Summary.—Characteristics of the AKB6F₁ mouse strain make it suitable as an assay animal for quantitating haemopoietic stem cells, or spleen colony-forming units (CFU-S), from leukaemic AKR mice. Marrow cells harvested from leukaemic mice were assayed for CFU-S in lethally irradiated AKR or AKB6F₁ hosts. Survival times and numbers of leukaemic colony-forming units (L-CFU) in unirradiated recipients were used to detect proliferation of transplanted leukaemic cells. In contrast to AKR recipients, the proliferation of transplanted leukaemic cells was suppressed in F₁ hosts. Injection of marrow cells from normal nonleukaemic AKR mice into AKR and F₁ hosts yielded significantly more CFU-S and spleen ^59Fe uptake in F₁ than in AKR hosts. In marked contrast, injection of marrow from leukaemic AKR mice suppressed CFU-S proliferation in the F₁ recipients. Thus it was possible to quantify CFU-S in marrow containing L-CFU.

AKR spontaneous and transplanted leukaemias are often used to measure the effects of anticancer agents on malignant and normal cell populations (Bruce, et al., 1966, 1969; Skipper et al., 1969; Schabel et al., 1969). Prior work has determined the growth characteristics and drug sensitivity of the thymus-derived malignant cells from leukaemic AKR mice (above references, plus Zatz et al., 1973; Barker & Waksal, 1974; Omine & Perry, 1972). However, fewer studies have addressed themselves to possible changes in the other haemopoietic cell lines (Hays et al., 1976; Chevalier et al., 1974; Frindel & Chevalier, 1975; Sainteny et al., 1977, 1978). One reason for this is that, when transplanted into irradiated syngeneic mice, leukaemic cells and normal haemopoietic stem cells give rise to spleen colonies that are macroscopically similar (Bruce & Van der Gaag, 1963). Furthermore, after marrow transplantation, lethally irradiated AKR mice fail to adequately support haemopoiesis (Legrand & Duplan, 1978; Perkins et al., 1971). Normal haemopoietic stem cells are less able to proliferate and differentiate in the spleen and marrow of the irradiated syngeneic AKR recipients (Legrand & Duplan, 1978; Perkins et al., 1971). Therefore, it has been difficult to use the spleen colony-forming unit (CFU-S) assay to measure the number of pluripotential haemopoietic stem cells in the tissues of leukaemic AKR mice.

Characteristics of the (AKR × C57BL/6)F₁ mouse suggested that with this mouse hybrid it might be feasible to use the CFU-S assay to quantitate haemopoietic stem cells in tissues of leukaemic AKR mice. Transplanted marrow cells from nonleukaemic AKR mice will proliferate and give rise to spleen colonies in irradiated AKB6F₁ mice (Trentin et al., 1973, 1976). However, the proliferation of transplanted leukaemic cells from leuk-
mechanism is suppressed (Trentin et al., 1973, 1976). The results presented in the present paper demonstrate that these F₁ mice provide a valid means to detect normal haemopoietic stem cells in the marrow of AKR mice with both early and late stages of spontaneous and first-passage leukaemias. In addition, these results show that haemopoietic precursors are decreased or suppressed in the marrow of AKR mice with spontaneous or first-passage leukaemia.

**MATERIALS AND METHODS**

**Mice.**—The AKB6F₁ or (AKR × C57BL/6)F₁ mice and male mice of the C57BL/6 parental strain were from a breeding colony maintained in our laboratory. AKR/J mice were purchased from Jackson Laboratories, Bar Harbor, Maine.

Normal donor and recipient mice were 3–4 months old, and leukaemic donors were 7–10 months old. For experimental studies, the mice were randomized into groups by age and weight. Palpation of the spleen and the inguinal lymph nodes was used to identify leukaemic mice. After killing, mice that also had an enlarged thymus (> 200 mg) were used for these studies. After irradiation and/or cell transplantation, the mice were housed 5 per shoebox polypropylene cage on Sanicel bedding, maintained in a laminar-flow hood, and allowed food and HCl-acidified water (pH 2-4) ad libitum.

**Irradiation.**—Mice were whole-body irradiated at a dose rate of ~1.2 Gy/min by a 137Cs irradiator (Mark I, Shepherd and Associates, Glendale, California).

**Preparation of cell suspensions.**—Mice were killed by cervical dislocation, the tissues were excised and weighed, and cells for injection were flushed from the tissues with Hanks’ balanced salt solution (HBSS) and dispersed through a 25-gauge needle. A ZBI Coulter Counter was used to determine the number of nucleated cells. The cell suspensions were then diluted to the desired concentrations for injection in 0.2 ml HBSS and injected into a caudal vein of each mouse.

**Spleen-colony and spleen 59Fe-uptake assays.**—CFU-S determinations were done basically as described by Till & McCulloch (1961). Recipient AKR and AKB6F₁ mice were irradiated at 9 Gy and 9.5 Gy respectively. Animals were injected with cells within 2 h after irradiation. Seventeen hours before the mice were killed for Day 8 spleen-colony determinations, they were injected i.p. with 0.1 μCi 59Fe-ferrous citrate (Mallinkrodt Nuclear) diluted in 0.2 ml of 0.005M citrate. The individual spleens were counted in a well-type scintillation counter (Nuclear Chicago).

Unlike normal cells, leukaemic cells may give rise to spleen colonies in unirradiated mice (Bruce & Van der Gaag, 1963; Bruce & Meeker, 1964). Thus, assays for leukaemic colony-forming units (L-CFU) are used as an estimate of the number of leukaemic cells capable of proliferating in vivo (Bruce & Van der Gaag, 1963; Bruce & Meeker, 1964). Unirradiated 3–4-month-old mice were used to assay for L-CFU in the marrow and thymus from leukaemic AKR mice.

**Marrow differential cell counts.**—Nucleated cell counts were made on the marrow from a humerus of individual mice, as described by Chervenick et al. (1968). Samples containing 1–5 x 10⁵ nucleated cells from the marrow wash-outs were centrifuged on to serum-coated (FCS-Gibco) slides using a cyto-centrifuge (Shandon Eiolit) at 800 rev/min for 5 min. The numbers of neutrophils and neutrophil precursors per humerus were determined using a modification of a staining method using a peroxidase reaction (Rytmäa, 1962). The number of neutrophilic cells was calculated by multiplying the number of nucleated cells per humerus by the proportion of peroxidase⁺ (brown to yellow) cells in a 400 cell count on the treated slides.

**First-passage leukaemias.**—These were initiated in 3–4-month-old normal AKR mice by i.v. injections of 10⁶ cells from the thymus or marrow of AKR mice with spontaneous leukaemia.

**Statistics.**—Cell counts and spleen colony counts tend to be skewed (Smith et al., 1954) so the geometric means were used to obtain a more normal distribution of the variables (Sokal & Rohlf, 1969). Zero colony counts were included in the geometric means, as described by Smith et al. (1966). The weighted means (± s.e.) were used to combine data from similar experiments (Sokal & Rohlf, 1969; Smith et al., 1966). The t test was used to define significant differences between groups of mice.
RESULTS

Growth of marrow stem cells from non-leukaemic AKR mice in irradiated AKR and AKB6F1 recipients

Background levels in the irradiated controls are similar for AKR mice given 9 Gy and AKB6F1 mice given 9.5 Gy γ-irradiation. The average number of colonies per spleen was less than 1, and the percentage of injected 59Fe per spleen was about 0.3%. Both of these measurements were higher in the recipients of transplanted marrow cells (Fig. 1). AKR recipients had a mean of 4.5 ± 1.77 colonies per spleen, which is significantly lower (P < 0.01) than the 13.5 ± 3.36 colonies per spleen in the F1 mice. The percentage of injected 59Fe uptake per spleen was also significantly higher (P<0.01) in the F1 (2.1 ± 0.44) than the AKR (0.8 ± 0.07) recipients. Thus the F1 mouse appears to be more sensitive than the AKR mouse in the detection of possible decreases in the number of CFU-S in the marrow of AKR mice with early, late, or terminal stages of leukaemia.

Survival of AKR mice after transplantation of cells from leukaemic AKB6F1 mice

Irradiated AKR and F1 mice were injected with 10^2, 10^3, or 10^4 cells pooled from the thymuses of 5 AKR mice with spontaneous leukaemia. For these cell doses, there was no evidence of proliferation of transplanted leukaemic cells in the spleens of either the AKR or F1 recipients. Eight days later, in all groups, the mean number of colonies per spleen was < 1, and the spleen weights were not significantly greater than for the irradiated control recipients AKR (23 mg ± 2) or F1 (21 mg ± 1). However, the deaths of unirradiated AKR recipients proved that the cell suspensions contained leukaemic cells capable of proliferating in vivo. Twenty to 100% of the AKR mice died with evidence of leukaemia within 20–89 days.

Table I.—Survival of AKR and AKB6F1 mice after transplantation of cells from leukaemic AKR mice

| Donor cells* | Cells injected | Recipients deaths (Mean survival in days) |
|--------------|---------------|------------------------------------------|
|              |               | AKR                                      |
| Thymus       | 10^2          | 2/10 (71 ± 18)                           |
|              | 10^3          | 5/10 (53 ± 4)                            |
| Thymus       | 10^3          | 9/9 (36 ± 4)                             |
|              | 10^4          | 10/10 (42 ± 3)                           |
| Marrow       | 10^6          | 10/10 (27 ± 1)                           |

*3-4-month-old unirradiated female AKR and AKB6F1 mice were injected with cells from the thymuses or marrows of 8-9-month-old female AKR mice with spontaneous leukaemia. Equal numbers of nucleated cells were pooled from 5 donor mice and the samples were then serially diluted for cell injections.

† Nonleukaemic death.

Fig. 1.—Growth of marrow stem cells from nonleukaemic AKR mice in irradiated AKR and AKB6F1 mice. In individual studies, 10^6 nucleated cells pooled from the marrow of 5 nonleukaemic AKR mice (3-4-month-old females) given 9 Gy (□) and AKB6F1 mice given 9.5 Gy (■). The geometric mean number of colonies and percentage of injected 59Fe uptake per spleen were measured 8 days after irradiation and cell injections. Results shown the totals from 4 experiments totalling 50 mice. Bars indicate s.e.

days after the injection 10², 10³, 10⁴, or 10⁶ cells (Table I). Only 2/74 (~3%) of the F₁ mice died with evidence of leukaemia (enlarged spleen and/or thymus), and these 2 received the largest cell doses.

These studies demonstrated that F₁ mice are able to suppress the growth of transplanted leukaemic cells. However, this resistance, as measured by survival, may be broken by the injection of sufficient leukaemic cells. The total number of cells necessary to overcome this resistance depends on the degree of infiltration of the donor tissues by clonogenic leukaemic cells. This may be different for each mouse, due to variability in characteristics of AKR mice with overt evidence of spontaneous leukaemia.

L-CFU as a measure of proliferation of transplanted lymphoma cells

The spleens of unirradiated AKR recipients of cells from each of the leukaemic donors were enlarged (Table II). The spleens were also whitish, and some had a mottled appearance with no distinct colonies, while others had >50 overlapping colonies. Both types of spleen were designated as having confluent colonies. In contrast, the spleen weights of the unirradiated F₁ recipients were within the range (80 ± 2 mg) measured in untransplanted F₁ mice, and in most cases the mean number of colonies per spleen was <1. Colonies were seen on some spleens (1–8 per spleen), and in 2 cases (donors 3 and 7) there was a significant number of colonies from leukaemic cells. However, compared to AKR recipients, the proliferation of transplanted L-CFU was suppressed in the spleens of unirradiated F₁ mice. Cells equivalent to 1% of a humerus (5 × 10⁴ to 5 × 10⁵ nucleated cells) were injected into irradiated recipients to assay for CFU-S. Table II demonstrates that the proliferation of L-CFU contained in 1% of a humerus of AKR mice with spontaneous leukaemia is suppressed in the spleens of unirradiated F₁ mice.

CFU-S in irradiated recipients of marrow from AKR mice with spontaneous leukaemia

Cells from the same leukaemic donors as in Table II were also injected into irradiated AKR and F₁ mice. As seen in the unirradiated AKR mice, the spleens of the irradiated AKR recipients of cells

§ > 50 colonies.

from the marrow of AKR mice with spontaneous leukaemia had a hotted appearance or > 50 colonies (Table III). In all but one example (Donor 5) the mean number of colonies per spleen of the F₁ mice was close to the background levels (0) in mice of the irradiated controls (no cells). These values were also signifi-
cantly lower (P < 0.001) than the 10–3 ± 1–81 colonies seen on the spleens of F₁ recipients of cells from 1% of a humerus of 3–4-month-old nonleukaemic AKR mice.

Spleen ⁵⁹Fe uptake was also lower in recipients of cells from the marrow of leukaemic AKR mice. F₁ recipients of cells from donors of Group 4 (Table III) had a mean uptake of only 0.5±0.1%; not much higher than the 0.3±0.0% seen in the irradiated controls. The data summarised in Table III suggest that the number and concentration of nonleukaemic haemopoietic stem cells were decreased in the marrow of AKR mice with spontaneous leukaemia.

**CFU-S in marrow of AKR mice with first-passage leukaemia**

Irradiated AKB6F₁ mice were used to assay for the number of nonleukaemic haemopoietic stem cells in the marrow of AKR mice with early and late stages of first-passage leukaemia. Four first-passage leukaemias were initiated in AKR mice by the injection of cells pooled from the thymus or marrow of AKR mice with spontaneous leukaemia. Five to 9 and 12–15 days later, the animals were killed. Marrow from the humerus of 5 mice were pooled, and 10⁵ cells were injected

*3–4-month-old AKR mice were injected i.v. with 10⁵ cells from the thymus of an AKR mouse with spontaneous leukaemia, and died within ~16 days.
† Geometric means.
into unirradiated 3–4-month-old AKR mice. The death of these recipients established the presence of leukaemic cells in the marrow of the mice with first-passage leukaemia. Cells were also injected into irradiated F1 mice, and 8 days later the number of colonies and the percentage of injected 59Fe were determined.

Changes in tissue weights and marrow cell counts were similar in mice from all 4 of the transplanted leukaemias (Table IV). The spleen and thymus weights of AKR mice with early (Day 5) stages of leukaemia were not significantly different ($P > 0.05$) from those of the nonleukaemic controls. Mice with terminal stages (Day 14) of the disease had very enlarged spleens. The number of cells and the percentage of peroxidase$^+$ cells in the humerus of mice with early stages of leukaemia were not significantly different ($P > 0.05$) from those of the nonleukaemic mice. However, AKR recipients died within 90 days, thus demonstrating the presence of some leukaemic cells in the marrow at this time. Mice with late stages of leukaemia had a somewhat, but not significantly, lower ($0.025 < P < 0.05$) number of cells per humerus. In contrast, the percentage, and thus the number, of peroxidase$^+$ cells per humerus was greatly reduced in the leukaemic mice (Table IV).

The percentage of 59Fe uptake in spleens of the F1 recipients of cells from the marrow of mice with early and late stages of this first-passage leukaemia is illustrated in Fig. 2. These measurements were not significantly different in recipients of cells from the nonleukaemic donors and from mice with Day 5 leukaemia. However, 59Fe uptake was only 0.4% in recipients of cells from donor mice with late stages of the disease. This approximated to the irradiated controls, and was significantly lower than the 2.2% measured in recipients of cells from nonleukaemic mice. For this and the other transplanted leukaemias studied, the haemopoietic precursors were decreased or suppressed in the marrow of AKR mice with late stages of the disease.

The number of colonies per spleen of F1 recipients of cells from mice with early stages of leukaemia was not significantly different ($P > 0.05$) from that of the nonleukaemic AKR mice. In addition, the 20 ± 7.8 colonies per spleen of recipients of cells from mice with late stages of the disease was not significantly different than the 19 ± 1.7 colonies on the spleens of the recipients of cells from the marrow of nonleukaemic AKR mice. This was similar for the other first-passage leukaemias studied, in that the number of colonies was somewhat higher or about the same on spleens from the leukaemic mice as on
spleens of recipients of cells from non-leukaemic donors.

**DISCUSSION**

The objectives of the present report were to expand the studies described by Trentin et al. (1976) and to evaluate the usefulness of the (AKR × C57Bl/6) F₁ mouse as a tool to discriminate between leukaemic and nonleukaemic haemopoietic stem cells in the marrow of AKR mice. The proliferation of leukaemic colony-forming units (L-CFU) was suppressed in the spleens of F₁ recipients of cells from leukaemic AKR mice. The present studies demonstrated that the spleens of F₁ mice were capable of resisting the growth of the number of L-CFU found in 1% of humerus (5 × 10⁴–5 × 10⁵ nucleated cells) from AKR mice with spontaneous leukaemia. Normal haemopoietic stem cells are less able to proliferate and differentiate in the spleen and marrow of irradiated syngeneic recipients (Legrand & Duplan, 1978; Perkins et al., 1971). However, from the data presented in this paper, the F₁ mouse appears to provide a suitable haemopoietic microenvironment for the proliferation and subsequent differentiation of nonleukaemic haemopoietic stem cells from AKR mice. Thus, the F₁ mouse may be a more sensitive assay animal than the AKR mouse to detect possible decreases in the number of CFU-S in the marrow of AKR mice with early, late or terminal stages of leukaemia.

The growth and development of parental marrow and lymphoid grafts are inhibited in certain F₁ mouse hybrid combinations (Snell & Stimpfin, 1966; Cudkowicz & Bennett, 1971; Cudkowicz & Lotzova, 1973; Bennett, 1972; Cudkowicz, 1968). This resistance is directed at Hh (Hybrid-histocompatibility or haemopoietic histocompatibility) antigens (Cudkowicz, 1968; Bennett, 1972). In some mouse strains the Hh antigens are expressed on both normal and leukaemic haemopoietic and lymphoid cells (Cudkowicz, 1968; Iorio et al., 1978). However, in other strains such as the AKR mouse, these antigens appear to be expressed only on the leukaemic cells (Trentin et al., 1973; 1976; Iorio et al., 1978). Also, the resistance of the F₁ mouse can be abrogated by the injection of a large number of cells, and in the marrow with lower cell numbers than in the spleen (Trentin et al., 1976).

Other investigators pretreated cell suspensions from leukaemic AKR mice with anti-θ serum plus complement, and the remaining cells were injected into irradiated syngeneic mice to assay for CFU-S (Chevalier, 1974; Sainteny et al., 1977, 1978). Neither the number of leukaemic cells nor the total number of cells eliminated by this procedure was determined. Anti-θ serum is capable of eliminating all cells bearing the θ-antigen surface molecule, whether leukaemic or nonleukaemic. Some populations of T cells in mice and humans may influence the differentiation responses of haemopoietic stem cells (Goodman et al., 1978; Resnitsky et al., 1971; Nathan et al., 1978; Wiktor-Jedrzejczak et al., 1977) and in mice small numbers of these cells exist in the marrow, spleen, and thymus (Wiktor-Jedrzejczak et al., 1977). With the AKB6F₁ mouse it is possible to flush cells from the tissues of AKR mice and, without pretreatment to remove the leukaemic cells, they can be injected into the irradiated recipients to assay for CFU-S and the subsequent differentiation of these stem cells. Some of the same cell suspensions can also be injected into unirradiated AKR mice to assay for L-CFU.

Results presented in this paper demonstrate that AKB6F₁ mice can be used to assay for CFU-S in the marrow of AKR mice with spontaneous or first-passage leukaemia. As seen by colony number and spleen ⁵⁹Fe uptake in irradiated mice, the number and concentration of CFU-S in the marrow of AKR mice with spontaneous leukaemia was significantly less than in nonleukaemic mice. A decrease in the concentration of CFU-S in the non-leukaemic cell population was also demon-
strated by other investigators, using the anti-θ+ complement protocol (Frindel & Chevalier, 1975). Our studies of the marrow of AKR mice with first-passage leukemias gave somewhat different results from those seen in mice with spontaneous leukemia. AKB6F1 recipients of cells from mice with late stages of the disease had low spleen 59Fe uptake, and the same number or slightly more spleen colonies. This apparent discrepancy may be because some of the colonies may have been derived from the proliferation of leukemic cells. Compared to AKR mice with spontaneous leukemia, mice with first-passage or long-passaged leukemia may have a higher proportion of L-CFU in the marrow (Bruce & Van der Gaag, 1963; Schwartz, 1980). The evidence for fewer neutrophils in the marrow of the leukemic mice also suggests that CFU-S may be reduced. Alternatively, the colonies may have been derived from CFU-S that were unresponsive to normal stimulation for erythropoietic differentiation (Goodman et al., 1978; Wiktor-Jedrzejczak et al., 1977).

The limitations of the AKB6F1 assay system are determined by the number of leukemic cells and the corresponding decrease in the normal cell populations. Spleen colony numbers are a good quantitative assay for CFU-S in the range of 5 x 10^4 to 5 x 10^5 injected cells from the marrow of normal mice (Smith, 1964). If the concentration of CFU-S were decreased, it would be necessary to inject more cells. However, the injection of more cells from the leukemic mice is not always feasible, since a larger number of leukemic cells would also be injected, and might then give rise to leukemic colonies. The sensitivity of this AKB6F1 assay system could be enhanced by the removal of leukemic cells by techniques such as velocity sedimentation or counterflow centrifugation. Also, it would be possible to differentiate between colonies derived from CFU-S and L-CFU. Cells or individual colonies from the spleens of the AKB6F1 recipients could be injected into nonleukemic AKR mice. If these mice die with leukemia within 90 days (Schabel et al., 1969), some of the injected cells were leukemic. The presence of an AKR subline, AKR(Rb6.15)Ald, makes it feasible to use cytogenetic analysis as another means of determining whether the colonies are derived from transplanted leukemic cells or host nonleukemic haemopoietic stem cells. Along with in vivo and in vitro clonal assays for CFU-S, BFU-E, CFU-E, and GM-CFU, the AKB6F1 mouse may be useful in studies to determine the mechanisms that regulate the haemopoietic stem-cell compartments during the development or treatment of leukemia in AKR mice.

Supported by American Cancer Society grant CH-101A.

This work is a portion of a dissertation submitted in partial fulfilment of the requirements for the doctoral degree from Department of Biological Sciences, University of Pittsburgh, Pittsburgh, PA 15260, U.S.A.

We are grateful to Kenneth D. Patrene and Marilyn Melithoniotes for their excellent technical assistance and to Dr Irwin Klein and Dr Thomas MacVittie for their editorial assistance.
