Continuous incremental interscalene block for proximal humerus in patients with severe pulmonary injury

**INTRODUCTION**

Regional anaesthesia techniques are indicated in patients with upper limb procedures having pulmonary injuries to avoid airway interventions and protect the lungs. However, 20 ml of local anaesthetic (LA) injected with ultrasound (US) guidance for interscalene block can lead to hemidiaphragmatic paresis in 17 to 46% of patients.[1,2] We describe our experience in three patients where an US-guided catheter was positioned in the interscalene area, and incremental doses of LA were injected with concomitant monitoring of diaphragmatic movements and oxygen saturation. Institutional ethics committee approval was obtained and the study was performed in accordance with the principles of the Declaration of Helsinki. Written informed consent was obtained from all patients.

**CASE REPORT**

From January 2018 until January 2021, three patients who sustained fracture of the proximal humerus and multiple ribs with a pulmonary injury were admitted in the intensive care unit (ICU). On arrival, the rib fracture score,[2] oxygen requirements, and numerical rating score (NRS) on parenteral analgesics were noted. Despite intravenous fentanyl infusion (0.5 µg/kg), NRS persisted more than 4 and all patients received a single-shot US-guided serratus anterior plane block (SAPB).[3] Computed tomography (CT) of chest was performed in all patients considering a persistent low oxygen saturation [Table 1] [Figure 1a and b]. In order to facilitate early fixation and subsequent mobilisation, patients were posted for surgery. A continuous incremental interscalene block (CIIB) was proposed with incremental LA injection and assessment of the oxygen saturation and diaphragmatic excursions on the ipsilateral side.

Patients were wheeled into the recovery room of the operation theatre with 6 L/min of oxygen through face mask. With the patient lying in a 45-degree semi-recumbent supine position, a linear array high-frequency US transducer (5-12 MHz, Sonosite

M-Turbo, United States of America) was placed in the mid-axillary line and diaphragm excursion was assessed prior to block, 5, 15 and 30 min after each injection of LA, in the immediate postoperative period, and at 2, 12 and 24 h postoperatively in the ICU. The domes of the hemidiaphragm (right and left separately) were identified and its excursion was measured in the M-mode during rest and maximal forced inspiration.

Baseline oxygen saturation, blood pressures and heart rate were monitored in each patient. The anterolateral neck on the side of surgery was prepared and draped for CIIB. A linear array (3-12MHz) probe was deployed in a transverse oblique axis, at the level of C7 vertebra (absence of anterior tubercle). After identification of C7 nerve root, the C5 and C6 roots were identified with a slight cephalad shift, sandwiched between the anterior and middle scalene muscles. The dorsal scapular and long thoracic nerves were identified in the middle scalene muscle and the phrenic nerve was recognised on the anterior scalene muscle. An out of plane approach was implemented, and 2 ml of 1% lidocaine was infiltrated until the middle scalene muscle. An 18 gauge insulated needle (Contiplex B - Braun, United States of America) was inserted [Figure 1c] as the tip penetrated the medial border of the middle scalene muscle and was positioned between the perimysium of the middle scalene muscle and sheath of the brachial plexus. After removal of the stylet, a 20 gauge catheter (Contiplex B - Braun, United States of America–single-end hole tip) was inserted through the cannula, in real-time sonographic guidance, and the tip was visualised protruding from the bevel of needle. The distance of the catheter from

the tip of the cannula was 1-2 cm. Injection of 2 ml of 0.9% saline confirmed position of the catheter with distention of the space between the perimysium and the sheath (extra-neural). Consequently, the following protocol was followed:

A fresh LA preparation containing 5 ml of 2% lidocaine and 5 ml of 0.5% bupivacaine (total 10 ml) was prepared. After each injection of boluses of 3 ml around 10 min apart, through the catheter, respiratory monitoring (respiratory rate, diaphragmatic excursion in real time, oxygen saturation), blockade of dermatomes (C5,6) and pain on slight motor movement of the shoulder joint was evaluated. Patient preparedness for the surgery was announced when sensory blunting to needle prick (26 gauge), no pain on slight shoulder movement, minimal diaphragmatic paresis (up to 50% of the original excursion) and oxygen saturation not less than 90% with supplemental oxygen of 4-6 l/minute were confirmed [Table 1]. Volumes of LA injected were 6 to 9 ml. In addition, all patients received superficial cervical plexus block with 2 ml of 0.25% bupivacaine.

Postoperatively, patients were counselled and an informed consent was obtained and in the 2nd postoperative hour patients were wheeled to the computed tomography (CT) suite in the same institute with monitoring. Omnipaque (300 mg/ml iodine) 1 ml diluted in 10 ml 0.9% normal saline was injected through the catheter in the same sequence as performed for the surgical procedure. CT analysis revealed contrast spread in the interscalene groove with a volume of 3 ml and to the scalene muscles with volumes of 6 and 9 ml. However, there was no neuraxial spread [Figures 1d-q].

Postoperatively, 0.2% ropivacaine 5 ml was injected intermittently whenever patient reported pain (NRS >4) even after 1 g of intravenous paracetamol. Catheters were removed at the end of the 48th hour. Neurological examination of the operated side did not reveal nerve injuries in all three patients.

**DISCUSSION**

US-guided interscalene blocks have resulted in hemi-diaphragmatic paresis even with lower volumes of LA. A 5 ml single bolus\(^5\) and 7 ml through the catheter\(^6\) have resulted in hemi-diaphragmatic paresis in 45% and 100% patients, respectively. A meta-analysis evaluating the advantages of single bolus interscalene block suggests that the duration of analgesia provided by interscalene block is limited to 6 and 8 h with motion and at rest, respectively, with rebound pain from 16th to 24th hour requiring parenteral analgesics.\(^1\) High volume [25-50 ml] hybrid block and a selective trunk block have also been reported for patients with proximal humeral fractures without pulmonary injuries.\(^2\) To our knowledge, a CIIB with incremental LA injections with respiratory monitoring is not reported yet.

**CONCLUSION**

CIIB with incremental LA injections with respiratory monitoring can provide adequate anaesthesia with minimal respiratory compromise in patients with pulmonary injury undergoing proximal humerus surgery.

**Declaration of patient consent**

The authors certify that they have obtained all appropriate patient consent forms. In the form, the patient(s) has/have given his/her/their consent for his/her/their images and other clinical information to be reported in the journal. The patients understand that their names and initials will not be published and due efforts will be made to conceal their identity, but anonymity cannot be guaranteed.
