High field charge order across the phase diagram of YBa$_2$Cu$_3$O$_y$

In hole-doped cuprates there is now compelling evidence that inside the pseudogap phase, charge order breaks translational symmetry. In YBa$_2$Cu$_3$O$_y$, charge order emerges in two steps: a 2D order found at zero field and at high temperature inside the pseudogap phase, and a 3D order that is superimposed below the superconducting transition $T_c$ when superconductivity is weakened by a magnetic field. Several issues still need to be addressed such as the effect of disorder, the relationship between those charge orders and their respective impact on the Fermi surface. Here, we report high magnetic field sound velocity measurements of the 3D charge order in underdoped YBa$_2$Cu$_3$O$_y$ in a large doping range. We found that the 3D charge order exists over the same doping range as its 2D counterpart, indicating an intimate connection between the two distinct orders. Moreover, our data suggest that 3D charge order has only a limited impact on low-lying electronic states of YBa$_2$Cu$_3$O$_y$.

npj Quantum Materials (2018)3:11; doi:10.1038/s41535-018-0084-5

INTRODUCTION

While both theoretical and experimental analysis have long suggested that charge order might play a significant role in the pseudogap phase of the cuprates, the more recent discovery of charge order in the putatively “cleanest” cuprate YBa$_2$Cu$_3$O$_y$ (YBCO) has triggered a surge of experimental$^{1-3}$ and theoretical$^{4-11}$ works. The relation between charge order and pseudogap is not yet settled but some models predict that they are intertwined$^{6,10}$. In some scenarios the pseudogap phase corresponds to a nematic phase precursor to charge ordering at lower temperature$^6,7$ or to a fluctuating charge order.$^{12,13}$ While superconductivity appears to compete with charge order experimentally, a class of theory suggests it could be collaborating.$^{14}$ Two distinct charge orders have been detected in YBCO. First a two-dimensional (2D) short-range CDW, originally detected using high field NMR,$^2$ appears below $T_c$ and the pseudogap temperature $T_n$. Comprehensive X-ray measurements$^{15,16}$ in YBCO have shown that the 2D CDW is incommensurate and occurs in the doping range $p = 0.08$ to $p = 0.16$. The propagation vectors along $a$ and $b$ directions are $Q_a = (\delta_a, 0, 0.5)$ and $Q_b = (0, \delta_b, 0.5)$ where $\delta_{a,b} \approx 0.3 - 0.34$ with in-plane correlation lengths that are at most 20 unit cells and weak anti-phase correlation between neighboring bilayers. The short-range CDW has also been detected through a broadening of the NMR lines.$^{17}$ The second CDW, originally detected using high field NMR,$^2$ appears below $T_c$ and above a threshold field.$^{7,18}$ Recent X-Ray measurements in high field have shown that it is a three-dimensional (3D) ordered state with in-plane CDW modulations along the $b$ direction only—though at the same $\delta_b$ value as the 2D CDW.$^{19-21}$ Moreover, the periodicity along $c$-axis is close to unity, meaning that the 3D CDW modulation is in-phase in neighbouring bilayers.$^{19-21}$ Compared to the 2D short-range CDW, the in-plane and $c$-axis correlation lengths are greatly enhanced and extend to the order of 60 lattice constants limited by the instrumental resolution$^{19-21}$ (we call it long-range order). The high field X-Ray measurements have been performed in the doping range $0.10 \leq p \leq 0.12$, where two different Cu–O chain superstructures are observed: ortho II (O-II) for $0.10 \leq p \leq 0.11$ and ortho VIII (O-VIII) for $p \approx 0.12$. The 3D CDW gives rise to an anomaly in the field dependence of the elastic constants via sound velocity measurements$^2,12$ and of the magnetization.$^{23}$ Those two techniques are so far the only thermodynamic probes that have detected a signature of a phase transition towards this 3D CDW state (note that ref. $^{23}$ had different interpretations than the present paper concerning the nature of the low-temperature phase diagram). It has been established by NMR$^{15}$ and X-ray$^{19-21}$ measurements that the two charge orders coexist at low temperatures but are related since they share the same periodicity along the $b$-axis. The coexistence of two distinct charge orders, with different boundaries in the temperature-doping phase diagram raises a certain number of interesting questions: Do both charge orders share the same critical doping? What is their respective impact on the Fermi surface at low temperature? What is the role of disorder in their occurrence?

Here we report a full doping dependence of high field sound velocity measurements, which probe the 3D charge order at low temperatures. Anomalies are now seen in the temperature dependence of sound velocity measured at high field showing a clear negative jump as expected for a second-order phase transition. From the doping dependence of the threshold field $H_{CO}$ and of the onset temperature $T_{CO}$ of the 3D charge order, we find that the two charge orders occur in the same doping range.

We observe that (i) the onset of 3D CDW barely affects the temperature dependence of the Hall coefficient $R_H$, and (ii) the

sign change of $R_s$ can occur at temperatures as high as 20 K above the onset of 3D CDW. The sign change of the Hall effect, which is observed in the same doping range of YBCO where 2D charge order is found, has been interpreted as a signature of the presence of an electron pocket due to a Fermi surface reconstruction.\textsuperscript{1,23,25} Our results point towards a minor role of the 3D CDW for this reconstruction. A comparison of the 2D CDW correlation length with the quasiparticle de Broglie wavelength furthermore suggests that the 2D CDW can affect the electronic properties above the transition towards 3D CDW.

RESULTS

The sound velocity is defined as $v_s = \sqrt{\frac{c}{\rho}}$ for propagation directions along high symmetry axis, where $\rho$ is the density of the material, $c_i = \frac{1}{\rho} \frac{\partial E}{\partial \varepsilon_i}$ the free energy, $V$ the volume and $\varepsilon_i$ the strain. Changes in the elastic constants $c_i$ are expected whenever a strain dependent phase transition occurs.\textsuperscript{26} This is the case at the superconducting transition where a negative jump of the elastic constant is seen at $T_C$ (see Supplementary Fig. S1). The amplitude of the jump of the elastic constants and of the heat capacity $\Delta C_p(T_c)$ are proportional through the Ehrenfest relation:

$$\Delta C_p(T_c) = -\frac{\partial c_i(T_c)}{\partial T} \left(\frac{dT}{dc_i}\right)^2,$$

where the minus sign explains the downward jump in the elastic constant (see discussion in the Supplementary data). This feature is also seen at the onset temperature $T_{CO}$ of the 3D charge order. Indeed, in Fig. 1 we show the in-field temperature dependence of the sound velocity (background subtracted, see Fig. S2 for raw data and fit) in YBCO at three different doping levels. At these dopings, $H_C < 30$ T (ref. 27) such that the normal state is reached down to low temperatures (here by normal state we mean a field-induced state where thermal conductivity\textsuperscript{27} and heat capacity\textsuperscript{28} and NMR Knight shift\textsuperscript{29} have reached a saturating value above a certain field). This feature is the first evidence of a second-order phase transition-like anomaly in the temperature dependence of a thermodynamic probe at $T_{CO}$. The size of the anomaly is similar for $p = 0.106$ and $p = 0.110$ but it gets smaller for $p = 0.122$. Figure 2a,b show the field dependence up to 35 T of the sound velocity at different temperatures in YBCO at $p = 0.122$. For magnetic field below the irreversibility field, there is a strong contribution from the vortex lattice (see discussion in the Supplementary and Fig. S3). At low fields in the pinned solid vortex phase, the vortex lattice contribution leads to an increase of the sound velocity. This vortex lattice contribution is lost when vortices are depinned to a large drop in the sound velocity. The midpoint of this step-like transition associated with vortex depinning is labeled $H_v$.

At field above $H_v$, the weakening of superconductivity with increasing magnetic field induces a progressive decrease of the sound velocity, until a pronounced hardening of the elastic constant that we attribute to the 3D charge order.\textsuperscript{25} It leads to a minimum at a field that we define as the threshold charge order field, $H_{CO}(T)$. By performing field sweeps at different temperatures, we can track $H_{CO}(T)$ vs. $T$ and draw up the phase diagram shown in Fig. 2c. Black squares and red circles correspond to $H_v$ ($T$) and $H_{CO}(T)$, respectively. The phase diagram can be interpreted as follows: at high fields, when superconductivity is mostly suppressed, the charge order transition is field independent, leading to a vertical phase boundary, within our error bars. Due to competition effect when lowering the field close to $H_{CO}$, superconductivity impedes charge order to appear, pushing the phase

\textbf{Fig. 2} \textbf{a, b} Field dependence of the sound velocity of the $c_{22}$ mode in YBCO ($p = 0.122$) measured at temperatures ranging from 9.8 to 45.2 K. The arrows indicate $H_{CO}$, the charge order onset field. Curves are shifted vertically for clarity. \textbf{c} Temperature–magnetic field phase diagram of YBCO ($p = 0.122$) deduced from sound velocity measurements. $H_{CO}$ (full red circles) and $H_v$ (open black squares) are obtained from measurements shown in the upper panels. $T_{CO}$ (open red circles) is deduced from the temperature dependence of the sound velocity shown in Fig. 1 and Fig. S2. Blue circles correspond to $H_{CO}$ measured at low temperatures using the field dependence of the transverse mode $c_{66}$ (see Fig. S5). Dashed line is a guide to the eye.
boundary, to go almost horizontal such that 3D charge order only appears at finite magnetic field at low $T$. Similar phase diagram has been obtained by high field X-ray$^{20}$ and Seebeck coefficient$^{30}$ measurements. Based on this phase diagram, we define two quantities: $H_{\text{CO}} = H_{\text{CO}}(T \rightarrow 0)$ and $T_{\text{CO}}$ which corresponds to the vertical line in Fig. 2c where 3D charge order sets in for $H > H_{\text{CO}}$. Several measurements have been performed in the doping range between $p = 0.071$ and $p = 0.154$ and Fig. 3 shows the field dependence of the sound velocity at $T = 20\,\text{K}$ at all doping. We use the minimum in $\Delta \nu / \nu_s (H)$ above $H_s$ as a criterion to pinpoint the 3D charge order $H_{\text{CO}}$ and extract its doping dependence in the range $p = 0.095$ to $p = 0.139$ (see Fig. 4a). It is worth noting that the field dependence of the sound velocity above $H_s$ at $p = 0.071$ (see curves at different temperatures in Fig. 5b) and $p = 0.154$ is featureless. In Fig. 5c, we show the field dependence for $p = 0.154$ of the $\varepsilon_{11}$ mode at $T = 4.2\,\text{K}$, for which there is no sign of transition up to 66 T. We conclude that there is no 3D CDW at these doping levels. The full set of data at all doping along with the temperature–magnetic field phase diagrams deduced from the measurements are shown in the Supplementary Fig. S4 and Fig. S5. The overall shape of these phase diagrams are in agreement with models based on competition between CDW and superconductivity, as discussed below.

**DISCUSSION**

Indeed, a theory based on a phenomenological nonlinear sigma model which formulates the competition between CDW and fluctuating superconductivity$^{31}$ gives qualitative agreement with the experiment if the effect of disorder is taken into account.$^{32,33}$ Within the model of ref. $^{31}$ where the effect of magnetic field is incorporated, the onset field for charge order would correspond to a crossover between a short-range 2D CDW order to a long-range 3D CDW at high fields. However, the transition detected by the sound velocity is not a crossover. The presence of a negative jump at $T_{\text{CO}}$ (see Fig. 1) clearly indicates the occurrence of a phase transition towards long-range order. Even if theory precludes long-range incommensurate CDW order in disordered systems, the notion of “failed thermodynamic transition” has been used to describe the anomaly observed at the temperature/magnetic field where the mean field theory predicts thermodynamic transition. Nevertheless, as the disorder increases, one expects the transition to become more gradual and it leads to crossover. In YBCO, the main source of disorder impacting the CuO$_2$ planes comes from the CuO chains. This effect is not straightforward to describe in detail but let assume for simplicity that oxygen disorder in the chain layer can create point-like defects (the ends of finite length chainlets) as well as domain walls caused by phase slips in the chain ordering pattern.$^{34}$ Since the correlation length of the chain order is higher at O-II doping compared to O-VIII and O-III doping,$^{35}$ it could explain the pronounced anomaly in the temperature dependence of the sound velocity at $T_{\text{CO}}$ around O-II doping (see Fig. 1). Another effect that needs certainly to be taken into account is the change in the $c$-axis correlation length of the 3D charge order across the phase diagram of YBa$_2$Cu$_3$O$_y$. The large drop signals the loss of this vortex contribution. At still higher fields the sound velocity decreases further as superconductivity is being suppressed by the magnetic field. Those features are also seen at other doping, but a change of slope is observed due to the occurrence of charge order (arrows). Curves are shifted vertically for clarity.

---

**Fig. 3** Field dependence of the sound velocity variation of the $c_{22}$ mode in YBCO at different doping from $p = 0.071$ to $p = 0.154$ measured at $T = 20\,\text{K}$. Data for $p = 0.154$ are divided by a factor 5. Measurements were done either in DC fields up to 37.5 T or in pulsed fields. At $p = 0.071$ and $p = 0.154$, where no charge order transition is observed, the sound velocity first increases with magnetic field due to the vortex contribution. The large drop signals the loss of this vortex contribution. At still higher fields the sound velocity decreases further as superconductivity is being suppressed by the magnetic field. Those features are also seen at other doping, but a change of slope is observed due to the occurrence of charge order (arrows). Curves are shifted vertically for clarity.

**Fig. 4** a Magnetic field–doping phase diagram of YBCO comparing $H_{\text{CO}}$ and the upper critical field $H_{c2}$ at $T \rightarrow 0$ determined from thermal conductivity and magneto-resistance measurements.$^{27}$ $H_{\text{CO}}$ is determined by NMR$^{28}$ (blue squares), X-ray$^{29}$ (black triangles), and sound velocity (red full circles). Note the good agreement between X-ray and sound velocity data. Sound velocity data at $p = 0.108$ was obtained in ref. $^{22}$ b Doping dependence of the ratio $H_{\text{CO}} / H_{c2}$, which appears to be almost constant over the entire doping range covered in this study.
conceivable that disorder in the chain structure along the c-axis for oxygen content away from O-II could smear out the transition towards the 3D CDW. While the nonlinear sigma model succeeds to explain most of the salient feature related to the 2D/3D CDW, one must admit that the situation is more complex in YBCO since it has been found that the 3D ordered CDW at high fields develops on top of the 2D CDW and it is not simply a crossover, that is to say they coexist at low temperature in the presence of a magnetic field. In addition, the two charge orders differ in the sense that the 3D CDW is 3D ordered but with uniaxial modulation along the b-axis in the plane (although with the same wave vector than the 2D CDW).

To reconcile the two closely related but yet distinct charge orders coexisting at low temperature, it has been proposed in ref. \(^{21}\) that the coexistence is inhomogeneous depending on the non-uniform distribution of the disorder strengths in the sample. Another scenario comes from a recent extension of the nonlinear sigma model of competing superconducting and CDW orders. This model shows that the coexistence of the two CDWs could be a consequence of the interplay between the disorder potential (that prevails at zero magnetic field) and the Coulomb interaction between CDWs on different CuO\(_2\) planes, that plays a more important role when magnetic field is applied. \(^{36}\)

In our previous paper, \(^{27}\) the sound velocity anomalies found at \(H_{CO}\) had been interpreted as being caused by a bi-axial order, as suggested by X-ray measurements. \(^{34}\) This interpretation was based on a group theory analysis of different acoustic modes. The fact that anomalies have been detected in all measured acoustic modes is not straightforward to reconcile with only a uniaxial CDW. The recent discovery of the field-induced long-range order with uniaxial character that coexists with the 2D CDW increases the level of complexity in terms of coupling of the order parameters. It is natural to interpret the sound velocity anomalies as being due to the uniaxial order since it corresponds to long-range order. A more thorough analysis, including the coupling between both charge modulations and superconductivity, the coupling to the lattice, and the effect of magnetic field, remains to be done in order to understand the impact of the charge modulations on the magnetic field dependence of the sound velocity.

From the temperature sweeps shown in Fig. 1 and the phase diagrams at different doping levels, we were able to compile the doping dependence of the onset field \(H_{CO}\) and the onset temperature \(T_{CO}\) of the 3D CDW shown in Figs. 4 and 5, respectively. In Fig. 4a, the doping dependence of \(H_{CO}\) shows that it is systematically lower than \(H_{C2}\). Figure 4b shows that in the limit \(T = 0\), 3D charge order always appears around \(H_{CO} \approx 0.8 H_{C2}\), despite the pronounced doping dependence of the ratio \(T_{CO}/T_{C2}\). (Note that a fixed relation between \(H_{CO}\) and \(H_{C2}\) in a limited doping range, has been discussed in refs. \(^{18,21}\).) Figure 4a reveals also that NMR gives lower \(H_{CO}\) than sound velocity measurements. The observation of in-plane precursor correlations of the 3D charge order \(^{20}\) can explain this difference. NMR would be sensitive to this precursor phase but not sound velocity since it is a thermodynamic probe and hence is mostly sensitive to the onset of a 3D long-range, static order parameter. \(H_{CO}\) measured by sound velocity is in better agreement with thermal Hall effect, \(^{37}\) X-ray, \(^{19,21}\) and recent Seebeck coefficient \(^{30}\) measurements in finite magnetic field. In Fig. 5 we plot the onset temperatures \(T_{CO}\) for the 3D ordered CDW. The comparison of \(T_{CO}\) with the 2D CDW onset temperatures deducted from X-ray measurements \(^{15,16}\) leads to our first main finding: 2D and 3D CDW occur in the same doping range, within experimental accuracy. In other words, the charge orders are intimately linked even though the situation does not correspond to a crossover between the two. Note that the putative critical point of pseudogap (\(p^* = 0.19\) from ref. \(^{39}\)) and of CDW are distinct and well separated, in agreement with Hall effect measurements. \(^{39}\) But it raises the question: why both charge orders occur only in such limited doping range? In YBCO spin density wave (SDW) occurs for \(p < 0.08\) and the competition between SDW and CDW \(^{40}\) can explain the location of the critical point at \(p = 0.08\). On the right side of the CDW dome (\(p = 0.16\)), assuming that the proximity of the critical point of the pseudogap (\(p = 0.19\)) leads to a change in the carrier density, \(^{39}\) thus in the Fermi surface topology, it can be detrimental for charge order.

Let us discuss our finding in the context of Fermi surface reconstruction. It has been suggested that the negative Hall coefficient is a signature of an electron pocket resulting from a reconstruction of the Fermi surface by the charge order. \(^{24,25}\) This interpretation relies on the concept of Fermi liquid and Landau quasiparticles, which is strictly valid at low temperature where quantum oscillations are observed, e.g. \(T < 20 K\) (ref. \(^{41}\)). At higher temperature, the quasiparticles are ill-defined in particular near the Brillouin zone boundaries (the anti-nodal direction) \(^{42}\) and the concept of Fermi surface reconstruction might not apply. However, through our discussion, we will assume that the concept of quasiparticle is valid at high temperature (e.g. quasiparticles near the nodal direction of the Fermi surface) and use simple arguments that describe conventional CDW systems although the situation is more complex in YBCO.

Our direct determination of the 3D CDW onset allows studying its impact on transport properties such as the Hall effect reported in the literature. \(^{24,25}\) In Fig. 5 we compare the onset temperature \(T_{CO}\) of the 3D CDW deduced from ultrasound and NMR measurements \(^{18}\) with \(T_m\) the temperature where the Hall coefficient \(R_H\) changes sign. \(^{24,25}\) While \(T_m = T_{CO}\) for \(p < 0.11\), \(R_H\) becomes negative at temperature higher than the onset temperature of 3D CDW for \(p > 0.11\). To better illustrate this fact we compare in Fig. 6a the in-field temperature dependence of the sound velocity and of the Hall effect for \(p = 0.12\), which shows that 3D CDW appears 20 K below the sign change in the Hall
coefficient. In addition, the onset of 3D CDW has little impact on the behavior of $R_\text{H}$.

This begs the question of how the low-lying (near-nodal) electronic states evolves through the charge ordering transitions in YBCO and which electronic order causes the Fermi surface reconstruction observed at low temperatures. The simplest explanation would be that the Fermi surface reconstruction process is governed by 2D CDW for $p > 0.11$, unambiguously observed by NMR and X-Ray. While we cannot exclude that another unidentified electronic order is responsible for the Fermi surface reconstruction, let us examine whether 2D CDW short-range correlations are enough to impact the electronic structure for temperatures above $T_{\text{CO}}$. In 2D systems, it has been theoretically demonstrated that antiferromagnetic fluctuations with correlation length becoming much greater (as $T$ is lowered) than the quasiparticle de Broglie wavelength $\xi_\text{th} = \hbar v_F / k_B T$ can cause changes in the low-lying electronic states. Here we apply this concept to the 2D charge order in YBCO, that is, the thermal de Broglie wavelength $\xi_\text{th}$ should be compared with the correlation length of the 2D charge order $\xi_{\text{CO}}$. If $\xi_{\text{CO}} > \xi_\text{th}$ quasiparticles become sensitive to the charge order correlations, which might lead to a Fermi surface reconstruction. Although this estimation is approximate, we use the average Fermi velocity $v_F$ deduced from quantum oscillations, \[ F = 540 T \text{ and } m^* = 1.8 m_e \text{ leading to } v_F = 8.2 \times 10^4 \text{ m s}^{-1}. \] In Fig. 6b, we compare the temperature dependence of $\xi_\text{th}$ and of the 2D charge order correlation length $\xi_{\text{CO}}$, measured in O-II YBCO in zero field. The de Broglie wavelength follows closely the correlation length of the charge order above $T_c$ and up to the temperature where the 2D charge order appears. Though the result of ref. 43 is strictly valid if $\xi_{\text{CO}} > \xi_\text{th}$, our comparison of the thermal wavelength and 2D CDW correlation length suggest that 2D short-range CDW correlation can impact low-lying (near-nodal) electronic states at high temperatures. An extension of the calculation of ref. 43 for charge order would be helpful to the present discussion.

At low temperatures, our interpretation leads to another question: Is the 2D CDW correlation length compatible with the quasiparticle mean free path inferred from quantum oscillations? In Fig. S6 we compare the quasiparticle mean free path deduced from quantum oscillation experiments with $\xi_{\text{CO}} (T = T_c)$, at different doping levels in YBCO. We see that, except for well-ordered YBCO O-II ($p = 0.11$), the two length scales are comparable, suggesting that quasiparticle mean free path is bounded by the 2D charge order correlation length. This observation further supports the scenario that the Fermi surface reconstruction is governed by the 2D CDW. Note that the two length scales might be limited due to a significantly enhanced quasiparticle scattering originating in the shorter correlation lengths of their CuO chain ordering. However, for YBCO O-II the mean free path is much longer than the 2D charge order correlation length and is comparable to the 3D charge order correlation length. Given that the wave vector of the modulation is close to a commensurate number ($\delta_0 = 0.33$ from ref. 21), it is tempting to invoke a ‘lock-in’ transition at high fields at this particular oxygen ordering, leading to a strong enhancement of the correlation length of both charge order. Note that if the Fermi surface is already reconstructed by the 2D charge order at high temperature, the occurrence of the 3D charge order with the same wave vector along the $b$-axis would not strongly affect the reconstructed Fermi surface.

This overall scenario would explain the negative Hall and Seebeck coefficients in HgBa$_2$CuO$_4$ (ref. 46) and La$_{2-x}$Sr$_x$CuO$_4$ (ref. 47) where only short-range charge orders have been observed\textsuperscript{48,49} and long-range charge order has been missing so far.

**METHODS**

**Samples and experimental technique**

The samples are detwinned single crystals of YBa$_2$Cu$_3$O$_y$ grown by the self-flux method.

The oxygen atoms in the CuO chains were made to order into the stable superstructure specific to the given oxygen concentration $y$. Samples with oxygen content $y = 6.55$ and $y = 6.51$ with ortho II order showed nice quantum oscillations in the sound velocity and attenuation (not shown), indicating high sample quality. The superconducting critical temperature $T_c$ were determined using the measurement of the elastic constant $c_{22}$ and are reported in Table S1. The hole carrier concentration is deduced from the measurement of $T_c$ and the $c$-axis lattice parameter, using a relationship between $T_c$, $c$-axis lattice parameter and doping in the CuO$_2$ planes.

Longitudinal (transverse) ultrasonic waves were generated using commercial LiNbO$_3$ 36° Y-cut (41° X-cut) transducers glued on oriented, polished, cleaned surfaces. The standard pulse-echo technique with phase comparison was used to measure sound velocity variation.

Experiments have been conducted in static field at the HFML, Nijmegen and the LNCMI, Grenoble, and in pulsed field at the LNCMI-Toulouse. The magnetic field was applied along the $c$-axis of the orthorhombic structure of YBCO.
