Influence of the shape of thermalized source on various characteristics of multifragmentation process as well as its interplay with effects of the angular momentum and the collective expansion are studied for the first time and the most pertinent variables are proposed. The analysis is based on the extension of the statistical microcanonical multifragmentation model.

PACS numbers: 25.70.-z, 25.70.Pq, 24.60.-k

In studying the multifragmentation process, a large range of incident energies, changing by about four orders in magnitude, was covered and various types of projectiles, from proton till heaviest available ions, were probed. The reaction mechanism is often considered in terms of two-step scenario where the first, off-equilibrium and dynamical step results in the formation of thermalized source which then, in the second step, decays statistically into light particles and intermediate-mass fragments (IMF’s). Assuming that the thermal equilibrium is attained, various statistical multifragmentation models were employed for the second step (see [1–3] and references quoted therein). These models were so successful in providing an understanding of basic aspects of the multifragmentation process that the deviations between their predictions and the experimental data have been often taken as an indication for dynamical effects in the multifragmentation. This kind of simplistic ‘cause-effect’ interpretation may however be misleading due to several oversimplifying assumptions in the statistical calculations, such as, e.g., the spherical shape of the thermalized source. Indeed, one expects that the spherical shape can be perturbed during the dynamical phase and the density evolution has both compressed and rarified zones which can give rise to a rather complicated source forms. Perhaps more important are the angular momentum induced shape instabilities which may cause large fluctuations of both the Coulomb barrier and the surface energy even for moderately high angular momenta ($L \sim 40\hbar$). Moreover, at high excitations, not only the quadrupole stiffness becomes small but also the fission saddle point moves towards larger elongations and smaller neck cross-sections, giving rise to some ‘neck effects’. Hence, before discussing dynamical effects in the multifragmentation decay, one should study the effects of different shapes in the freeze-out configuration. In this paper, the non-spherical fragmenting source is considered within the statistical model and the observables sensitive to the shape of this source are searched for.

Our statistical consideration is based on the MMMC method of the Berlin group [4]. In the MMMC method, one calculates all accessible states equally populated in the decay of thermalized system into N fragments. The microscopic thermodynamics used here describes the dependence of the volume of 6N-dimensional phase space on globally conserved quantities (energy, mass, charge, ... ) and external constraints (like the spatial volume) to be defined by the first stage of the reaction. Within the microcanonical ensemble method, an explicit treatment of the fragment positions in the occupied spatial volume allows for a direct extension of the MMMC code [4] to the case of non-spherical shapes. Here, the source deformation is considered as an additional external constraint. Main results of our paper will be given for the source described as an axial ellipsoid: $(x/R_x)^2 + (y/R_y)^2 + (z/R_z)^2 = 1$, with $R_x = R_y \neq R_z$. We assume that the freeze-out density of deformed system is the same as that of a spherical system with the radius $R_{sys} = (R_x R_y R_z)^{1/3}$, i.e., the volume of deformed system is conserved. This condition changes neither the pass scheme nor the weight $w_r$ due to the accessible volume of the fragments in the Metropolis scheme of calculations [4]. On the other hand, it means that the ellipsoidal source shape depends on one additional parameter: the ratio of ellipsoid axes $R = R_z/R_x$. The ratio $R < 1$ corresponds to the prolate form, while for the oblate form one has $R > 1$.

An essential feature of non-spherical systems is that the deformation ‘costs’ some extra energy $E_{def}$ which is proportional to a change of nuclear surface with respect to the spherical shape. Since we do not consider shape evolution of the system but rather the influence of source shape on its thermodynamics, this energy $E_{def}$ will be inaccessible for thermal motion and may be disregarded in the total energy balance. However this point should be kept in mind if one tries to refer to the real values of energy pumped into the system.

The source deformation will noticeably affect the moment of inertia and, together with the Coulomb energy which is calculated exactly for every multifragment configuration of non-spherical nucleus, becomes very important for describing rotating systems. As to the general scheme to account for the total angular momentum and the calculation of the statistical weight $w_{pd}$ of the configuration in the rotating frame, we closely follow Ref. [4].
to be realized in the available code. For each spatial configuration of fragments, part of the total energy goes into rotation and hence the temperature of the system will slightly fluctuate. We take into account fluctuations of the moment of inertia arising from fluctuations in the positions of fragments and light particles. In the calculation of statistical decay of fragmenting system, the angular velocity of the source is added to the thermal velocity of each fragment.

In calculating all accessible states within the standard MMMC method, the source should be averaged with respect to the spatial orientation of its axes, which is assumed to be homogeneously distributed in the whole 4π - solid angle. If the angular momentum of fragmenting system, caused by the dynamical first step of the reaction, is strictly conserved then not all these states will be accessible and a formal averaging over the 4π - solid angle will result in the violation of angular momentum conservation. In the considered reactions, the angular momentum vector is perpendicular to the reaction plane. So, we disentangle in the MMMC code the beam angular momentum vector is perpendicular to the reaction angle will result in the violation of angular momentum conservation, part of the total energy goes to be realized in the available code. Assuming $\nu \sim r$, a simplified scaling solution of the non-relativistic hydrodynamic equations describing the radial expansion of a spherical source provides the following general form for the radial velocity profile:

$$v_b(r) = v_0 (r/R_0)^\alpha . \quad (1)$$

Here $v_0$ and $R_0$ are strength and scale parameters of the flow respectively, and the power-low profile is characterized by the exponent $\alpha$, which commonly is taken in the interval $0.5 \leq \alpha \leq 2$. For the non-spherical expansion, the velocity profile may have a more complicated form and depends on the direction. But, in the case of axially symmetric expansion, the scaling relation was successfully applied for describing the profile of the transverse expansion velocity. Below it is assumed that the radial expansion at the freeze-out point is described by eq. (1). In the hydrodynamic interpretation, the scaling parameter $R_0$ corresponds to the size of the system at the initial time of the scaling regime and, therefore, it should be less than the effective radius of the spherical source at the freeze-out point, i.e., $R_0 \leq R_{sys}$. The strength parameter $v_0$ is then equal to the blast velocity at the surface of this effective sphere. As can be seen from eq. (1), the kinetic energy of fragments produced in the 'interior' will be mainly sensitive to the variation of the exponent $\alpha$ while the total collective flow energy may be fitted by different combination of all these three parameters. Note that the average collective energy of expansion, similarly as the deformation energy, is not included in the value of the total excitation energy.

As an example, let us consider the multifragmentation of $^{197}$Au having the angular momentum $L = 40h$ and the excitation energy $6 \cdot MeV$. These parameters correspond to the source formed in central $Xe + Sn$ collisions at 50 $A \cdot MeV$. All calculations were carried out at the standard break-up density $\rho \approx \rho_0/6$, what gives $R_{sys} = 12.8 \cdot fm$ for the radius of spherical $^{197}$Au nucleus. We consider two ellipsoidal shapes characterized by the axis ratio $R = 0.6$ (prolate shape) and $R = 1/0.6 = 1.667$ (oblate shape). We have found that none of the observables related to the fragment-size distribution is sensitive to the deformation of fragmenting source at such high excitation energies. The c.m.s. angular distribution of the largest fragment, i.e., the fragment with the largest charge ($Z = Z_{max}$), is shown in Fig.1. In the absence of collective expansion, the angular distribution is isotropic for oblate configurations and

In our version of the MMMC code the program error made in is corrected (see also Ref. 2).
has small forward - backward peaks for prolate configurations if the averaging around \( \mathbf{L} \) is performed in the whole available interval \( 0 \leq \psi \leq 2\pi \). For the 'frozen' spatial configuration (\( \psi = 0 \)), the 'deformation effect' is clearly seen: for the prolate form there are strong forward - backward peaks, while for the oblate form the heaviest fragment is predominantly emitted in the sideward direction (\( \theta_{cm} = \pi/2 \)), like in the scenario of hydrodynamic splashing. This deformation effect is definitely not due to the angular momentum as can be seen by comparing Figs. 1a, 1b (\( L = 0 \)) with Figs. 1c, 1d (\( L = 40h \)). The collective expansion (\( \alpha = 2 \)) enhances the deformation effect. One may notice a strong enhancement of forward and backward peaks in the prolate case and the appearance of a strong peak at \( \theta_{cm} = \pi/2 \) in the oblate case. Similar features can be seen also in the cumulative angular distributions if the averaging around \( \psi \leq 2\pi \) is performed in the whole available interval \( 0 \leq \psi \leq 2\pi \).

The angular momentum \( L \) in (2) can be represented as an ellipsoid in the momentum space. The shape of this ellipsoid can be described by three axes \( h_{\alpha} \), \( vb_{\alpha} \), whereas plots on the r.h.s. correspond to the averaging over the whole available interval \( 0 \leq \psi \leq 2\pi \).

Large sensitivity to the source shape is expected in the analysis using global variables on an event-by-event basis \[15\]. Here we shall associate the global variables with the momentum tensor:

\[
Q_{ij} = \sum_{\nu=1}^{N} \gamma^{(\nu)} p^{(\nu)}_i p^{(\nu)}_j ,
\]

where \( p^{(\nu)}_i \) is the \( i \)th Cartesian coordinate (\( i = 1, 2, 3 \)) of the c.m.s. momentum \( p^{(\nu)} \) of the fragment \( \nu \). The sum in (2) is running over all IMF’s (\( Z \geq 3 \)). The factor \( \gamma^{(\nu)} \) depends on the physical interpretation which one wants to give to the tensor (2). We use \( \gamma = 1/2m^{(\nu)} \), where \( m^{(\nu)} \) is the mass of fragment \( \nu \). The tensor \( Q_{ij} \) can be represented as an ellipsoid in the momentum space. The shape of this ellipsoid can be described by three axes and its orientation can be fixed by three angles in the 3D-momentum space. This is usually done by referring to the eigenvalues \( 0 \leq \lambda_1 \leq \lambda_2 \leq \lambda_3 \) (\( \lambda_1 + \lambda_2 + \lambda_3 = 1 \)) of the tensor \( Q_{ij} \) and to the Euler angles defining the eigenvectors \( \mathbf{e}_1, \mathbf{e}_2, \mathbf{e}_3 \). From various possible combinations of these parameters defining global variables \[15\], we consider here the sphericity: \( s = (3/2)(1 - \lambda_3) \), the coplanarity: \( c = (\sqrt{3}/2)(\lambda_2 - \lambda_1) \), the aplanarity: \( a = (3/2)\lambda_1 \), and the flow angle \( \theta_{flow} \) defined as an angle between \( \mathbf{e}_1 \) and the \( z \)-direction (the beam direction) in the c.m.s.

Distribution over the flow angle is presented in Fig. 2. Different physical situations considered in Fig. 2, are

\[\text{FIG. 2. } \theta_{flow} \text{ distribution. The plots on the l.h.s. correspond to the averaging over the whole available interval } 0 \leq \psi \leq 2\pi, \text{ whereas the plots on the r.h.s. correspond to the 'frozen' configuration } \psi = 0. \text{ (a),(b): } L = 0, \nu_b = 0; \text{ (c),(d): } L = 40h, \nu_b = 0; \text{ (e),(f): } L = 40h, \nu_b = 0.08c, \alpha=2.\]

\[\text{FIG. 1. } \text{Angular distribution of } Z_{max} \text{ in the c.m.s. Plots on the l.h.s. correspond to averaging over the whole available interval } 0 \leq \psi \leq 2\pi, \text{ whereas plots on the r.h.s. correspond to the 'frozen' configuration } \psi = 0. \text{ (a),(b): } L = 0, \nu_b = 0; \text{ (c),(d): } L = 40h, \nu_b = 0; \text{ (e),(f): } L = 40h, \nu_b = 0.08c, \alpha=2.\]
narity distributions for $L$.

The whole effect is extremely sensitive to the presence of collective expansion (see Figs. 2e and 2f) and is enhanced furthermore for the 'frozen' configuration ($\psi = 0$). In general one expects that the $\cos(\Theta_{flow})$ - distribution for highly central events is uniform [3]. However this naive expectation may be altered by many effects, such as the spatial shape of the source, the non-vanishing collective radial expansion, the high angular momentum and last but not least the detection bias.

![FIG. 3. (a) Sphericity, (b) coplanarity and (c) aplanarity distributions for $L = 40h$. Bold lines correspond to $v_b = 0.08c$, $\alpha = 2$. The continuous lines show prolate $R=0.6$ shape whereas dashed lines show oblate $R=1.667$ shape.](image)

The reason for this sensitivity can be seen from (1). Depending on the source shape, a different number of fragments can be placed in the two regions: $r < R_0$ and $r > R_0$ (we put everywhere $R_0 = 0.7R_{sys}$), in which the expansion acts differently. For the same reason, these distributions are insensitive to the radial expansion for the spherical source. Particularly interesting are the sphericity and coplanarity distributions where the evolution of distributions with $v_b$ is clearly different for prolate and oblate source shapes. Lack of sensitivity of the aplanarity distribution to the deformation effects and to the expansion happens accidentally for chosen parameters. One should also mention that the sensitivity of $dP/ds$ and $dP/dc$ distributions to the source deformation and their insensitivity to the time-scales involved (the $\psi$ - averaging) provides interesting and supplementary informations to those contained in the $Z_{max}$-angular distribution and in the $\cos(\Theta_{flow})$ - distribution.

The $Z$-dependence of average kinetic energy $E_k$ of IMF’s for different source shapes and different $\alpha$-parameters is shown in Fig.4. The calculations have been done for the 'frozen' configuration ($\psi = 0$). The collective expansion energy is a dominant contribution to the average kinetic energy of fragments, and its value differs noticeably for prolate and oblate source shapes. It is of interest to note that the average kinetic energy of fragments exhibits a flattening or even a maximum at large $Z$ (see , e.g., the curve for $\alpha = 2$). The precise position of this maximum depends also on the deforma-

![FIG. 4. Kinetic energy of fragments is plotted as a function of $Z$. (a) Prolate shape, $L = 40h$. Different curves correspond to: $v_b = 0$ (circles), and : $v_b = 0.08c$, $\alpha = 1/2$ (diamonds), 1 (triangles), 2 (squares). (b) The same as in (a) but for the oblate shape. (c) The same as in (a) but for the spherical shape. (d) Comparison between the experimental data and the calculation ($\alpha = 2$) for both prolate and oblate freeze-out configurations and the blast velocities : $v_b = 0.088c$ (prolate shape), $v_b = 0.063c$ (oblate shape), chosen as to reproduce the experimental mean kinetic energy per nucleon of IMF’s : $5.2 \pm 0.1 MeV/nucleon$.](image)
tion (see Figs. 4a and 4b). An attempt to reduce this large observed kinetic energy to angular momentum effects results in a value of the average angular momentum \( L \approx 640a \) which is completely unrealistic for selected central events \([4]\). Fig. 4c shows \( E_{k}(Z) \) for the spherical source shape. Fig. 4d compares results of the present model with the experimental data for central \( Xe+Sn \) collisions at 50 \( A\cdot MeV \) \([4]\). All calculated events have been filtered with the INDIRA software replica, and then selected with the experimental centrality condition: complete events (i.e. more than 80\% of the total charge and momentum is detected) and \( \Theta_{flow} \geq \pi/3 \).

In conclusion, external constraints on the shape of equilibrized fragmenting source have been considered within the extended MMC method. Due to the change in the Coulomb energy for deformed freeze-out configuration, the shape effect is clearly seen in the IMF's angular distributions (\( Z_{max} \)-angular distribution) as well as in the \( \Theta_{flow} \)-distribution. A surprising interplay between effects of non-spherical freeze-out shapes and the memory effects of nonequilibrium phase of the reaction, such as the rotation and the collective expansion of the source, has been demonstrated for the first time. The influence of shape on rotational properties of the system is not only reduced to the modification of the momenta of inertia. The limits on the averaging interval over the angle \( \psi \) about the rotation axis, which are defined by the appropriate time scales, affect strongly the angular observables and are able to enhance strongly the 'shape effect'. These constraints may be important for certain observables used in experimental procedures of selecting specific class of events. Other striking finding is that the collective expansion allows to disclose the source shape in the analysis using global variables as well as in the study of \( Z \)-dependence of the average kinetic energy. The latter observable is independent of \( \psi \)-averaging but, unfortunately, it is specified by a poorly known profile function \([8]\). Nevertheless, the careful analysis with eq. \([8]\) might shed some light on the problem how different fragments are situated in the freeze-out configuration.

In the experimental analysis, if the average kinetic energy of fragments is fixed by an appropriate choice of \( v_{h}, R_{0} \) for each source deformation, then the shape of \( E_{k}(Z) \) contains information about the exponent \( \alpha \) in the parametrization (1) and to the lesser extend about the deformation of the source. The form of the \( dP/ds \) and \( dP/dc \) distributions permits then to find the average deformation of the fragmenting source. Having fixed the parametrization (1) and the deformation of the source, the analysis of the angular distribution of \( Z_{max} \) and/or the \( \Theta_{flow} \) distribution gives an access to the information about the time-constraints (the limits on the \( \psi \)-averaging) in the multifragmentation process. We have discussed here the freeze-out shape effect for only one value of the excitation energy. Certainly, the manifestation of this effect in observables is energy/angular momentum dependent and the modifications of the MMC method, presented in this Letter, open a promising way to follow up the shape evolution of equilibrized source in the broad range of incident energies. Alongside with the observables discussed here, it would be interesting to study the velocity correlations between fragments which are sensitive to the source shape at the freeze-out. Such a work is now in progress \([10]\).
