves. Consequently, the transcendental equation for the modes is more complex (see derivation in Appendix A), even if we focus on a particular symmetry of both the components. Nevertheless, it submits to numerical solution. As in the out-of-plane polarization case, we focus on symmetric modes for simplicity. Furthermore, to observe anti-resonant behavior of longitudinal waves, characterized by substantially longer wavelengths (since $v_p^{(2)}/v_s^{(2)} \approx 1.6$), we consider claddings of larger thickness, comparable to the longitudinal wavelength in the cladding medium.

In the following discussion, it is useful to draw from the analytical framework presented in Appendix A and treat $S$ (shear) and $P$ (longitudinal) components of the acoustic wave (denoted as $u_s$ and $u_p$) as if they were independent, and characterize regimes in which these components behave as evanescent (exponentially decaying away from interfaces in either direction), conventionally guided (in the inner cladding) or leaky waves. While, as we show below, the coupling between the $S$ and $P$ waves necessarily blurs the characteristics of these regimes, this approach is instructive in developing intuition about the...
in-plane polarization acoustic guidance.

The dispersion relations and loss of the symmetric, in-plane modes are shown in Fig. 3(a) and (b), respectively. The field distributions (separated into S and P components described as the norms of $u_s$ and $u_p$ fields defined in Appendix A) of modes marked as A-F are shown in (c), chosen to best represent 4 distinct regimes of acoustic guidance. The first, denoted in Fig. 3(a) as conventional $S$ and evanescent $P$ ($1 < n_{\text{eff}} < v_s^{(1)}/v_p^{(2)}$), is characterized by real $\beta$, $k_s^{(2)}$, and imaginary $k_s^{(1)}$ (indicating conventional $S$ guidance in the cladding), as well as purely imaginary transverse $P$ wave $k_p^{(i)}$ (indicating surface states with fields exponentially decaying away from the interface in the core and the outer layer). Two examples of such modes are shown in panels A and B in Fig. 3(c).

For $n_{\text{eff}} < 1$, $\beta$ becomes complex, and the shear components of the fields diverge exponentially outside of the structure as in the out-of-plane case (see panels C-F), as expected for the leaky $S$ modes. In particular, as $n_{\text{eff}}$ is reduced below $v_s^{(1)}/v_p^{(2)} \approx 0.89$, we first find the regime ($n_{\text{eff}} > v_s^{(1)}/v_p^{(2)} \approx 0.6$) in which $P$ components become conventionally guided in the inner cladding (see modes D and E). Modes found in this regime exhibit very particular characteristics, as they mix the conventional-like localization of the $P$ waves with the leaky-like exponential increase of displacement fields in the outer cladding layer (see blue lines in D and E) due to the negative imaginary component of $k_p^{(1)}$ (resulting from complex $\beta$, or equivalently, coupling to the $S$ waves). Furthermore, for particular geometric parameters the normalized loss of these modes (Fig. 3(b)) appears to dip towards 0 — a behavior which we identify with the onset of the simultaneous anti-resonant guidance of $S$ waves (note the localization of $S$ waves represented by orange lines to the core in D and E) and conventional $P$ guidance.

Finally, further reducing $n_{\text{eff}}$ below $v_s^{(1)}/v_p^{(1)}$ brings us to the leaky $S$ and $P$ regime, in which the displacement fields of both the $P$ and $S$ contributions oscillate in the core and in the inner cladding layer. We can therefore

FIG. 4. (a) Dispersion, (b) loss, and (c) field distribution plots of azimuthally symmetric ($m = 0$) torsional modes of a cylindrical waveguide. Radius of the silicon core is set to 0.5 $\mu$m, and the cladding thickness $d$ (cladding region is marked with gray background in (c)) is normalized by the wavelength of $S$-waves in the cladding material (silicon) $\lambda_s^{(2)} \approx 0.25$ $\mu$m at the angular frequency of $2\pi \times 15$ GHz. Field distributions represent conventionally guided $S$ (A,B), and leaky (C-E) modes.
expect to find modes for which both the $P$ and $S$ waves build up an anti-resonance in the inner cladding, by approximating the ARRAW condition given for $S$ waves in Eq. (9). These conditions will not be fulfilled exactly, since the transverse wavenumbers $k_s^{(2)}$ and $k_p^{(2)}$ are imaginary, and the two components are coupled. Nevertheless, we can find ARRAW modes, such as the one shown in panel F, which meet our previous definition: they are characterized by a local minimum of loss, lie immediately below the $n_{\text{eff}} = v_s^{(1)}/v_p^{(1)}$ sound line, and exhibit a strong localization of both the $P$ and $S$ components in the core.

We should also note that the combination of Si/SiO$_2$ materials forbids the formation of modes with both $S$ and $P$ components which are conventionally guided, since the regions of effective mode velocities $(v_s^{(2)}, v_s^{(1)})$ and $(v_p^{(2)}, v_p^{(1)})$ do not overlap. Such regions could be found for other combinations of materials, e.g. Si/As$_2$S$_3$ or SiO$_2$/As$_2$S$_3$.

III. ARRAW MODES IN CYLINDRICAL WAVEGUIDES

In order to bring the concept of ARRAW closer to applications in nonlinear optical system, we now investigate ARRAW behavior in cylindrical waveguides, as shown schematically in Fig. 1(b). In these designs, the core (medium ‘1’) of radius $a$ is surrounded by a cladding ‘2’ of thickness $d$ and, as for layered waveguides, the core and outer semi-infinite layer ‘3’ are made up of the same material. The mathematical formulation of this problem is discussed in detail in Appendix B, where we expand the fields into a basis of torsional ($S$ wave components only) and dilatational modes. For simplicity, we will consider only the azimuthally symmetric case ($m = 0$), in which the two are decoupled, and the torsional modes have azimuthal component $u = u_\theta \hat{\theta}$ only (see Appendix B). We thus arrive at a system much like that found in planar waveguides, where one family of modes (torsional) depends on the shear velocities only, while the other family (dilatational) mixes $S$ and $P$ components. We thus expect to recover the optics-like ARROW characteristics of the former, and the ARRAW-like, complex modes of the latter.

A. Torsional modes

In Fig. 1(a) we present the dispersion of torsional modes, and identify two families of modes: conventional $S$, with $1 < n_{\text{eff}} < v_s^{(1)}/v_s^{(2)}$, and leaky $S$, with $n_{\text{eff}} < 1$. The azimuthal (and only) component of the displacement field is shown, for a collection of modes, in Fig. 1(c). For A and B, the conventionally guided $S$ modes are localized to the cladding layer, and decay exponentially in the outermost layer due to the purely imaginary transverse wavenumber $k_s^{(3)} = i\kappa_s^{(3)}$ (with $\kappa_s^{(3)} > 0$). For the leaky modes C-E, we find that the effective index $n_{\text{eff}}$ of all the modes increases with the cladding thickness $d$, until the dispersion crosses into the conventional $S$ guidance regime. In particular, by tracing the evolution of the branch with modes C and D, we see that as the dispersion approaches the $v_s^{(1)}$ sound line, oscillations in the cladding layer become more pronounced, and the anti-resonant response becomes significantly stronger, leading to substantial quenching of losses, as observed previously in optical ARROW systems.

B. Dilatational modes

Dilatational modes share the fundamental dispersion characteristics of in-plane modes in planar waveguides, with the four regimes marked in Fig. 1(a) and illustrated in (c), mixing evanescent, conventional, and leaky characteristics of the $S$ (orange lines) and $P$ (blue lines) waves of the displacement field.

In particular, for $v_s^{(1)}/v_p^{(1)} < n_{\text{eff}} < v_s^{(1)}/v_p^{(2)}$ we again find the peculiar modes (C and D) characterized by very small loss, for which the $P$ waves have the dual characteristic of conventional-like localization to the inner cladding, and leaky-like exponential growth in the outer cladding. For these modes, $S$ waves are clearly localized through the anti-resonance to the core of the waveguide.

Furthermore, as for the in-plane modes of the planar waveguide, we expect to find the ARRAW modes right below the fastest sound velocity $v_p^{(1)}$, in the leaky $S$ and $P$ regime. While these modes are not clearly defined by a dip in loss, we can nevertheless identify ARRAW behavior in the field distributions of the mode. For example, mode E carries the characteristics of both the $S$ and $P$ components localized to the core, and oscillatory behavior of the components in the cladding layer.

The above-identified ARRAW modes would clearly not constitute very good acoustic waveguiding channels, as their normalized loss barely reaches $10^{-2}$ (see point F in Fig. 3 and point E in Fig. 4). This is mostly due to the fact that the core layers of both the planar and cylindrical systems investigated to this point are too narrow to fit multiple wavelengths of the longer, $P$ acoustic waves $(k_p^{(1)} a, k_p^{(1)} c < \pi)$. While their geometric parameters were chosen to provide insights into the different regimes of operation of layered acoustic waveguides, we can now consider systems with larger core thicknesses that will provide much better examples of ARRAW guidance, characterized by lower losses and stronger localization of the field to the core, for application in nonlinear Brillouin scattering.
IV. STIMULATED BRILLOUIN SCATTERING IN CYLINDRICAL ARRAYS

In the previous section, we considered the acoustic response of cylindrical silicon/silica ARRAYS. Below, we show that such systems, slightly modified to suppress acoustic losses, can simultaneously support propagation of conventionally guided optical waves, and — thanks to the co-localization of optical and acoustic excitations — enable nonlinear Brillouin scattering of light propagating through the waveguide. We will focus on the particular case of Backward Stimulated Brillouin Scattering (BSBS). In BSBS, two counter-propagating optical modes with wavenumbers $k_i$ and frequencies $\omega_i$ ($i = 1, 2$) couple via scattering with an acoustic wave characterized by $\beta$ and $\Omega$. The general phase- and frequency-matching conditions

$$k_1 + \text{Re}(\beta) = k_2, \quad \omega_1 + \Omega = \omega_2,$$

(11)

can be simplified if we consider the special case of intramodal BSBS, in which the counter-propagating optical fields occupy the same mode. Furthermore, since the acoustic frequencies (up to tens of GHz) are much smaller than the optical ones ($\omega_1 \approx \omega_2 \sim 2\pi \times 4 \times 10^{14} \text{ Hz} \gg \Omega$), we find a simple relationship between the acoustic and optical wavenumbers: $\beta \approx 2|k_1|$.

The nonlinear Brillouin interaction can be used to transfer energy between the two propagating optical fields, at the rate determined by the Brillouin gain $[1, 2, 9, 13, 22]$. In a typical realization, Brillouin interaction amplifies the flux of energy of a weak Stokes optical field $P^{(S)}$ co-propagating (for Forward SBS) or counter-propagating (BSBS) with respect to a much stronger pump field $P^{(p)}$ according to $P^{(S)}(z) = P^{(S)}(0) \exp(\Gamma P^{(p)} z)$. The Brillouin gain coefficient can be expressed as

$$\Gamma = 4\omega_1 \frac{Q_m |Q^{(\text{PE})}_1 + Q^{(\text{MB})}_1|^2}{\mathcal{E}_b P^{(1)}(p) P^{(2)}},$$

(12)

where $\mathcal{E}_b$ denotes the energy density of the acoustic wave, and $P^{(i)}$ describes the energy flux of optical mode $i$. $Q^{(\text{PE})}_1$ and $Q^{(\text{MB})}_1$ describe two physical processes governing the Brillouin interaction: the photoelastic effect and
radiation pressure (referred to as the Moving Boundary, or MB effect), respectively, localized in the bulk and at the boundary of the waveguide. We expect, and verify, that the ARRAWs will primarily enhance the former effect, quantified by the transverse overlap integral between the electric ($e^{(i)}$) and acoustic ($u$) fields:

$$Q_{1}^{(PE)} = -\varepsilon_0 \int d^2r d^2\rho \sum_{ijkl} \langle e_{i}^{(1)} \rangle \langle e_{j}^{(2)} \rangle p_{ijkl} \partial_k u_p$$

$$= \int_0^\infty dr \tilde{Q}_{1}^{(PE)}(r),$$

and the Pockels tensor ($p_{ijkl}$). The interaction due to the radiation pressure is typically negligible for waveguides with transverse sizes over 1 µm. Finally, $Q_m$ is the mechanical quality factor, typically used in lieu of the propagation loss, and here defined by the real and imaginary components of the longitudinal acoustic wavenumber $Q_m = \text{Re}(\beta)/[2\text{Im}(\beta)]$.

For simplicity, we focus on the interaction between conventionally guided optical TM, TE and hybrid (HE/EH) modes localized to the core of the waveguide.

To optimize the BSBS gain, we look for parameters of the system that will simultaneously maximize the mechanical quality factors $Q_m$, and the overlap term $Q_1^{(PE)}$:
1. Optimizing the mechanical quality factor

The mechanical quality factor $Q_m$ is optimized by tuning the geometric parameters of the structure (core radius $a$ and cladding thickness $d$), and mechanical frequency $\Omega$. Since the underlying physics of acoustic systems is linear, the modes are invariant under simultaneous rescaling of the geometric parameters and wavelength (or inverse frequency), and consequently, we can consider two of these three parameters as independent. Here, we fix $\Omega/2\pi = 15$ GHz, and optimize $a$ and $d$. For clarity, in Fig. 6(a) we show the dispersion relation and mechanical quality factors of the highest-$Q_m$ ARRAW modes lying right below the last sound line ($n_{\text{eff}} \leq v_p^{(1)}/v_s^{(1)}$), as function of the cladding thickness $d$.

Since we aim to optimize the waveguiding properties of the structure, we consider larger core radii $a = 1.5 \mu m$, which offer mechanical quality factors over 1000 (structures with different core radii are analyzed in Table I). The oscillatory dependence of $Q_m$ on $d$ describes the transition between resonant and anti-resonant response of the cladding. As the maximum $Q_m$ increases with the core radius (see results in Table I), it is tempting to favour the larger core geometries. However, we should note that our calculations do not account for the viscous losses in the material, which typically limit the $Q_m$ to the order of ~1000, and thus suppress the advantage of eliminating the acoustic radiative dissipation channels. Furthermore, it was shown in previous reports that the PE contribution to SBS gain exhibits an approximate $a^{-2}$ scaling with the transverse dimension of the waveguide.

2. Overlap term $Q_1^{(PE)}$

The particular choice of the optical mode which can undergo BSBS coupling via a selected ARRAW mode is predominantly limited by the phase-matching condition (Eq. (11)), which dictates the magnitude of the longitudinal wavenumber $k_1$ of the optical mode. Therefore, the only parameters which we can optimize here are the type of optical mode (TE, TM or hybrid), and its effective mode index $n_{\text{eff}}$. We first focus on the lowest $n_{\text{eff}}^{\text{opt}}$ (and high-order) modes supported by the core, and later (Fig. 6(d) explore the dependence on the order of the optical mode) In particular, in Fig. 6(b) we analyze the BSBS gain coupling between these three types of modes (TM$_4$, TE$_4$ and EH$_{17}$/HE$_{17}$) as a function of cladding thickness — a parameter which should have little effect on the optical guidance, but governs the ARRAW behavior. We find that the gain closely follows the dependence of the quality factor $Q_m$, suggesting that neither the overlap integral $Q_1^{(PE)}$ nor the normalization factors $E_b$ and $P^{(i)}$ change significantly with $d$.

The orange dot in the plots in Fig. 6(a,b) denotes the parameters of optical and acoustic modes analyzed in detail in Fig. 6(c). The radial profile of the acoustic field, shown in the top panel of Fig. 6(a), indicates significant localization to the core — as expected for large-$Q_m$ ARRAW modes. Together with the core-localized optical mode (middle panel), this results in a strong localization of the $Q_1^{(PE)}(r)$ overlap integral kernel shown in the bottom panel.

To further enhance the Brillouin gain, we can consider changing the geometric parameters of the waveguide (e.g. core radius $a$), operating mechanical frequency $\Omega$, or explore coupling to different orders of the optical modes. We provide a comparison of selected BSBS ARRAW systems in Table I, and find a few guiding principles for designing such systems:

- as reported by Rakich et al., the smaller cross section waveguides yield larger BSBS gain — however, this principle trades off against the sharp decrease in mechanical quality factor for small core radii; simultaneous increase of mechanical frequencies (e.g. towards 30 GHz frequency) should allow us to retain high $Q_m$’s due to the linear nature of the acoustic physics, but the overall gain would likely become suppressed by the increased non-radiative acoustic losses at higher frequencies,

- dependence on the order of optical mode (or effective optical mode index) is not monotonic, and in fact is the smallest for the most homogeneous field of the lowest order mode; this dependence is shown, for a number of hybrid modes from HE$_{17}$ to HE$_{12}$, in Fig. 6(d).

A. Comparison to other BSBS waveguides

It is instructive to compare the nonlinear performance of the investigated ARRAW to other BSBS waveguiding systems. The mechanical quality factor $Q_m$ of our structure can easily reach $10^3$, which is a result comparable to that found in suspended waveguides, in which the radiative dissipation of acoustic waves is suppressed, and $Q_m$ becomes limited by the intrinsic viscous losses in silicon. Furthermore, the maximum Brillouin gain found in our system (nearly 1000 (W m$^{-1}$)) is of a similar order to that reported in GHz BSBS systems, including those based on sub-micron silicon slot waveguides where the optoacoustic interaction is dominated by radiation pressure, or relying on materials with different optoacoustic properties, such as chalcogenides.

B. Outlook

Our simple designs can be further modified to better suit integrated platforms by considering finite outer-cladding layers or multiple anti-resonant layers.

TABLE I. Backwards SBS gain between acoustic ARRAW modes and optical modes of a silicon/silica/silicon cylindrical waveguide shown in Fig. 1(b).

principles of ARRAW guidance can also be combined with other mechanisms, for example by using the anti-resonant reflection to suppress the acoustic dissipation from exposed cores of rib waveguides into the substrate. Alternatively, the entire designs could be reversed and implement optical anti-resonant guidance and conventional acoustic TIR.

V. SUMMARY

We have proposed a new type of multilayered optoacoustic Anti-Resonant Reflecting Acoustic Waveguide capable of supporting the simultaneous and co-localized guidance of GHz acoustic and near-IR optical signals. While the optical waves are TIR-guided in the high-refractive index core, the acoustic waves are localized to the core by anti-resonant reflection in the inner cladding layer. This mechanism can be harnessed to efficiently suppress the dissipation of acoustic waves into the outermost layers, and enable efficient Brillouin scattering between the counter-propagating optical waves. Our estimates indicate that silicon/silica ARRAWs can match the record performance of the Backwards Stimulated Brillouin Scattering in silicon/silica platforms without relying on sub-micron confinement of fields or interactions induced by radiation pressure.

Appendix A: Planar waveguide

In this section we present the transfer matrix method used to derive transcendental conditions for waveguiding modes of the planar structure shown in Fig. 1(a).

To find waveguiding modes, we require that fields in the first and last media be continuous at each interface are outgoing only, i.e.

\[
\begin{bmatrix}
e^{-ik_1 j x_j} & e^{-ik_2 j x_j} \\
-ik_1 j x_j & -ik_2 j x_j
\end{bmatrix}
\begin{bmatrix}
u_1^{(j)} \\
u_2^{(j)}
\end{bmatrix}
= \begin{bmatrix}
M^{(j)}(x_j) \\
M^{(j+1)}(x_j)
\end{bmatrix}
\begin{bmatrix}
u_1^{(j+1)} \\
u_2^{(j+1)}
\end{bmatrix}
= S^{(j)} \tilde{u}^{(j)} = \tilde{u}^{(j+1)}.
\]

This formalism relates the fields in the last medium \(j = 5\) with the first medium \(j = 1\) \((S^{(all)} \tilde{u}^{(1)} = \tilde{u}^{(5)})\), through the matrix

\[
S^{(all)} = S^{(4)} S^{(3)} S^{(2)} S^{(1)}.
\]

To find waveguiding modes, we require that fields in the first and last medium should be outgoing only, i.e.

\[
\tilde{u}^{(1)} = \begin{bmatrix} 0 \\ u_{(1)}^{(5)} \end{bmatrix}, \quad \tilde{u}^{(5)} = \begin{bmatrix} u_{(5)}^{(1)} \\ 0 \end{bmatrix}.
\]

This condition only holds when \(S^{(2)}_{22} = 0\), which defines a 4th order polynomial in the quantities \(k_s^{(j)}\). We can simplify it by considering the symmetric and antisymmetric modes of the structure separately. Expressing the field \(u^{(3)}\) through the transfer matrix, imposing the above symmetry conditions, and accounting for the vanishing of the incident wave in medium 1, we arrive at the resonance condition:

\[
\left(W^\pm S^{(2)} S^{(1)}\right)_{22} = 0,
\]

where \(W^\pm\) imposes the symmetry/antisymmetry of \(u^{(3)}\).  

1. Out-of-plane polarization

We start with the simpler case of out-of-plane polarization, in which modes are composed of shear waves only, and displacement fields have \(u_y\) components only, meaning that the boundary conditions demand the continuity of \(u_y\) components of the displacement field and continuity of the \(T_{xy}\) element of the stress tensor.

We use the ansatz

\[
u^{(j)}(x, z, t) = \hat{y} (u_{+}^{(j)} e^{ik_{+}^{(j)} x} + u_{-}^{(j)} e^{-ik_{-}^{(j)} x}) e^{i(\beta z - \Omega t)} + c.c.,
\]

where \(u_{+}^{(j)}\) and \(u_{-}^{(j)}\) are undetermined coefficients for the right- and left-propagating fields in the \(j\)th layer respectively. We can thus represent the boundary conditions at \(x = x_j\) between the \(j\)th and \((j + 1)\)th layer as

\[
W^\pm = \begin{bmatrix} 1 & 0 \\ 1 & \pm 1 \end{bmatrix}.
\]

The condition \(\text{(A6)}\) is equivalent to Eqs. (3) and (4).

2. In-plane polarization

For in-plane polarization, the displacement fields lie in the \(\hat{x}-\hat{y}\) plane, and they have both longitudinal and transverse contributions. Importantly, these two contributions exhibit different transverse wavevectors. The displacement field components thus have two right- and left-propagating field coefficients each \((u_{+}^{(j)}\) and \(u_{-}^{(j)}\)):

\[
u^{(j)}_p(x, z, t) = \left[ \hat{x} k_p^{(j)} x + \hat{z} \beta \right] u_{p+}^{(j)} e^{ik_p^{(j)} x} + \left[ -\hat{x} k_p^{(j)} + \hat{z} \beta \right] u_{p-}^{(j)} e^{-ik_p^{(j)} x} e^{i(\beta z - \Omega t)} + c.c.,
\]

\[
u^{(j)}_s(x, z, t) = \left[ -\hat{x} \beta + \hat{z} k_s^{(j)} \right] u_{s+}^{(j)} e^{ik_s^{(j)} x} + \left[ \hat{x} \beta + \hat{z} k_s^{(j)} \right] u_{s-}^{(j)} e^{-ik_s^{(j)} x} e^{i(\beta z - \Omega t)} + c.c.,
\]

\[
u^{(j)}(x, z, t) = \nu_p^{(j)}(x, z, t) + \nu_s^{(j)}(x, z, t).
\]

The relevant elements of the stress tensor which need to be continuous at each interface are \(T_{2x}^{(j)}\) and \(T_{2z}^{(j)}\).

The matrices \(M^{(j)}(x)\) and vectors \(\tilde{u}^{(j)}\) are thus given by:

\[
\tilde{u}^{(j)} = \left[ u_{p+}^{(j)} u_{p-}^{(j)} u_{s+}^{(j)} u_{s-}^{(j)} \right]^T.
\]
with
\[ m_{31} = \left[ (\lambda^{(j)} + 2\mu^{(j)}) (k_p^{(j)})^2 + \lambda^{(j)} \beta^2 \right] e^{ik_p^{(j)}x}, \]
\[ m_{32} = \left[ (\lambda^{(j)} + 2\mu^{(j)}) (k_p^{(j)})^2 + \lambda^{(j)} \beta^2 \right] e^{-ik_p^{(j)}x}, \]
\[ m_{33} = -2\mu^{(j)} \beta k_s^{(j)} e^{ik_s^{(j)}x}, \]
\[ m_{34} = -2\mu^{(j)} \beta k_s^{(j)} e^{-ik_s^{(j)}x}, \]
\[ m_{41} = 2\mu^{(j)} \beta k_p^{(j)} e^{ik_p^{(j)}x}, \]
\[ m_{42} = 2\mu^{(j)} \beta k_p^{(j)} e^{-ik_p^{(j)}x}, \]
\[ m_{43} = \mu^{(j)} \left( \left( k_s^{(j)} \right)^2 - \beta^2 \right) e^{ik_s^{(j)}x}, \]
\[ m_{44} = -\mu^{(j)} \left( \left( k_s^{(j)} \right)^2 - \beta^2 \right) e^{-ik_s^{(j)}x}. \]

As in the previous section, this formulation of matrices \( M^{(j)} \) allows us to construct matrices \( S^{(j)} \) as in Eq. (A4), which will readily mix the \( S \) and \( P \) components of the fields in layers \( j \) and \( j+1 \). This behavior signals coupling between the \( S \) and \( P \) waves through scattering at interfaces.

To find waveguiding modes, we again require that fields in the first and the last layers should be \textit{outgoing} only, i.e.
\[
\tilde{u}^{(5)} = \begin{bmatrix} u_p^{(5)} \\ u_p^{(5)} \\ u_s^{(5)} \\ 0 \\ 0 \end{bmatrix}, \quad \tilde{u}^{(1)} = \begin{bmatrix} u_p^{(1)} \\ u_p^{(1)} \\ u_s^{(1)} \\ 0 \\ 0 \end{bmatrix}. \tag{A13}
\]

Thus, we formulate the transfer problem as \( \tilde{u}^{(5)} = S^{(\text{all})} \tilde{u}^{(1)} \), and look for the solutions to
\[
\det \begin{bmatrix} (S^{(\text{all})})^{22} & (S^{(\text{all})})^{24} \\ (S^{(\text{all})})^{42} & (S^{(\text{all})})^{44} \end{bmatrix} = 0, \tag{A14}
\]

for discreet values of \( \beta \) and fixed \( \Omega \). As discussed in the main text, this transcendental equation will have both real and complex solutions, corresponding to conventional and ARRAW modes, respectively. Treating the real and imaginary parts of \( \beta \) as independent variables and applying one of the many standard multidimensional root-finding algorithms is computationally intensive and time-consuming. However, by treating \( \beta \) as a complex variable, we are able to apply methods of complex analysis; \( \text{Appendix A} \) is analytic everywhere except along a branch cut on the real axis. In order to calculate the dispersion relations presented in the main text, we applied the \textit{Global Complex Roots and Pole Finding} (GRPF) algorithm developed in [18].

**Appendix B: Cylindrical waveguide**

In this section we present the transfer matrix method used to derive transcendental conditions for waveguiding modes of the cylindrical structures shown in Fig. 1(b).

1. **Basis of modes for a layered cylindrical waveguide**

The problem in question is that of a cylindrical rod of isotropic material and infinite length, as shown in Fig. 1(b). The problem is solved using cylindrical coordinates \((r, \theta, z)\) and assuming a time-harmonic solution of the form
\[
\mathbf{u}(r, \theta, z, t) = \mathbf{U}(r, \theta)e^{i(\beta z - \Omega t)} + \text{c.c.} \tag{B1}
\]

The relevant elements of the stress tensor in cylindrical coordinates are identified as
\[
T_{rr} = \lambda \left( \partial_r u_r + \frac{1}{r} \partial_\theta u_\theta + \frac{u_r}{r} + \partial_z u_z \right) + 2\mu \partial_r u_r, \tag{B2}
\]
\[
T_{r\theta} = \mu \left( \frac{1}{r} \partial_\theta u_r - \frac{u_\theta}{r} + \partial_r u_\theta \right), \tag{B3}
\]
\[
T_{rz} = \mu \left( \partial_z u_r + \partial_r u_z \right). \tag{B4}
\]

A convenient expansion for the modes of the cylinder can be derived by expressing the displacement fields \( \mathbf{u} \) through two scalar potentials \( \Phi \) and \( \Psi \) as
\[
\mathbf{u} = A \nabla \Phi + B \nabla \times (\hat{z} \Psi) + C \nabla \nabla \times (\hat{z} \Psi), \tag{B5}
\]
where \( A, B \), and \( C \) are free coefficients. These potentials are solutions to the scalar wave equations
\[
\nabla^2 \Phi + \left( \frac{\partial^2}{\partial z^2} - \frac{1}{v_p^2} \frac{\partial^2}{\partial t^2} \right) \Phi(r, \theta, z, t) = 0, \tag{B6}
\]
\[
\nabla^2 \psi + \left( \frac{\partial^2}{\partial z^2} - \frac{1}{v_s^2} \frac{\partial^2}{\partial t^2} \right) \Psi(r, \theta, z, t) = 0, \tag{B7}
\]
where we have made a similar ansatz for the scalar fields as for \( \mathbf{u} \) (see Eq. (B1)). The resulting equations for the transverse scalar fields \( \phi \) and \( \psi \) can be solved by supposing an azimuthal dependence of \( e^{im\theta} \), which yields the radial dependence of the potentials as solutions to the
Bessel equation \( \chi_m(k_z r) \) (we will comment on the particular choice of \( \chi \)), where \( k_z^2 = (\Omega/v_l)^2 - \beta^2 \) for \( i = p (\phi) \) or \( s (\psi) \).

We thus arrive at the general form of the displacement field:

\[
U_r = Ak_p \chi_m'(k_p r) + B i \beta k_s \chi_m(k_s r) + C i m \chi_m(k_z r) \tag{B8}
\]
\[
U_\theta = A i m \chi_m(k_p r) - B m \beta \chi_m(k_z r) - C k_s \chi_m(k_s r), \tag{B9}
\]
\[
U_z = A i \beta \chi_m(k_p r) + B k_s^2 \chi_m(k_s r). \tag{B10}
\]

Therefore, we can observe that in the axially symmetric case, when \( m = 0 \), the displacement field decouples into torsional modes with only a \( u_\theta \) component (\( A = B = 0 \), and dilatational modes (\( C = 0 \)) with \( u_r \) and \( u_z \) components. We will focus on this case throughout.

2. Torsional modes

Just as for the planar waveguide structure, we can decompose the displacement field in each layer into a basis of outgoing and incoming waves. This is determined by the choice of the functions \( \chi \) from the family of Bessel and Hankel functions. To represent the outgoing wave, we choose \( \chi \) in the form of Hankel functions of the first kind \( H_0^{(1)} \); we will suppress the \( (1) \) superscript in all the following equations for clarity. To describe the incoming waves, we could use the Hankel functions of the second kind. However, since \( H_0^{(2)} \) diverge at \( r = 0 \), we instead consider the Bessel functions of the first kind \( J_0 \) — while this component will not strictly describe incoming waves only, our expansion will remain complete. The displacement field is thus given by

\[
\mathbf{u}^{(j)}(r, z, t) = \theta \left( u_+^{(j)} H_0^{(1)}(k_s r) + u_-^{(j)} J_0(k_s r) \right) e^{i(\beta z - \Omega t)}. \tag{B11}
\]

Here the derivatives of special Bessel and Hankel functions (denoted by \( ' \)) are calculated with respect to the entire argument of the respective function. The only relevant non-zero component of the stress tensor is \( T_{r\theta} \). Thus, the matrices \( M^{(j)}(r) \) and coefficient vectors \( \mathbf{u}^{(j)} \) defined in Appendix A are given by

\[
\mathbf{u}^{(j)} = \begin{bmatrix} u_+^{(j)} & u_-^{(j)} \end{bmatrix}^T, \tag{B12}
\]

\[
M^{(j)}(r) = \begin{bmatrix}
H_0^{(1)}(k_s r) & J_0(k_s r) \\
\mu(j) k_s^2 (2 H_0^{(1)}(k_s r) + H_0(k_s r)) & \mu(j) k_s^2 (2 J_0(k_s r) + J_0(k_s r)) \\
H_1(k_s r) & J_1(k_s r)
\end{bmatrix}, \tag{B13}
\]

The waveguiding condition is formulated in exactly the same manner as for the planar structure, by connecting the vectors of coefficients in the outermost \( \mathbf{u}^{(3)} \) and innermost layer \( \mathbf{u}^{(1)} \) through the \( M \) matrices (see Eq. A3), and requiring that the innermost field is non-singular at \( r = 0 \) (no outgoing wave in layer \( 1 \); \( u_+^{(3)} = 0 \)) and the outermost field has no incoming wave components (since the Bessel function can be expressed as a sum of incoming and outgoing waves, we put \( u_-^{(3)} = 0 \)).

3. Dilatational modes

Following the same arguments as in the previous subsection, we again write down the displacement field as a sum of '+'- and '-'-components, with each one including contributions from both the \( P \) and \( S \) waves:

\[
u^{(j)}_p(x, z, t) = \left[ \begin{array}{c}
\hat{r} k_p H_0^{(1)} + \hat{z} i \beta H_0^{(1)} \\
\hat{r} k_p J_0 + \hat{z} i \beta J_0
\end{array} \right] u_p^{(j)} + c.c., \tag{B14}
\]

\[
u^{(j)}_s(x, z, t) = \left[ \begin{array}{c}
\hat{r} i \beta H_0^{(1)} + \hat{z} k_s J_0 \\
\hat{r} i \beta J_0 + \hat{z} k_s H_0^{(1)}
\end{array} \right] u_s^{(j)} + c.c., \tag{B15}
\]

where we have introduced the abbreviations \( H_{0i} = H_0(k_i r) \) and \( J_{0i} = J_0(k_i r) \), for \( i = s, p \). The relevant components of the stress tensor are \( T_{rr} \) and \( T_{rz} \). Therefore, we obtain the coefficients vectors

\[
\mathbf{u}^{(j)} = \begin{bmatrix} u_+^{(j)} & u_-^{(j)} & u_+^{(j)} & u_-^{(j)} \end{bmatrix}^T, \tag{B17}
\]
and matrices $M$ for each layer $j$

$$M^{(j)}(r) = \begin{bmatrix}
M_{31} & M_{32} & M_{33} & M_{34} \\
M_{41} & M_{42} & M_{43} & M_{44}
\end{bmatrix},$$

where

$$M_{31} = 2\mu^{(j)}(k_p^{(j)})^2 H''_{0p} - \lambda^{(j)} \left((k_p^{(j)})^2 + \beta^2\right) H_{0p},$$

$$M_{32} = 2\mu^{(j)}(k_p^{(j)})^2 J''_{0p} - \lambda^{(j)} \left((k_p^{(j)})^2 + \beta^2\right) J_{0p},$$

$$M_{33} = 2\beta\mu^{(j)}(k_s^{(j)})^2 H''_{0s},$$

$$M_{34} = 2\beta\mu^{(j)}(k_s^{(j)})^2 J''_{0s},$$

$$M_{41} = 2\beta\mu^{(j)}(k_p^{(j)})^2 H_{0p},$$

$$M_{42} = 2\beta\mu^{(j)}(k_p^{(j)})^2 J_{0p},$$

$$M_{43} = \mu^{(j)}k_s^{(j)} \left((k_s^{(j)})^2 - \beta^2\right) H''_{0s},$$

$$M_{44} = \mu^{(j)}k_s^{(j)} \left((k_s^{(j)})^2 - \beta^2\right) J''_{0s}.$$
