Abstract

Water Deficit is an important limiting factor for crop growth and production in some regions of the world. It elicits several morphological responses in crop plants. Most of these responses are adaptive mechanisms to withstand water deficit or drought and to ensure both survival and reproduction. Balanced and integrated use of nitrogen fertilizer and straw mulch may enhance the accumulation of soil organic matter, improves soil physical properties and increase crop yield. Hence, impact of deficit irrigation, nitrogen fertilizer and straw mulch on the vegetative growth of maize were examined in a green house. The objective is to determine measures which will enhance resistance to drought and increase maize growth with improved soil conservation. Twelve treatments were considered by varying irrigation, rice mulch, and nitrogen fertilizer. Results obtained based on statistical analysis reveal that: (i) Mulch reduces the amount of water needed for irrigation. (ii) Mulch significantly (P<0.05) affect plant height, leaf number, leaf area and shoot biomass. (iii) The interactions of fertilizer mulch and fertilizer water significantly affect shoot biomass. Further field studies are needed to extrapolate the findings to a wider range of seasonal and site conditions.

Keywords

Water stress, Green house, Straw mulch, Biomass, Fertilizer, Maize

Introduction

Maize (Zea mays L.) is one of the most important crops in the world, ranking third behind rice and wheat (WMO, 2012). It is now the most widely produced cereal crop with an overall production of approximately 1006.18 million tones (FAO-AMIS, 2016). Maize is currently produced on nearly 184 million hectares in 125 developing countries (FAO, 2014).

Drought is the foremost stress which decreases the production of crops worldwide (Yang et
al., 2004). Yield losses include more than two thirds of the total damage of abiotic stresses due to drought, salinity and other factors. Maize is highly sensitive to drought, especially two weeks prior and post silking (Tollenaar and Lee, 2011). Adequate water and nutrient supply are important factors affecting optimal plant growth and successful crop production. Moreover, application of irrigation deficit alone does not gives positive results regarding crop production or soil quality and under such critical condition, mulching may be one of the suitable alternatives to maintain optimum moisture and thermal environment in soil. The effects of rice straw mulch on crop yield and nitrogen use efficiency is inconclusive and has been shown to vary with the characteristics of the site and the climate (Erenstein, 2002). Experiences so far have highlighted positive, neutral and negative short-term yield responses to rice straw mulch. Therefore, an integrated nutrient management, in which both residue mulch and chemical Nitrogen fertilizer are simultaneously used, may be a more compatible approach in dry land.

Several studies have reported that Farm yard manure plus inorganic N applications in irrigated systems resulted in reduced bulk density, higher soil organic matter and hydraulic conductivity and improved soil structure and microbial communities (Bhattacharyya et al., 2007). Kaur et al., (2008) stated that a judicious combination of organic amendments and inorganic fertilizers is widely recognized strategy of integrated nutrient management to sustain agronomic productivity and improve soil fertility.

There is very scanty information on the vegetative growth of maize when exposed to water stress at seedling stage under the condition of mulch, especially when chemical fertilizer was applied after water recovery from stress. Thus, the objectives of the study are:

To evaluate the impact of water stress on the growth of maize.

To appraise specifically the effect of mulch and fertilizer on the growth of maize.

To examine the interactive effects of irrigation water supply, crop residues mulch and fertilization on vegetative growth of maize.

Materials and Methods

Experimental site

A greenhouse experiment was carried out in 2005 and 2006 at the experimental farm of Agricultural Engineering Department, Hohai University, Nanjing, China (31°95’ N latitude and 118°83’ E longitude). The climate is sub humid with an average annual rainfall of 1106 millimeter (mm).

The soil of the experimental site is clay loam with 33.81% clay, 65% silt, 0.97% sand and a pH (1:2.5 soil: water) of 7.96. The organic matter content is 12.26 mg kg⁻¹. The available nitrogen and available phosphorus are 47.4 and 10.13 mg kg⁻¹ respectively. Nanjing Agricultural University Maize Variety 108 (Nongda 108) was used as a test crop. Nongda 108 was planted on June 19 and harvested on October 17 in 2005 and 2006.

Experimental details

The experimental design is a Randomized Complete Block Design with three replications. Twelve treatments were considered (Table 1). Each plot is 2.25m x 1.5 m. The seeds were sown at 5 cm depth and 40 x30 cm row spacing in plots. Five (5) seeds were planted in each hole and thinned to 1 after two weeks of emergence. So, each plot
has 30 plants. Prior to sowing; urea was applied in rows 10 cm deep at the rate of 375 kg ha\(^{-1}\) for all plots. The first weeding was carried out at two weeks after planting. Rice residues were applied as mulch at the rate of 6 t ha\(^{-1}\), 15 days after maize emergence to some plots. Mulch residues have been cut into pieces of nearly 5 cm prior to application.

Plant parameters measurements started 3 weeks after plant emergence, which is when 40% of plants have 5 leaves. Plant diameter that is maize stem was measured with a Vernier Caliper at 5 cm above the ground, while plant height was measured with a measuring tape, and leaf area, with a ruler and results calculated based on the formula below:

\[ L_A = 0.75 \times L_m \times W_m \]

Where,

\( L_A \) is the leaf area of maize; \( L_m \) is length of maize leaf and \( W_m \) the width. The total area was calculated by summing up individual leaf area, and in counting the number of leaves, dry leaves were not been considered. Plant height, number of leaves, leaf area and plant diameter were measured every two weeks from July 13\(^{th}\) to September 24\(^{th}\) in 2005 and 2006. Plants were exposed to stress at seedling stage at 31 Days after planting (DAP). At the end of stress time, that is at 45 DAP, fertilizer urea (CO\((\text{NH}_2)_2\)) at the rate of 240 kg ha\(^{-1}\) was applied to some plots. Harvesting was done on October 17\(^{th}\) each year. For analysis, shoot and root biomass were taken, oven dried for 72 hours at 65\(^{\circ}\) C and thereafter weighed.

Soil water content at 0-60 cm depth was measured with neutron probe meter at intervals of 7-10 days. The water absorbed from the soil for a given interval was taken as the decrease in soil water in 0-60 cm depth interval. Evapotranspiration for the same interval was considered to be the total amount of water absorbed from the soil plus irrigated water.

**Statistical analyses**

All statistical analyses were performed using General Linear Models (GLM) procedures in SPSS, Version 20 package. Three way ANOVA analyses were carried out over all twelve treatments to test explicitly the effects of deficit irrigation, mulch and fertilizer on growth parameters of maize. Water application, mulch and fertilizer were treated as fixed factors in all the analyses while plant diameter, height, number of leaves, leaf area, plant biomass as dependent variables. Correlation analyses were carried out between number of leaves and plant diameter, plant height and leaf area.

**Results and Discussion**

**Irrigation water used**

Table 2 shows the irrigation water used in millimeters for different treatments during the growing of maize. Mulch reduces the amount of water need for irrigation by 11.63%, 6.36% and 6.10% under full irrigation, mild and severe stress treatments in 2005. In 2006, the decrease was 13.71%, 4.95% and 7.47% for full irrigation, mild and severe stress respectively. Chakraborty et al., (2008) indicated that mulching reduces unproductive evaporation from the soil surface, so more water is available for transpiration, which is of benefit in water limited conditions and plant water status is maintained. Similar findings were reported by Rahman et al., (2005).

**Stem diameter and plant height**

Figure 1 showed the stem diameter of maize in response to varying treatments in 2005 and 2006 respectively. The results indicated that the highest stem diameter (13.91 cm) in 2005
and (13.80 cm) in 2006 were obtained under no mulch full irrigation plus fertilizer (-M-S+F) treatment and plus mulch full irrigation plus fertilizer (+M-S+F) treatment. Various researchers reported that continuous availability of water improve the stem diameter in maize (Dogan and Kimak, 2010) and established the need of higher irrigation for better plant girth (Stone et al., 2006). Both, fertilizer, mulch, water and their interaction did not have any significant effect on stem diameter. Only the interaction of fertilizer and water application affect stem diameter at 13 Weeks after planting (WAP) (Figure 1). However, in 2006, mulch significantly (p < 0.05) affect stem diameter during maize growth (Figure 1). A decrease observed at 13 WAP is due to the period of maturity.

The effect of the treatment applications (water, mulching, fertilizer and the combination of treatments) on maize height are shown in Figure 2. In 2005, the maximum plant height (1.98m) was obtained at 9 WAP for no mulch full irrigation plus fertilizer (-M-S+F) (Figure 2a). Irrigation plays a vital role in vegetative growth of plant and causing improvement in plant height. Findings of present study are similar to the findings of Yazar et al., (2012) who observed highest maize plant height in full irrigation. Similarly, English, 2010 suggested that, maize crop are highly sensitive to drought stress conditions. Tahir et al., (2006) reported increase in plant height and spike length with increasing amount of irrigation. Higher application rate of fertilizer resulted in taller plant. Cheema et al., 2001 also described the increase in plant height and spike length with the application of phosphorus fertilizers. In 2006, the no mulch plus mild stress no fertilizer (-M+S1-F) treatment had the highest (2.01m) plant height (Figure 2d). Mulch significantly (p<0.05) affect plant height at 11 and 13 WAP in 2005 and 2006 respectively. These results concurred with those of Makus et al., (1994) who observed that plant height was significantly affected by different mulching materials.

**Number of leaves, leaf area and Shoot biomass**

The numbers of leaves in response to varying treatments are presented in Figure 3. Both mulch and fertilizer have no significant effect on number of leaves in 2005. While, water significantly affects number of leaves (Figure 3). The highest number of leaves (13.80) in 2005 and (12.83) in 2006 were recorded at 9 WAP for no mulch mild stress no fertilizer (-M+S1-F) and plus mulch mild stress no fertilizer (+M+S1-F) (Figures 3c and 3d). During the second year of cropping period, mulch significantly affect number of leaves, except at 3 WAP. The number of leaves gradually increased with increasing irrigation frequency. The results are in agreement with the findings of Bozkurt et al., (2011) in Mediterranean climatic conditions. Yildirim and Kodal, (2008) reported that seasonal rainfall ranging from 30 to 120 cm produced maximum effective leaves in maize in Ankara, Turkey. Our results corroborate with those of Lamn et al., (2005) who stated that deficit irrigation reduced the number of leaves. Figure 4 represent leaf area of maize in 2005 and 2006 respectively. Mulch, fertilizer and their interaction have no significant effect on leaf area in 2005. However, in 2006, leaf area is significantly (p<0.05) affected by mulch at 9, 11 and 13 WAP (Figure 4). Maximum leaf area (4460.09cm$^2$) in 2005 was observed at 9 WAP in those plots in which there is fertilizer, severe stress and no mulch (-M+S2+F) followed by 4439.96cm$^2$ in plots which was treated with fertilizer full irrigation without mulch (-M-S+F). In 2006, maximum leaf area (4406.11 cm$^2$) was recorded at 9 WAP in plots treated with mulch mild stress without fertilizer followed by 4239.70 cm$^2$ in the plots which was treated with fertilizer full irrigation and mulch.
Table 1: Treatments combinations for maize

| Treatments | Soil moisture | Combination | Descriptions |
|------------|---------------|-------------|--------------|
| 1          | 70%-100%      | -M-F-S      | No mulch No fertilizer No stress |

1) WAP: weeks after planting, 2) SD: stem diameter, PH: plant height, NL: number of leaves, LA, leaf area, ** Correlation is significant at the 0.01 level, * Correlation is significant at the 0.05 level
Fig. 1 Stem diameter of maize in response to varying treatment in 2005 and 2006
Fig. 2 Plant height of maize in response to varying treatment in 2005 and 2006.
Fig. 3 Number of leaves of maize in response to varying treatment in 2005 and 2006
Fig. 4 Leaf area of maize in response to varying treatment in 2005 and 2006
Leaf area is dependent upon rate and duration of leaf expansion which is very sensitive to water and nitrogen availability. Water stress at early growth stage resulted in lower leaf area index. Water shortage reduced nutrient accumulation and leaf expansion (Hammad et al., 2011) that finally boosted crop leaf area index (Awais et al., 2013).

The effect of the treatment applications (irrigation, mulching and fertilizer) on maize total shoot biomass are shown in Table 3. Results show that the straw mulching significantly (p<0.05) increase dry weight of plant when compare with the no mulching treatment. This may be due to the capacity of mulching to effectively improve soil nutrient availability, increase plant growth (Fang et al., 2011) and influence soil physical and chemical properties (Jin et al., 2009). The effect of fertilizer is only significant in 2005, which is the first year of cropping.

The interactions of fertilizer mulch and fertilizer water significantly affect dry weight of plant and total aboveground biomass in 2005. During that period, the highest aboveground biomass (6564 kg ha⁻¹) was obtained under no mulch mild stress no fertilizer (-M+S1-F) and the lowest yield (3130 kg ha⁻¹) was recorded with no mulch mild stress plus fertilizer (-M+S1+F) treatment.

Correlations between growth parameters

Correlations between maize growth parameters in 2005 and 2006 are presented in Tables 4 and 5. It was found that most correlations between the growth characteristics were highly significant (p<0.01) and also that correlation coefficients were high. These high levels of correlations indicate that the physiological characteristics were highly dependent on each other. Results also revealed that correlation coefficients decreases with plant age.

The effects of combinations of deficit irrigation and straw mulch on growth yield and yield contributing parameters were studied in the greenhouse. Rice straw reduces the amount of water needed to grow wheat irrespective of the severity of stress. Mild stress at seedling stage produces higher biomass. Deficit irrigation of wheat should coincide with earlier growth stages to ensure minimal yield reduction.

Further research should consider carrying this work on the field unlike the case here where all the parameters are controlled under the ambient greenhouse conditions.
