NGC 1097 is a nearby SBb galaxy with a Seyfert nucleus and a bright starburst ring. We study the physical properties of the interstellar medium (ISM) in the ring using spatially resolved far-infrared spectral maps of the circumnuclear starburst ring of NGC 1097, obtained with the PACS spectrometer on board the Herschel Space Observatory. In particular, we map the important ISM cooling and diagnostic emission lines of [OI] 63 μm, [OIII] 88 μm, [NII] 122 μm, [CII] 158 μm and [NII] 205 μm. We observe that in the [OI] 63 μm, [OIII] 88 μm, and [NII] 122 μm line maps, the emission is enhanced in clumps along the NE part of the ring. We observe evidence of rapid rotation in the circumnuclear ring, with a rotation velocity of ∼220 km s⁻¹ (inclination uncorrected) measured in all lines. The [OI] 63 μm/[CII] 158 μm ratio varies smoothly throughout the central region, and is enhanced on the northeast part of the ring, which may indicate a stronger radiation field. This enhancement coincides with peaks in the [OI] 63 μm and [OIII] 88 μm maps. Variations of the [NII] 122 μm/[NII] 205 μm ratio correspond to a range in the ionized gas density between 150 and 400 cm⁻³.

1. Introduction
NGC 1097 is a Seyfert 1 galaxy with a bright starburst ring with a diameter of 2 kpc and a strong large-scale bar (Gerin et al. 1988; Kohno et al. 2003; Hsieh et al. 2008) with a length of 15 kpc. Optical and near-infrared images reveal dust lanes that run along the primary large-scale (15 kpc) bar and curve into the ring, which is formed by two very tight spiral arms, and a second bar inside the ring (Quillen et al. 1995; Prieto et al. 2005). This bar may be responsible for driving gas into the nucleus, possibly fueling the central super-massive black hole (Prieto et al. 2005; Fathi et al. 2006; Davies et al. 2009), and may also have triggered the formation of a compact star cluster seen near the nucleus. NGC 1097 provides an excellent opportunity to study the physical conditions of the interstellar medium (ISM) in a nearby galaxy with both a starburst and an active nucleus.

The nucleus and the star-forming ring are prominent in CO and HCN line emission (Kohno et al. 2003). Near-infrared spectroscopy (Reunanen et al. 2002; Kotilainen et al. 2000) reveals emission from both ro-vibrational H₂ and H-recombination lines at the nucleus, the star-forming ring, and the region in between. Optical long-slit spectroscopy (Storchi-Bergmann et al. 1996) shows strong ionized gas emission from both the nucleus and the ring, along with faint line emission from the inner region, exhibiting a LINER-type spectrum.

With Herschel/PACS (Poglitsch et al. 2010) we are now able to target the most important cooling lines of the warm ISM on physical scales much smaller than ever before possible in external galaxies. The KINGFISH project (Key Insights on Nearby Galaxies: a Far-Infrared Survey with Herschel – PI: R. C. Kennicutt) is an open-time Herschel key program which aims to measure the heating and cooling of the gaseous and dust components of the ISM in a sample of 61 nearby galaxies with PACS and SPIRE instruments. The far infrared spectral range covered by PACS includes several of the most important cooling lines of the atomic gas, notably [CII] 158 μm, [OI] 63 μm, [OIII] 88 μm, [NII] 122 μm, and [NII] 205 μm. NGC 1097 is one of the KINGFISH targets selected for the Herschel science demonstration program (SDP) for PACS imaging of NGC 1097 see Sandstrom et al. 2010 and for SPIRE observations see Engelbracht et al. 2010.

In this letter, we present far-infrared spectral line maps of the circumnuclear starburst ring and the large-scale bar of NGC 1097, obtained with the PACS spectrometer on board the ESA Herschel Space Observatory (Pilbratt et al. 2010). The maps presented in this letter are the first PACS spectral maps from the KINGFISH program. Throughout this paper we assume a distance to NGC 1097 of 19.1 Mpc (Willick et al. 1997), which gives a projected scale of 1'' = 92 pc.

2. Observations and data reduction
NGC 1097 was observed with the 5 × 5 pixel integral field unit (IFU) of the PACS Spectrometer in both chop-nod (CN) and
to in-flight observations of calibrators\(^1\). The uncertainty in the line fluxes is dominated by the absolute flux calibration. The flux calibration uncertainties are on the order of 30\%, and pixel-to-pixel relative calibration uncertainties are on the order of 10\%.

Fig. 2. Spectral maps of the lines observed with PACS at the nuclear position, and an image of the ring at 70 \(\mu m\) with PACS. The maps represent the integrated flux over \(-500 < v_{sys} < 500\) km s\(^{-1}\), with \(v_{sys} = 1271\) km s\(^{-1}\). North is up and East is to the left. In all cases the size of the image is \(51' \times 51'\). The cross marks the location of the radio position of the nucleus.

### 3. Results

In Fig. 1 we present an overlay of the [CII] 158 \(\mu m\) maps of the nuclear and extranuclear regions of NGC 1097 on a 24 \(\mu m\) image taken with the Multiband Imaging Photometer for Spitzer (MIPS) (Rieke et al. 2004). The 24 \(\mu m\) emission is well traced by the [CII] 158 \(\mu m\) emission in all the regions where [CII] 158 \(\mu m\) emission is observed. As there are no CN observations of the northern extranuclear region, we show a WS map, which clearly follows the detailed structure evident in the 24 \(\mu m\) image. The signal-to-noise ratio in the minor axis strips is very low, and these data are not shown in Fig. 1.

In Fig. 2 we present continuum-subtracted maps of the center of NGC 1097, for the [CII] 158 \(\mu m\), [OI] 63 \(\mu m\), [OIII] 88 \(\mu m\), [NII] 122 \(\mu m\), and [CII] 158 \(\mu m\) emission lines. For comparison, we also show a PACS 70 \(\mu m\) continuum image (see Sandstrom et al. 2010). The [OI] 63 \(\mu m\), [OIII] 88 \(\mu m\), and [NII] 122 \(\mu m\) maps are the most similar. There is a partial clumpy ring-like structure, with peaks NW, N and E of the nucleus in the [OI]...
63 μm and [OIII] 88 μm maps, whereas the N clump is absent in the [NII] 122 μm map. The peaks observed in the [CII] 158 μm coincide with the clumps observed in the [NII] 122 μm map, but the overall distribution is much smoother. Only the N and NW peaks have a counterpart in the PACS 70 μm image. The [NII] 205 μm looks strikingly different than the other maps. It has a peak NE of the nucleus but lacks the NW and E hotspots present in the other maps. The lack of a resolved ring in the [CII] 158 μm and [NII] 205 μm may be partially due to the large beam at these wavelengths. A careful measurement of the spectrometer PSF on 10″ scales will be required in order to further separate real physical components in a system as small as the NGC 1097 ring.

To extract integrated spectra from the line maps, we selected a circular region of 23″8 in radius centered on the nucleus which includes the ring, but avoids the noisy edges of the map. The continuum subtracted velocity profiles for each line are shown in Fig. 3. In all cases, zero velocity was defined as \( v_{sys} = 1271 \text{ km s}^{-1} \). An overplot of the [CII] 158 μm velocity profile made from the WS data is also shown for comparison, which has a peak flux of ~90% of the CN peak, within the flux uncertainty. The smooth appearance of the [CII] 158 μm and the [NII] 122 μm line profiles is due to the worse spectral resolution at these wavelengths. The small difference is attributed to transients in the CN data which are not present in the WS data. The most notable characteristic of these profiles is that they are all double-peaked, which is expected for a rotating ring. In Fig. 4 we show the velocity map of [OI] 63 μm. The velocity spans a range of ±220 km s\(^{-1}\), being redshifted to the SE, and blueshifted to the NW. The [OI] velocity field is consistent with circular rotation also seen in ionized (Hα, Fathi et al. 2006) and molecular gas (CO (2-1), Hsieh et al. 2008). In Table 1 we present the integrated line fluxes for the nucleus and extranuclear positions.

4. Diagnosing the ionized and neutral gas properties

With the line maps we can study spatial variations in the properties of the warm atomic gas. Fine structure line ratios trace the intensity of the incident radiation field \( G_0 \) on the neutral gas and the electron gas density \( n_e \), respectively (e.g., Kaufman et al. 1999). In Fig. 5 we show maps of the [OI] 63 μm/[CII] 158 μm and the [NII] 122 μm/[NII] 205 μm line ratios, overlaid with the contours of the PACS 70 μm image. Before making the ratio maps, each image was smoothed to the beam size at the longer wavelength using a Gaussian profile, while conserving flux. The [OI] 63 μm/[CII] 158 μm ratio varies smoothly with values ranging between 0.25–0.45 throughout the central region, and is enhanced on the northeast part of the ring. This enhancement partially coincides with the peaks in the [OI] 63 μm and [OIII] 88 μm line maps and the peak of the Hα emission (Hummel et al. 1987), which indicates that the [OI] 63 μm/[CII] 158 μm ratio traces the most massive star forming knots in the ring. The values of [OI] 63 μm/[CII] 158 μm are a factor of 2 lower than for the starburst galaxy M82 (Colbert et al. 1999), but similar to the values found for most star-forming galaxies (Malhotra et al. 2001). The ratio is also enhanced on a region where the ring and the dusty spiral arms intersect, which indicate a possible shock contribution to the [OI] 63 μm flux. Models of emission lines from shocks (Hollenbach & McKee 1989) predict values of the [OI] 63 μm/[CII] 158 μm ratio of at least 10. Our measured value of ~0.4 are at odds with a pure-shock interpretation of the line.

---

**Table 1.** Integrated line fluxes (10\(^{-15}\) W m\(^{-2}\)).

| Position | [OI] 63 μm | [OIII] 88 μm | [NII] 122 μm | [CII] 158 μm | [NII] 205 μm |
|----------|-----------|-------------|-------------|-------------|-------------|
| Nuc      | 3.5       | 0.28        | 0.07        | 1.2         | 0.9         |
| Emuc S   | 0.13      | 0.13        | 0.79        | 1.2         | 0.9         |
| Emuc N   | –         | –           | –           | –           | –           |

Notes. (1) “Nucleus” comprises a circular region of 23″8 in radius (~2 kpc) centered on the Seyfert nucleus. The fluxes for the other positions were measured over the whole maps (50″ × 50″ × 4 × 4 kpc). All measured fluxes have an uncertainty of 30%.
Fig. 5. Top: map of the [OI] 63 μm/[CII] 158 μm ratio. The [OI] 63 μm map was smoothed to match the resolution at 158 μm. Bottom: map of the [NII] 122 μm/[NII] 205 μm ratio. The [NII] 122 μm map was smoothed to match the [NII] 205 μm map. Both maps are overlaid with contours from the PACS 70 μm map, after smoothing to the resolution of each map. All the ratio maps were built from line maps clipped at a 2σ level above the noise. The cross marks the location of the nucleus.

The [NII] 122 μm/[NII] 205 μm ratio varies between 4.0–6.0 throughout the central 40′′. The values that correspond to the [NII] 122 μm peaks are 4.8 and 4.5, whereas at the [NII] 205 μm peak, the [NII] 122 μm/[NII] 205 μm ratio is 4.0. From the comparison with the 70 μm contours, we see that the highest values of the [NII] 122 μm/[NII] 205 μm ratio coincide with the ring, while the lowest are found in the inner region of the ring and also where the dust lanes meet the ring. The variations in the [NII] 122 μm/[NII] 205 μm ratio are therefore due to a variation in the ionized gas density between the ring and the inner region. Using a five level model of N+ we find that the variation of [NII] 122 μm/[NII] 205 μm ratios between the inner region and the ring corresponds to a variation of the electron density from 150 to 400 cm−3. The results are insensitive to typical gas temperatures (T = 6000–10 000 K) in photoionized gas. This means that the density increases by at least a factor of 5 in the ring compared to the inner region and the region where the dust lane and the ring meet. These values are similar to the central region of M82, in which a mean ratio value of 4.2 ± 1.5 was measured, corresponding to a mean electron density of 180–200 cm−3 across the central 50′′ (Petuchowski et al. 1994). This is also consistent with the value of ∼220 cm−3 from the mid-infrared [SIII]18 μm/33 μm ratio over the same region (Dale et al. 2006).

The peak in the [NII] 205 μm emission line map in Fig. 2 has a line flux of −0.11 × 10−7 W m−2 sr−1 and a [CII] 158 μm/[NII] 205 μm ~ 45. For 150 < n < 400 cm−3 the [CII] 158 μm/[NII] 205 μm ratio in ionized gas is expected to be ~ 3 (Oberst et al. 2006) and thus most (~90%) of the [CII] 158 μm emission we measure is coming from neutral gas. The gas heating efficiency, measured by the ([OI] + [CII])/FIR ratio, seems to stay constant in the mapped area. The log of the ratio is ~ −2.2 inside the ring and ~ −2.3 on the ring, both consistent with the values found in nearby galaxies by Malhotra et al. (2001).

In summary, we have used the PACS Spectrometer to map the [OI] 63 μm, [OIII] 88 μm, [CII] 158 μm, [NII] 122 μm and 206 μm far-infrared cooling line emission in the central 5 kpc of NGC 1097 for the first time. While the [OI] 63 μm, [OIII] 88 μm and [NII] 122 μm line maps appear qualitatively similar, the [OI] 205 μm map shows a different distribution. The [OI] 63 μm/[CII] 158 μm map shows a relative hotspot on the NE portion of the ring indicative of a stronger radiation field or a region of shocked gas. The [NII] 122 μm/[NII] 205 μm map shows a clear increase of ionized gas density in the ring, associated with massive star formation activity.

Acknowledgements. This work is based in part on observations made with Herschel, a European Space Agency Cornerstone Mission with significant participation by NASA. Support for this work was provided by NASA through an award issued by JPL/Caltech. PACS has been developed by a consortium of institutes led by MPE (Germany) and including UVIE (Austria); KUL, CSL, IMEC (Belgium); CEA, OAMP (France); MPIA (Germany); IFSI, OAP/AOT, OAA/CAISMI, LENS, SISSA (Italy); IAC (Spain). This development has been supported by the funding agencies BMVIT (Austria), ESA-PRODEX (Belgium), CEA/CNES (France), DLR (Germany), ASI (Italy), and CICT/MCT (Spain). Data presented in this paper were analyzed using The Herschel Interactive Processing Environment (HIPE), a joint development by the Herschel Science Ground Segment Consortium, consisting of ESA, the NASA Herschel Science Center, and the HIPI, PACS and SPIRE consortia. We would like to thank Dario Fadda and Jeff Jacobson for software support and Hanae Inami for the help on the velocity diagram.
